ELSEVIER

Hematopathology

THIRD EDITION

Elaine S. Jaffe, MD

Pathologist, Bethesda, Maryland

Daniel A. Arber, MD

Donald West and Mary Elizabeth King Professor and Chair, Department of Pathology, University of Chicago, Chicago, Illinois

Elias Campo, MD, PhD

Senior Consultant and Professor, Department of Anatomic Pathology, Hospital Clinic of Barcelona, Institute for Biomedical Research August Pi i Sunyer (IDIBAPS), University of Barcelona, Barcelona, Spain

Attilio Orazi, MD, FRCPath

Professor and Chair, Department of Pathology, Texas Tech University Health Sciences Center, El Paso, Texas

Leticia Quintanilla-Martinez, MD

Professor of Pathology, Institute of Pathology, University Hospital Tübingen, Eberhard-Karls-University, Tübingen, Tübingen, Germany

Lisa M. Rimsza, MD

Professor and Consultant, Department of Laboratory Medicine and Pathology, Mayo Clinic, Scottsdale, Arizona

Steven H. Swerdlow, MD

Emeritus Professor of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Preface

Part I. Technical Aspects

Chapter 1. Processing of the Lymph Node Biopsy Specimen

- ASSESSING AND PRIORITIZING FRESH TISSUE
- GROSS PROCESSING OF THE LYMPH NODE BIOPSY
- ROUTINE HISTOLOGIC, HISTOCHEMICAL, AND SPECIAL STAINS
- REPORTING THE LYMPH NODE BIOPSY
- Pearls and Pitfalls

Chapter 2. Fine-Needle Aspiration of Lymph Nodes

SPECIMEN COLLECTION AND PROCESSING

ANCILLARY STUDIES

NON-NEOPLASTIC ASPIRATES

ASPIRATES OF LYMPHOID NEOPLASMS

LIMITATIONS OF FINE-NEEDLE ASPIRATION

ROLE OF CORE NEEDLE BIOPSY IN LYMPHOMA DIAGNOSIS

Pearls and Pitfalls

Chapter 3. Immunohistochemistry for the Hematopathology Laboratory

INTRODUCTION

BASIC IMMUNOHISTOCHEMISTRY

ANTIGENS OF HEMATOPATHOLOGIC INTEREST

BEYOND DIAGNOSTICS: THE EVOLVING ROLE OF IMMUNOHISTOCHEMISTRY

IN SITU HYBRIDIZATION

APPROACH TO USING IMMUNOHISTOCHEMISTRY

Pearls and Pitfalls

Chapter 4. Flow Cytometry

GENERAL PRINCIPLES

TECHNICAL CONSIDERATIONS

MATURE B-CELL NEOPLASMS

PLASMA CELL NEOPLASMS

MATURE T-CELL NEOPLASMS

NATURAL KILLER CELL NEOPLASMS

FLOW CYTOMETRY IN DIAGNOSIS AND CLASSIFICATION OF ACUTE LEUKEMIA

CHRONIC MYELOID NEOPLASMS

Acknowledgements

Pearls and Pitfalls

Chapter 5. Molecular Pathology of Hematologic Neoplasms

INTRODUCTION

BIOLOGICAL AND TECHNOLOGIC ISSUES

LYMPHOID NEOPLASMS

MYELOID NEOPLASMS

POTENTIAL PITFALLS OF MOLECULAR TESTING

SUMMARY AND CONCLUSIONS

Acknowledgments

Pearls and Pitfalls

Chapter 6. Important Chromosomal Aberrations in Hematologic Neoplasms and Key Techniques to Diagnose Them

TYPES OF CHROMOSOMAL ABERRATIONS IN HEMATOLOGIC MALIGNANCIES

CONVENTIONAL CYTOGENETIC METHODS

MOLECULAR CYTOGENETIC METHODS

CLINICAL RELEVANCE OF CHROMOSOMAL ABNORMALITIES IN HEMATOLOGIC MALIGNANCIES

CONCLUSION

Pearls and Pitfalls

Acknowledgments

Part II. Normal and Reactive Conditions of Hematopoietic Tissues

Chapter 7. Normal Lymphoid Organs and Tissues

NORMAL LYMPHOID TISSUES

B-CELL AND T-CELL DIFFERENTIATION

Acknowledgements

Pearls and Pitfalls

Chapter 8. Reactive Lymphadenopathies

FOLLICULAR AND NODULAR PATTERNS

PREDOMINANTLY SINUS PATTERN

INTERFOLLICULAR OR MIXED PATTERNS

DIFFUSE PATTERN

Pearls and Pitfalls

Chapter 9. The Normal Bone Marrow

INTRODUCTION

MEDICAL INDICATIONS FOR BONE MARROW EXAMINATION

COMPONENTS OF A BONE MARROW EVALUATION

COLLECTION OF BONE MARROW ASPIRATE AND CORE BIOPSY

PROCESSING OF MARROW TREPHINE BIOPSY AND ASPIRATE

BONE MARROW EVALUATION

CYTOCHEMISTRY AND HISTOCHEMISTRY

BONE MARROW EXAMINATION AND REPORTING

CONCLUSION

Acknowledgments

Pearls and Pitfalls

Chapter 10. Evaluation of Anemia, Leukopenia, and Thrombocytopenia

EVALUATION OF ANEMIA

EVALUATION OF LEUKOPENIA

EVALUATION OF THROMBOCYTOPENIA

EVALUATION OF SPECIFIC BONE MARROW FAILURE SYNDROMES

Pearls and Pitfalls

Chapter 11. Bone Marrow Findings in Inflammatory, Infectious, and Metabolic Disorders

REACTIVE NEUTROPHILIA

REACTIVE LYMPHOCYTOSIS

REACTIVE EOSINOPHILIA

REACTIVE BASOPHILIA

REACTIVE MONOCYTOSIS

BONE MARROW IN INFECTIOUS DISORDERS

BONE MARROW IN NON-INFECTIOUS SYSTEMIC AND INFLAMMATORY DISORDERS

CONCLUSION

Pearls and Pitfalls

Part III. Lymphoid Neoplasms

Section 1. MATURE B-CELL NEOPLASMS

Chapter 13. Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma, Monoclonal B-Cell Lymphocytosis, and B-Cell Prolymphocytic Leukemia

CHRONIC LYMPHOCYTIC LEUKEMIA/SMALL LYMPHOCYTIC LYMPHOMA

MONOCLONAL B-CELL LYMPHOCYTOSIS

B-CELL PROLYMPHOCYTIC LEUKEMIA

Pearls and Pitfalls

Chapter 14. Lymphoplasmacytic Lymphoma and Waldenström Macroglobulinemia

DEFINITION OF THE DISEASE

SYNONYMS AND RELATED TERMS

EPIDEMIOLOGY

CLINICAL FEATURES

MORPHOLOGY

IMMUNOPHENOTYPE

MOLECULAR GENETIC FINDINGS

POSTULATED NORMAL COUNTERPART AND PATHOGENESIS

CLINICAL COURSE, TREATMENT, AND PROGNOSIS

DIFFERENTIAL DIAGNOSIS

Pearls and Pitfalls

Chapter 15. Hairy Cell Leukemia

DEFINITION OF DISEASE AND NOMENCLATURE

EPIDEMIOLOGY

ETIOLOGY

CLINICAL FEATURES

MORPHOLOGY

PHENOTYPE

GENETICS AND MOLECULAR FINDINGS

POSTULATED CELL OF ORIGIN AND NORMAL COUNTERPART

VARIANTS

DIFFERENTIAL DIAGNOSIS

CLINICAL COURSE AND TREATMENT

PROGNOSTIC AND PREDICTIVE FACTORS

Pearls and Pitfalls

Chapter 16. Splenic Marginal Zone Lymphoma and Other Small B-Cell Neoplasms in the Spleen

DEFINITION

SYNONYMS AND RELATED TERMS

EPIDEMIOLOGY

ETIOLOGY

CLINICAL FEATURES

MORPHOLOGY

IMMUNOPHENOTYPE

GENETICS

OTHER SPLENIC B-CELL LYMPHOMAS

Pearls and Pitfalls

Chapter 17. Follicular Lymphoma

Definition

Epidemiology

Clinical Features

Morphologic Features

Grading and Terminology

Related B-Cell Lymphomas and Follicular Proliferations

Immunophenotype

Cytogenetic and Genetic Features

Postulated Normal Counterpart and Pathogenesis

Etiology

Clinical Course

Differential Diagnosis

Pearls and Pitfalls

Chapter 18. Extranodal Marginal Zone Lymphoma: MALT Lymphoma

Definition

Synonyms and Related Terms

Epidemiology

Etiology

Histopathology of Acquired Malt

Pathology of Malt Lymphoma

Immunohistochemistry

Genetic Features of Malt Lymphoma

Postulated Cell of Origin

Clinical Course

Differential Diagnosis

Pearls and Pitfalls

Chapter 19. Primary Cutaneous B-Cell Lymphomas

Historical Background

Primary Cutaneous MARGINAL ZONE Lymphoproliferative Disorder

Primary Cutaneous FOLLICLE CENTER Lymphoma

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

Intravascular Large B-Cell Lymphoma

B-Lymphoblastic Lymphoma

Ebv-Positive Mucocutaneous Ulcer and Other Cutaneous Immunodeficiency-Associated B-Cell LymphOproliferative Disorders

Pearls and Pitfalls

Chapter 20. Nodal Marginal Zone Lymphoma

Definition

Epidemiology, Etiology, and Cofactors

Clinical Features

Morphology

Immunophenotype

Genetics and Molecular Findings

Postulated Cell of Origin

Clinical Course and Prognostic Factors

PEDIATRIC-TYPE NODAL MARGINAL ZONE LYMPHOMA (PT-NMZL)

Differential Diagnosis

Pearls and Pitfalls

Chapter 21. Mantle Cell Lymphoma

DEFINITION

EPIDEMIOLOGY

CLINICAL MANIFESTATIONS

MORPHOLOGY

IMMUNOPHENOTYPE

MANTLE CELL LYMPHOMA VARIANTS

CYTOGENETIC FINDINGS

MOLECULAR CHARACTERISTICS

POSTULATED CELL OF ORIGIN

MULTISTEP DEVELOPMENT OF MANTLE CELL LYMPHOMA

Clinical Course

PROGNOSTIC PARAMETERS

THERAPY

DIFFERENTIAL DIAGNOSIS

Pearls and Pitfalls

Chapter 22. Aggressive B-Cell Lymphomas Including Diffuse Large B-Cell Lymphoma, Not Otherwise Specified and Other Nodal and Extranodal Large B-Cell Lymphomas

INTRODUCTION

DEFINITIONS, SYNONYMS, AND TERMS

DIFFUSE LARGE B-CELL LYMPHOMA, NOT OTHERWISE SPECIFIED

T-CELL/HISTIOCYTE–RICH LARGE B-CELL LYMPHOMA

PRIMARY MEDIASTINAL LARGE B-CELL LYMPHOMA

INTRAVASCULAR LARGE B-CELL LYMPHOMA

Pearls and Pitfalls

Chapter 23. Burkitt Lymphoma, High-Grade B-Cell Lymphoma Not Otherwise Specified, High-Grade B-Cell Lymphoma With MYC and BCL2/BCL6 Rearrangements, Large B-Cell Lymphoma With 11q Aberration, and Provisional Entity High-Grade B-Cell Lymphoma With MYC and BCL6 Rearrangements

Why These Four Entities in One Chapter? A Historical Perspective On the Development of Disease Concepts

BURKITT LYMPHOMA

LARGE/HIGH-GRADE B-CELL LYMPHOMA WITH 11Q ABERRATION

DIFFUSE LARGE B-CELL LYMPHOMA/HIGH-GRADE B-CELL LYMPHOMA WITH MYC AND BCL2 REARRANGEMENTS

PROVISIONAL ENTITY: HIGH-GRADE B-CELL LYMPHOMA WITH MYC AND BCL6 REARRANGEMENTS

HIGH-GRADE B-CELL LYMPHOMA, NOT OTHERWISE SPECIFIED

Pearls and Pitfalls

Chapter 24. Plasmablastic Neoplasms Other Than Plasma Cell Myeloma

Plasmablastic Lymphoma

Alk-Positive Large B-Cell Lymphoma

Pearls and Pitfalls

Chapter 25. Plasma Cell Neoplasms

Classification Of Plasma Cell Neoplasms

Pathogenesis of Plasma Cell Neoplasms

Multiple Myeloma

Monoclonal Gammopathy Of Undetermined Significance

Plasmacytoma

Immunoglobulin Deposition Diseases

Plasma Cell Neoplasms With Associated Paraneoplastic Syndrome

Pearls and Pitfalls

Chapter 26. Nodular Lymphocyte-Predominant B-Cell Lymphoma

Definition

SYNONYMS AND RELATED TERMS

Historical Background

Epidemiology

Clinical Features

Morphology

Immunophenotype

Genetics and Molecular Findings

Relationship With Progressively Transformed Germinal Centers

Transformation To Diffuse Large B-Cell Lymphoma

Relationship With T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

Other Differential Diagnoses

Treatment

Prognosis

Conclusion

Pearls and Pitfalls

Chapter 27. Classic Hodgkin Lymphoma

Definition

Synonyms and Related Terms

Epidemiology

Etiology

Clinical Features

Morphology

Immunophenotype

Genetics and Molecular Findings

Postulated Cell of Origin

Clinical Course and Prognostic Factors

Related Lesions and Differential Diagnoses

Pearls and Pitfalls

Chapter 28. Virally Associated B-Cell Lymphoproliferative Disease

Ebv-Associated Lymphoproliferative Disorders

HHV-8-Associated Lymphoproliferative Disorders

Pearls and Pitfalls

Section 2. MATURE T-CELL AND NK-CELL NEOPLASMS

Chapter 29. Epstein-Barr Virus–Associated T-Cell and Natural Killer–Cell Lymphoproliferative Disorders

INTRODUCTION

Epstein-Barr Virus–Associated Hemophagocytic Lymphohistiocytosis

Chronic Active Epstein-Barr Virus Disease

Severe Mosquito Bite Allergy

Hydroa Vacciniforme Lymphoproliferative Disorder

Systemic Epstein-Barr Virus–Positive T-Cell Lymphoma of Childhood

Extranodal NK/T-Cell Lymphoma, Nasal Type

Extranasal NK/T-Cell Lymphoma

Aggressive Nk-Cell Leukemia

Primary Nodal Epstein-Barr Virus–Positive T/Nk-Cell Lymphoma

Pearls and Pitfalls

Chapter 30. T-Cell and NK-Cell Large Granular Lymphocyte Proliferations

History and Classification

Definitions

Synonyms and Related Terms

Etiology and Epidemiology

Clinical Features

Morphology

Immunophenotype

Genetics and Molecular Findings

Postulated Cell of Origin and Pathogenesis

Clinical Management and Prognosis

Differential Diagnosis

Pearls and Pitfalls

Chapter 31. T-Cell Prolymphocytic Leukemia

Definition

Consensus Criteria For Diagnosis

Epidemiology

Clinical Features

Morphology

Immunophenotype

Genetics and Molecular Findings

Postulated Cell of Origin

Clinical Course

Treatment

Differential Diagnosis

Pearls and Pitfalls

Chapter 32. Adult T-Cell Leukemia/Lymphoma

Definition

Epidemiology

Clinical Features

Morphology

Immunophenotype

Genetics, Molecular Findings, and Role of HTLV-1

Postulated Normal Counterpart

Clinical Course

Differential Diagnosis

Pearls and Pitfalls

Chapter 33. Hepatosplenic T-Cell Lymphoma

Definition

Epidemiology

Etiology

Clinical Features

Morphology

Phenotype

Cytogenetic and Molecular Findings

Postulated Cell of Origin

CLINICAL Course

Differential Diagnosis

Pearls and Pitfalls

Chapter 34. Peripheral T-Cell Lymphoma, Not Otherwise Specified

Definition

SYNONYMS AND RELATED TERMS

Epidemiology

Clinical Features

Morphology

Immunophenotype

Genetic and Molecular Characteristics

Variants and Subgroups

Extranodal Peripheral T-Cell Lymphoma, Not Otherwise Specified

Prognosis and Predictive Features

Primary Nodal Epstein-Barr Virus–Positive T/Natural Killer–Cell Lymphoma

Diagnostic Approach To Peripheral T-Cell Lymphoma, Not Otherwise Specified And Differential Diagnoses

Pearls and Pitfalls

Chapter 35. Follicular Helper T-Cell Lymphoma

Definition

Synonyms and Related Terms

Epidemiology

Etiology

Follicular Helper T Cells

Clinical Features

Morphology

Immunophenotype

Genetics

Clinical Course and Prognosis

Differential Diagnosis

Pearls and Pitfalls

Chapter 36. Anaplastic Large Cell Lymphoma, ALK Positive and ALK Negative

Definition and Background

Anaplastic Large Cell Lymphoma, Alk Positive

Anaplastic Large Cell Lymphoma, Alk Negative

Breast Implant–Associated Anaplastic Large Cell Lymphoma

Differential Diagnosis of Anaplastic Large Cell Lymphoma

Pearls and Pitfalls

Chapter 37. Enteropathy-Associated T-Cell Lymphoma and Other Primary Intestinal T-Cell Lymphomas

Enteropathy-Associated T-Cell Lymphoma

Refractory Celiac Disease

Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma

Intestinal T-Cell Lymphoma, Not Otherwise Specified

Indolent Natural Killer–Cell and T-Cell Lymphoproliferative Disorders of the Gastrointestinal Tract

Pearls and Pitfalls

Chapter 38. Mycosis Fungoides and Sézary Syndrome

Mycosis Fungoides

Sézary Syndrome

Pearls and Pitfalls

Chapter 39. Primary Cutaneous CD30-Positive T-Cell Lymphoproliferative Disorders

Definition

SYNONYMS AND RELATED TERMS

Epidemiology

Etiology

Clinical Features

Morphology

Immunophenotype

Genetics and Molecular Findings

Postulated Cell of Origin

Clinical Course

Differential Diagnosis

Pearls and Pitfalls

Chapter 40. Primary Cutaneous T-Cell Lymphomas: Rare Subtypes

Introduction

Primary Cutaneous CD8-Positive Aggressive Epidermotropic Cytotoxic T-Cell Lymphoma

Primary Cutaneous γδ T-Cell Lymphoma

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Primary Cutaneous CD4-Positive Small/Medium T-Cell Lymphoproliferative Disorder

Primary Cutaneous Acral CD8-Positive T-Cell Lymphoproliferative Disorder

Other Types of Cutaneous T-Cell Lymphoma

Pearls and Pitfalls

Section 3. PRECURSOR B-AND T-CELL NEOPLASMS

Chapter 41. Precursor B-Cell and T-Cell Neoplasms

- Classification of Precursor Lymphoid Neoplasms
- B-Cell Lymphoblastic Leukemia/Lymphoblastic Lymphoma
- T-Cell Lymphoblastic Lymphoma/Lymphoblastic Leukemia
- Conclusion
- Pearls and Pitfalls

Chapter 42. Acute Leukemias of Ambiguous Lineage

- Definitions
- Synonyms and Related Terms
- Epidemiology
- Clinical Features
- Diagnostic Criteria and Lineage Assignment
- Genetic and Molecular Findings
- Clinical Course
- Lineage Switch

Differential Diagnosis

Pearls and Pitfalls

Chapter 12. Principles of Classification of Lymphoid Neoplasms

INTRODUCTION

HISTORICAL BACKGROUND

THE ICC AND WHO 5TH ED. PROPOSALS: SIMILARITIES AND DIFFERENCES

CONCLUSION

Pearls and Pitfalls

Part IV. Myeloid, Histiocytic, and Related Proliferations

Chapter 43. Principles of Classification of Myeloid Neoplasms

Introduction

Evaluation of Myeloid Neoplasms

International Consensus Classification

Conclusion

Acknowledgment

Chapter 44. The Myelodysplastic Syndromes

Incidence

Synonyms and Related Terms

Clinical Features

Laboratory Features

Diagnosis

Classification

Differential Diagnosis

Etiology and Pathogenesis

Conclusion

Pearls and Pitfalls

Chapter 45. Myeloid and Hematologic Neoplasms With Germline Predisposition

Definition and Introduction

Synonyms and Related Terms

Hematologic Neoplasms with Germline Predisposition Without A Constitutional Disorder Affecting Multiple Organ Systems

Hematologic Neoplasms with Germline Predisposition Associated with A Constitutional Platelet Disorder

Hematologic Neoplasms with Germline Predisposition Associated with A Constitutional Disorder Affecting Multiple Organ Systems

Acute Lymphoblastic Leukemia with Germline Predisposition

Pearls and Pitfalls

Chapter 46. Acute Myeloid Leukemia

SYNONYMS AND RELATED TERMS

EPIDEMIOLOGY

ETIOLOGY

CLINICAL FEATURES

MORPHOLOGY

CYTOCHEMISTRY

IMMUNOPHENOTYPE

GENETICS

PROGNOSIS

ACUTE MYELOID LEUKEMIA DISEASE TYPES

MYELOID PROLIFERATIONS OF DOWN SYNDROME

MYELOID SARCOMA

DIAGNOSTIC QUALIFIERS IN ACUTE MYELOID LEUKEMIA

INTEGRATED APPROACH TO THE DIAGNOSIS OF ACUTE MYELOID LEUKEMIA

Pearls and Pitfalls

Chapter 47. Myeloproliferative Neoplasms

Introduction

Etiology and Pathogenesis

Chronic Myeloid Leukemia (CML)

Chronic Neutrophilic Leukemia (CNL)

Classic Bcr::Abl1-Negative Myeloproliferative Neoplasms

Essential Thrombocythemia (ET)

Primary Myelofibrosis (PMF)

Polycythemia Vera

Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL, NOS)

Myeloproliferative Neoplasms, Unclassifiable (MPN-U)

Conclusion

Acknowledgments

Pearls and Pitfalls

Chapter 48. Myelodysplastic/Myeloproliferative Neoplasms and Premalignant Conditions

Introduction

Chronic Myelomonocytic Leukemia (CMML)

Clonal Cytopenia With Monocytosis of Undetermined Significance and Clonal Monocytosis of Undetermined Significance

Atypical Chronic Myeloid Leukemia (aCML)

Myelodysplastic/Myeloproliferative Neoplasm With Sf3b1 Mutation and Thrombocytosis (MDS/MPN-SF3B1-T)

Myelodysplastic/Myeloproliferative Neoplasm With Ring Sideroblasts and Thrombocytosis, Not Otherwise Specified (MDS/MPN-RS-T, NOS)

Myelodysplastic/Myeloproliferative Neoplasm, Not Otherwise Specified (MDS/MPN, NOS)

Myelodysplastic/Myeloproliferative Neoplasm With Isolated Isochromosome (17q) (MDS/MPM With i[17q];

ICC Provisional Subentity)

Acknowledgments

Pearls and Pitfalls

Chapter 49. Mastocytosis

Definition

Synonyms and Related Terms

General Aspects

Epidemiology and Etiology

Postulated Cell of Origin and Normal Counterpart

Genetics and Molecular Findings

Cytologic and Histologic Diagnosis

Differential Diagnosis

Classification

Pearls and Pitfalls

Chapter 50. Eosinophilia, Chronic Eosinophilic Leukemia, Not Otherwise Specified, and Myeloid/Lymphoid Neoplasms With Eosinophilia and Tyrosine Kinase Gene Fusions

Overview

Introduction

Classification

Clinical Presentation

Approach To Diagnosis

Myeloid/Lymphoid Neoplasms with Eosinophilia and Rearrangements Of PDGFRA, PDGFRB, FGFR1, FLT3, OR JAK2 or with ETV6::ABL1

CEL, NOS, IHE/IHES, and other Rare Reported Genetic Alterations Associated with Clonal Eosinophilia

Conclusion

Acknowledgments

Pearls and Pitfalls

Chapter 51. Blastic Plasmacytoid Dendritic Cell Neoplasm

Definition

Synonyms and Related Terms

Epidemiology

Etiology

Clinical Features

Morphology

Immunophenotype

Cytochemistry

Genetics and Molecular Findings

Postulated Cell of Origin and Normal Counterpart

Clinical Course and Prognosis

Differential Diagnosis

Pearls and Pitfalls

Chapter 52. Histiocytic and Dendritic Cell Proliferations—Systemic and Neoplastic

Non-Neoplastic Histiocytic Disorders

Histiocytic and Dendritic Cell Neoplasms

Acknowledgment

Pearls and Pitfalls

Part V. Immunodeficiency Disorders

Chapter 53. The Pathology of Primary Immunodeficiencies

Classification

Synonyms and Related Terms

Epidemiology

Severe Combined Immunodeficiency

PI3K-Related Immunodeficiencies

Defects that Affect Homeostasis of The Immune System

Defects in Synapse Formation and Crosstalk Between Antigen-Presenting Cells and T Cells

Pearls and Pitfalls

Chapter 54. Iatrogenic Immunodeficiency-Associated Lymphoproliferative Disorders

Definition

Synonyms and Related Terms

Classification

Posttransplant Lymphoproliferative Disorders

Iatrogenic Immunodeficiency-Associated Lymphoproliferative Disorders in Nontransplant Settings

Pearls and Pitfalls

Part VI. Site-Specific Issues in the Diagnosis of Lymphoma and Leukemia

Chapter 55. Bone Marrow Evaluation for Lymphoma

Distinction Between Benign Lymphoid Aggregates and Lymphoma

Non-Hodgkin Lymphoma Involving Bone Marrow

B-Cell Lymphomas Involving Bone Marrow

T-Cell Lymphomas Involving Bone Marrow

Hodgkin Lymphoma Involving Bone Marrow

Nonlymphoid Malignancies That Mimic Lymphomas

Pearls and Pitfalls

Chapter 56. Evaluation of the Bone Marrow After Therapy

Effects of Selected Therapies and Bone Marrow Transplantation

Acute Leukemia or Myelodysplastic Syndrome

Chronic Myeloid Leukemia

BCR::ABL1-Negative Myeloproliferative Neoplasms

Chronic Lymphoproliferative and Plasma Cell Disorders

Other Bone Marrow Changes after Therapy

Pearls and Pitfalls

Chapter 57. Non-hematopoietic Neoplasms and Other Lesions of the Bone Marrow and Lymph Nodes

Introduction

Metastatic Tumors of the Bone Marrow

Primary Tumors of Bone

Vascular Tumors Involving Bone

Other Soft-Tissue Tumors Involving Bone

Malignant Lymphomas Involving Bone and Bone Marrow

Benign Lesions of Bone

Metastatic Tumors to Lymph Nodes

Benign Lymph Node Inclusions

Mesenchymal Proliferations in Lymph Nodes

Conclusion

Pearls and Pitfalls

Chapter 58. Spleen: Normal Architecture and Neoplastic and Non-neoplastic Lesions

The Normal Spleen

Gross Examination

Lymphoid Hyperplasia

Castleman Disease

Autoimmune Lymphoproliferative Syndrome

Hodgkin Lymphoma

Non-Hodgkin Lymphomas

Precursor Lymphoid Neoplasms

Systemic or Secondary Mature B-Cell Lymphomas and Leukemias

Primary B-Cell Lymphoid Neoplasms Presenting With Prominent Splenomegaly

Mature T-Cell and Natural Killer–Cell Neoplasms

T-Cell Lymphoid Neoplasms Presenting With Prominent Splenomegaly

Myeloid Neoplasms

Systemic Mastocytosis

Proliferations of the Monocyte-Macrophage System

Mesenchymal Tumors and Non-Neoplastic Disorders That Mimic Neoplasms

EPSTEIN-BARR VIRUS—POSITIVE INFLAMMATORY FOLLICULAR DENDRITIC CELL/FIBROBLASTIC RETICULAR CELL TUMOR AND REACTIVE PSEUDOTUMORAL LESIONS OF THE SPLEEN

Splenic Cysts

Other Tumors

Storage Diseases

Pearls and Pitfalls

Chapter 59. Diagnosis of Lymphoma in Extranodal Sites Other Than Skin

Lymphomas of Immune-Privileged Sites

Lymphoma of The Nervous System and Meninges

Ocular Adnexal Lymphoma

Lymphomas of Waldeyer's Ring

Lymphomas of The Nasal Cavity and Paranasal Sinuses

Salivary Gland Lymphomas

Lymphomas of The Oral Cavity

Thyroid Lymphomas

Laryngeal Lymphomas

Pulmonary Lymphomas

Lymphomas of The Pleura and Pleural Cavity

Lymphomas of The Thymus

Cardiac Lymphomas

Lymphomas of The Breast

Gastrointestinal Lymphomas

Gastric Lymphoma

Small and Large Intestinal Lymphomas

Lymphomas of The Liver and Pancreatobiliary Tract

Adrenal Lymphomas

Urinary Tract Lymphomas

Male Genital Tract Lymphomas

Lymphomas of The Female Genital Tract

Lymphomas of Bone

Pearls and Pitfalls

Appendix A. The International Consensus Classification of Myeloid, Lymphoid, and Histiocytic Neoplasms

Preface

The first edition of *Hematopathology* was published in 2011, shortly after the introduction of the fourth edition of the *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*. The second edition was coordinated with the release of the revised fourth edition *Bluebook* in 2017. The third edition is being released at a critical time in the evolution of the classification of hematolymphoid neoplasms, as for the first time in nearly 30 years the field has seen the publication of two major classifications in 2022. Most of the principal editors of the 3rd and 4th edition WHO Classifications collaborated to produce the International Consensus Classification (ICC) in 2022, under the auspices of the Society for Hematopathology and the European Association for Haematopathology. The classification was developed following a Clinical Advisory Committee meeting, with the participation of more than 200 pathologists, clinicians, and scientists from 24 countries in September 2021, and published in a series of articles in *Blood* in 2022.[1-4] Concurrent with these events, the International Agency for Research on Cancer (IARC) invited a panel of editors and authors to develop the 5th edition of the WHO Classification, published in draft form in *Leukemia* in 2022.[5,6] The third edition of *Hematopathology* has adopted the ICC system to present the basic framework for the discussion of neoplastic disorders of lymphoid, myeloid, and

histiocytic neoplasms. However, each chapter will present key synonyms, where appropriate, for the WHO 5th edition, and importantly discuss the rationale for the preferred terminology adopted in the book.

The reader will find not only the most current terminology, but also a discussion of key changes in the classification of lymphomas and leukemias and of histiocytic disorders. Thus this book will be a valuable resource for the pathologist trying to keep up with this rapidly changing field.

Hematopathology is a discipline in which traditional methods of clinical and morphologic analysis are interwoven with newer, biologically based studies to achieve an accurate diagnosis. Scientific advances are proceeding at a rapid pace, with a greater emphasis today on the integration of newer genomic studies as a basis for diagnosis, and, in many cases, treatment. Studies of hematologic malignancies have been at the forefront in applying the principles of basic research to the understanding of human disease. All cancers are increasingly recognized as genetic diseases, with precise genetic alterations often defining entities. Advances in immunologic and molecular genetic technology have rapidly migrated to the clinical laboratory, where they play a role in routine diagnosis, and the introduction of next-generation sequencing is changing the face of molecular diagnostics. The reader will find valuable guidance in how to integrate these new advances in daily practice.

The discussion of each disease includes a description of morphologic, immunophenotypic, and clinical features, along with relevant genetic findings. These data inform our understanding of

disease pathogenesis and provide valuable and often critical adjuncts to diagnosis and treatment. The goal is to provide concise, up-to-date, and practical information that is easily accessed by the reader. Equally relevant to the diagnostic pathologist is an appreciation of the spectrum of reactive and inflammatory lesions of hematolymphoid tissues occurring in immunocompetent patients and in those with altered immune states. Thus the reader will find a discussion of reactive lymphadenopathies and primary and iatrogenic immunodeficiency disorders. Additional chapters deal with the bone marrow response to inflammatory, infectious, and metabolic diseases; germline changes impacting hematopoiesis myeloid neoplasia; and the impact of therapy on bone marrow morphology. The book offers a comprehensive guide to benign and malignant hematopathology that will be a valued resource for the practicing pathologist, hematologist, and oncologist.

It is increasingly important that clinicians be aware of basic principles of hematopathology diagnosis; hematologists and hematopathologists must work as a team to achieve the correct diagnosis. Just as the pathologist must use clinical data to make an accurate diagnosis, the clinician should have sufficient knowledge of diagnostic principles to appreciate when the pathologic diagnosis just does not quite fit.

The Editors appreciate that the reader needs to have access to key source material and that a richly referenced book provides important information for those who wish to delve further into the topic. The scientific literature is voluminous, and we thought it was important to include older historical references, as well as the most recent scientific data. All the references are accessible on the Elsevier

eBooks+ website, with the benefit of electronic access to the PubMed links instantaneously. However, the authors provide key references in print in each chapter to provide the reader with the most useful sources to examine the topic in greater depth.

We were delighted to add several new experts to the editorial team for the third edition. Two international experts in lymphoid diseases, Lisa Rimsza and Steven Swerdlow, have joined as editors. Dr. Rimsza is a leader in the integration of new biological approaches to diagnosis, while Dr. Swerdlow was a key figure in the development of the modern lymphoma classification. Attilio Orazi, an international expert in myeloproliferative and myelodysplastic diseases, joins Dan Arber to complete the bone marrow and myeloid squadron. We acknowledge the valuable contributions of Nancy Lee Harris and James Vardiman, who were editors for earlier editions and were critical in establishing this book as the classic reference in its field. We hope this book will prove to be a constant and valued resource for pathologists and clinicians dealing with hematologic diseases and will ultimately benefit patients and their families.

Cytogenetic and Molecular Studies

REPORTING THE LYMPH NODE BIOPSY

A multiparameter approach that integrates clinical, histologic, immunophenotypic, cytogenetic, and molecular data for precise diagnostic classification is central to the World Health Organization (WHO) and International Consensus Classification (ICC) schemes of hematolymphoid tumors.[1,2] Other than clinical information, all of the information necessary for the correct diagnosis depends on the availability of an adequate quantity of appropriately processed tissue.[3] If the initial processing of a lymph node biopsy specimen is not performed correctly, all subsequent morphologic, immunophenotypic, cytogenetic, and molecular studies are compromised, potentially leading to a nondiagnostic result that may necessitate a follow-up procedure, a delay in diagnosis, increased patient anxiety, and increased costs. With the current mandate to provide cost-effective health care and with mounting pressure to diagnose based on needle aspirations and cytologic preparations, repeating an open lymph node biopsy procedure is not trivial. Thus it is imperative that the pathologist play an active role in optimal handling, triaging, and processing of lymph node specimens. In particular, when small pieces of tissues are available, pathologists

may play a pivotal role in deciding which ancillary studies should be prioritized to maximize the likelihood of achieving a definitive diagnostic, prognostic, or theranostic result.

The lymph node presents certain unique challenges for pathologists and histotechnologists because of its innate organizational structure.[4] It is composed of millions of small cells held together by fine strands of connective tissue surrounded by a fibrous capsule that is relatively impervious to fixation and to processing chemicals. Histologic sections of excellent quality can be obtained only if each step in the processing of a lymph node is handled with care and knowledge of the underlying factors that result in optimal preparations. This chapter reviews the essential steps for triage, handling, and stewardship of lymph node tissue for a variety of morphologic, immunophenotypic, molecular, and other ancillary techniques that are crucial to optimal patient care.

ASSESSING AND PRIORITIZING FRESH TISSUE

Knowledge of the patient's clinical history and the suspected or differential diagnosis facilitates the targeting of a lymph node that best represents the underlying pathologic process. Despite the obvious appeal of convenient access, minimal discomfort, and the procedural simplicity of excising a superficial lymph node, these are not always of diagnostic value. Given that most lymphomas are fluorodeoxyglucose (FDG) avid, combined imaging modalities such as 18F-fluorodeoxyglucose positron-emission tomography/computed tomography (^{18}F-FDG PET/CT) have revolutionized the targeting, staging, and monitoring of lymphomas.[5,6] By assessing the

standardized uptake value (SUV), a surgeon may target highly FDG-avid lymph nodes, which are accessible and safe for sampling (**Fig. 1-1**). Radiologic assistance to guide optimal acquisition of lymph nodes is particularly relevant in cases of suspected large cell transformation and is recommended by the International Conference on Malignant Lymphomas Imaging Working Group.[7] This approach should lead to a precise, targeted lymph node excision and avoids the erroneous sampling of nondiagnostic tissue.

Excisional biopsy of an entire lymph node has the significant benefit of providing a complete view of the lymph node architecture, which can reveal patterns of malignant cell involvement that serve as diagnostic and histologic features to lead to the correct diagnosis. The benefit of excisional lymph node biopsy is especially relevant at initial diagnosis, whereas smaller-volume biopsies may be sufficient in patients with some forms of recurrent lymphoma.[8,9] Excisional biopsies are particularly preferred when diagnostic cells are admixed in a reactive background, as, for example, in nodular lymphocyte predominant B-cell (Hodgkin) lymphoma (NLPBL)[10]; when intact architecture contributes substantially to diagnosis because of substantial overlap with other malignant or benign entities, such as follicular helper T-cell lymphoma (TFH) of the angioimmunoblastic-type (AITL)[11]; or when there is partial involvement of lymphoma. When an infectious cause is suspected, the surgeon should submit a portion from one pole of the lymph node for appropriate microbiological studies directly from the sterile environment of the operating room. It should be noted, however, that such specimens are prone to contamination.[12]

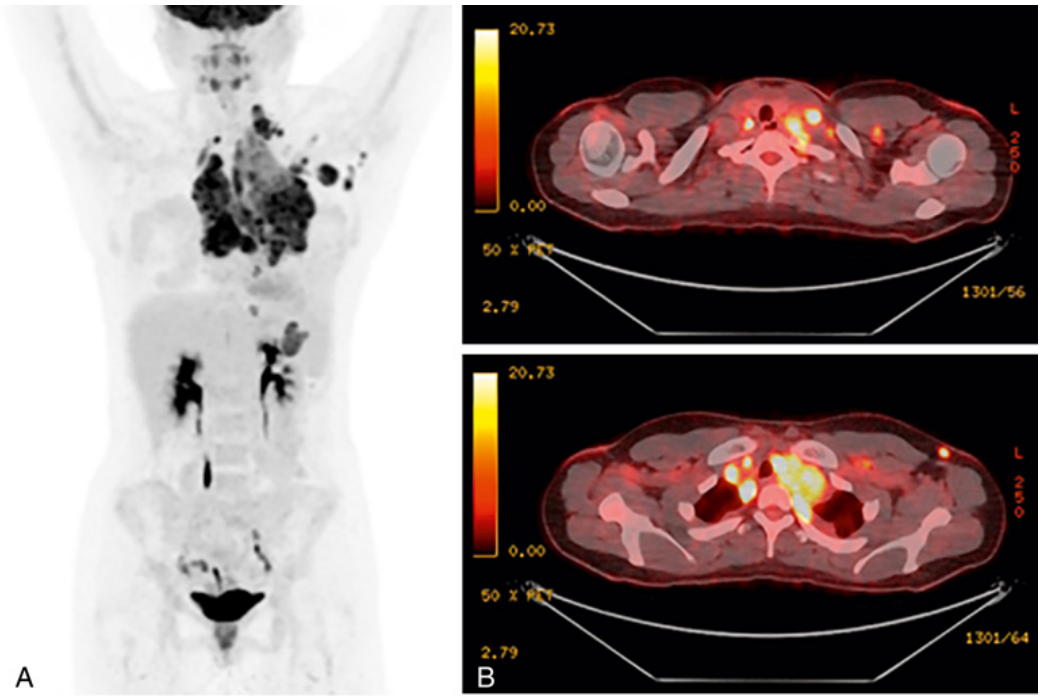

FIGURE 1-1. Using PET-CT to aid in the selection of a lymph node for biopsy.**A,** Coronal positron-emission tomography (PET) scan showing increased fluorodeoxyglucose (FDG) avidity *(black)* in the left cervical, left axillary, mediastinum, and hilar lymph nodes. **B,** Axial PET-computed tomography (CT) scan showing increased FGD avidity *(yellow)* in the left cervical lymph nodes *(upper)* and mediastinum *(lower)*. By selecting a PET-avid lymph node with a high standardized uptake value (SUV), the likelihood of obtaining a diagnostic specimen may be higher, especially when evaluating for large cell transformation.

In all other circumstances, the intact specimen should be submitted fresh to the pathologist in a specimen container and

immersed in saline or a culture medium such as RPMI (Roswell Park Memorial Institute) medium to ensure the specimen does not dry out during transit. Wrapping the specimen or laying it on gauze, sponges, or towels should be avoided, because this leads to desiccation of the lymph node cortex, especially when the specimen is exposed to air. Request for a "lymph node workup" should be clearly indicated on the requisition slip, specimen tag, or both. Ideally, the pathologist should be notified at the time of the biopsy to avoid a delay in the handling of the specimen. When a delay in delivery to the pathologist is anticipated, the specimen should be refrigerated to minimize autolysis. Storage at 4° C for up to 24 hours can yield satisfactory but not optimal morphologic, immunohistochemical, and genetic preservation.[13] When long delays are expected before the pathologist receives the specimen, the surgeon may be instructed to bisect the lymph node and make air-dried imprints, after which the fresh specimen can be sliced thinly, a portion placed in a culture medium such as RPMI for flow cytometry, and the remaining portion placed in buffered formalin for fixation. Certain specific clinical situations call for very specific handling and apportionment of fresh tissue, as when breast implant-associated anaplastic large cell lymphoma is suspected.[14]

A general workflow for lymph node tissue appropriation and processing is depicted in **Figure 1-2** and discussed in detail herein.

Once a well-targeted lymph node is excised within the operative room, a sterile intraoperative specimen can be submitted for cultures if infection is a clinical consideration. The specimen should be transported in saline or RPMI medium to the pathologist for gross processing, cytologic preparation, and possible intraoperative

consultation (frozen section). A fresh portion should be provided in RPMI medium for flow cytometry, fluorescence in situ hybridization (FISH), or molecular assays. The remaining tissue should be fixed in formalin for generation of formalin-fixed paraffin embedded (FFPE) tissue blocks for histology (hematoxylin and eosin [H&E]), immunohistochemistry (IHC), FISH, and select molecular assays.

GROSS PROCESSING OF THE LYMPH NODE BIOPSY

Gross Examination

The gross appearance of lymph nodes, including their color, consistency, and changes in contour, may provide useful information about the diagnosis and should be recorded during gross inspection of the fresh specimen (**Fig. 1-3**). Preservation of the hilus and the presence or absence of nodularity and fibrosis can offer important diagnostic clues. Preservation of the hilus is rare in lymphomas, and its presence suggests a reactive process (**Fig. 1-3A** and **B**). Necrosis within the node indicates the possibility of an infectious process and may prompt microbiological studies. Adherence of the node to the surrounding fat may denote extracapsular extension of disease and should also be noted in the gross description. Most lymphomas completely efface the nodal architecture, and a nodular appearance or fibrosis can be seen on gross examination (**Fig. 1-3C** to **E**).

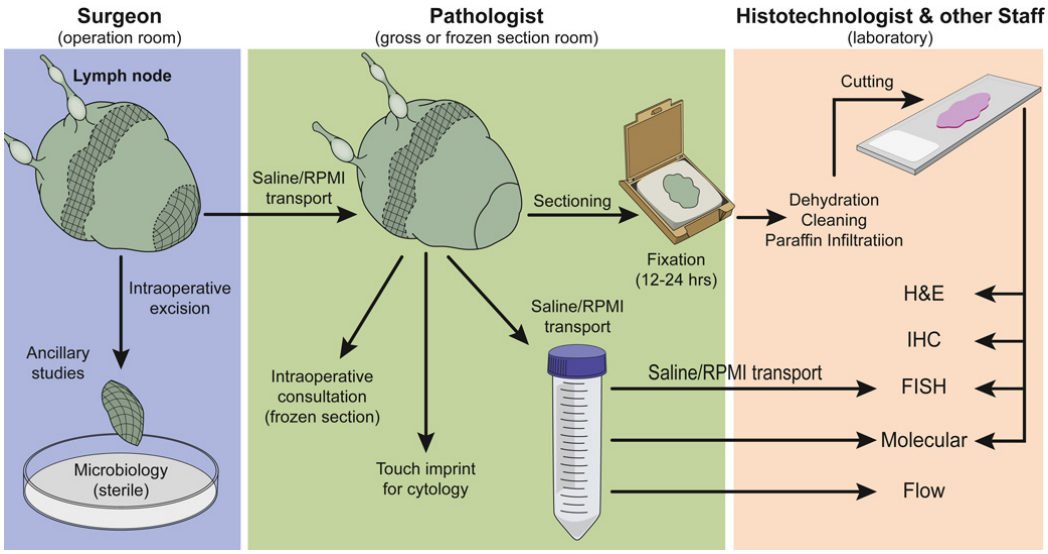

FIGURE 1-2. Appropriation of lymph node tissue.*FISH,* Fluorescence in situ hybridization; *H&E,* hematoxylin and eosin; *IHC,* immunohistochemistry; *RPMI,* Roswell Park Memorial Institute medium.

Although gross findings can be helpful in narrowing the differential diagnosis, an accurate pathologic diagnosis is virtually never possible based on gross findings alone. Thus, these findings must be interpreted in conjunction with microscopic features and immunophenotypic and genetic studies to establish a definitive diagnosis.

Intraoperative Consultation

The diagnosis of lymphoid malignancies can be challenging even on permanent sections. Because of the numerous artifacts generated during the preparation of a frozen section, a diagnosis of lymphoma based on frozen tissue is perilous and best avoided; moreover, even after fixation, previously frozen tissue contains artifacts that can

influence diagnostically relevant features, including cell size and chromatin characteristics. In addition, frozen tissue cannot be used for flow cytometry immunophenotyping. Although certain lymphomas can be distinguished on frozen sections, clinical colleagues should be advised of the unreliability of frozen sections for the accurate diagnosis and classification of lymphoma. In the rare event that a rapid interpretation is necessary for patient care, cytologic preparations (touch imprints or scrape preparations, as appropriate) should be examined in conjunction with frozen sections. Imprints require a negligible amount of material, thus preserving tissue for ancillary studies and yielding cytologic details that may not be appreciated on frozen tissue sections.[15]

The appropriate use of cytologic preparations, including touch or scrape imprints, and/or frozen sections of lymph node biopsy specimens is to estimate the adequacy of the tissue for diagnosis and to assess for morphologically evident non-hematolymphoid processes such as metastatic carcinoma. Touch imprints and/or frozen sections also offer pathologists the opportunity to allocate tissue for ancillary studies based on the preliminary differential diagnosis. This allows for rapid initiation of microbiological, cytogenetic, or flow cytometry studies with optimal preservation of cell viability. If the changes seen on touch imprint and/or frozen sections suggest a reactive process in a patient in whom there is a strong clinical suspicion of lymphoma, the surgeon or interventional radiologist can be advised to sample further to obtain diagnostic tissue.

Cytologic Preparations

The utility of cytologic preparations in the evaluation of lymphoid lesions should not be underestimated. Cytologic touch imprint or scrape preparations complement tissue diagnosis and are useful both at the time of frozen section and when examining permanent tissue sections. Touch and scrape imprints are encouraged for all intraoperative consultations for lymphoid lesions and should be examined in conjunction with the frozen tissue sections. Imprints can also facilitate the intraoperative assessment of hematolymphoid lesions of bone when frozen sections cannot be obtained.

When cytologic imprints are prepared from lymph node specimens, it is best to prepare and label six to eight slides ahead of time. For touch imprints, the cut surface of the lymph node should be positioned on a flat surface, such as a towel (**Fig. 1-4A**). While the slide is held firmly at one end, it is gently lowered and brought into contact with the cut surface of the node, avoiding smearing or sideways movement. This process can be repeated three to five times, creating a series of touch imprint slides. The imprint slide should immediately be placed in a Coplin jar with 95% alcohol. Buffered formalin or formaldehyde can also be used as a fixative. A few imprint slides may be air dried. Although there is almost always enough material available to make touch imprints without compromising specimen integrity, scrape preparations may not be necessary if touch preparations are informative and are best avoided when dealing with very small samples to prevent inadvertent crushing or distortion of the tissue. For scrape preparations, the fresh-cut surface of the lymph node is gently scraped with the edge of a slide or the blunt edge of a scalpel and immediately smeared onto a

previously labeled slide. Alcohol-dried and air-dried slides can be generated as for touch imprints.

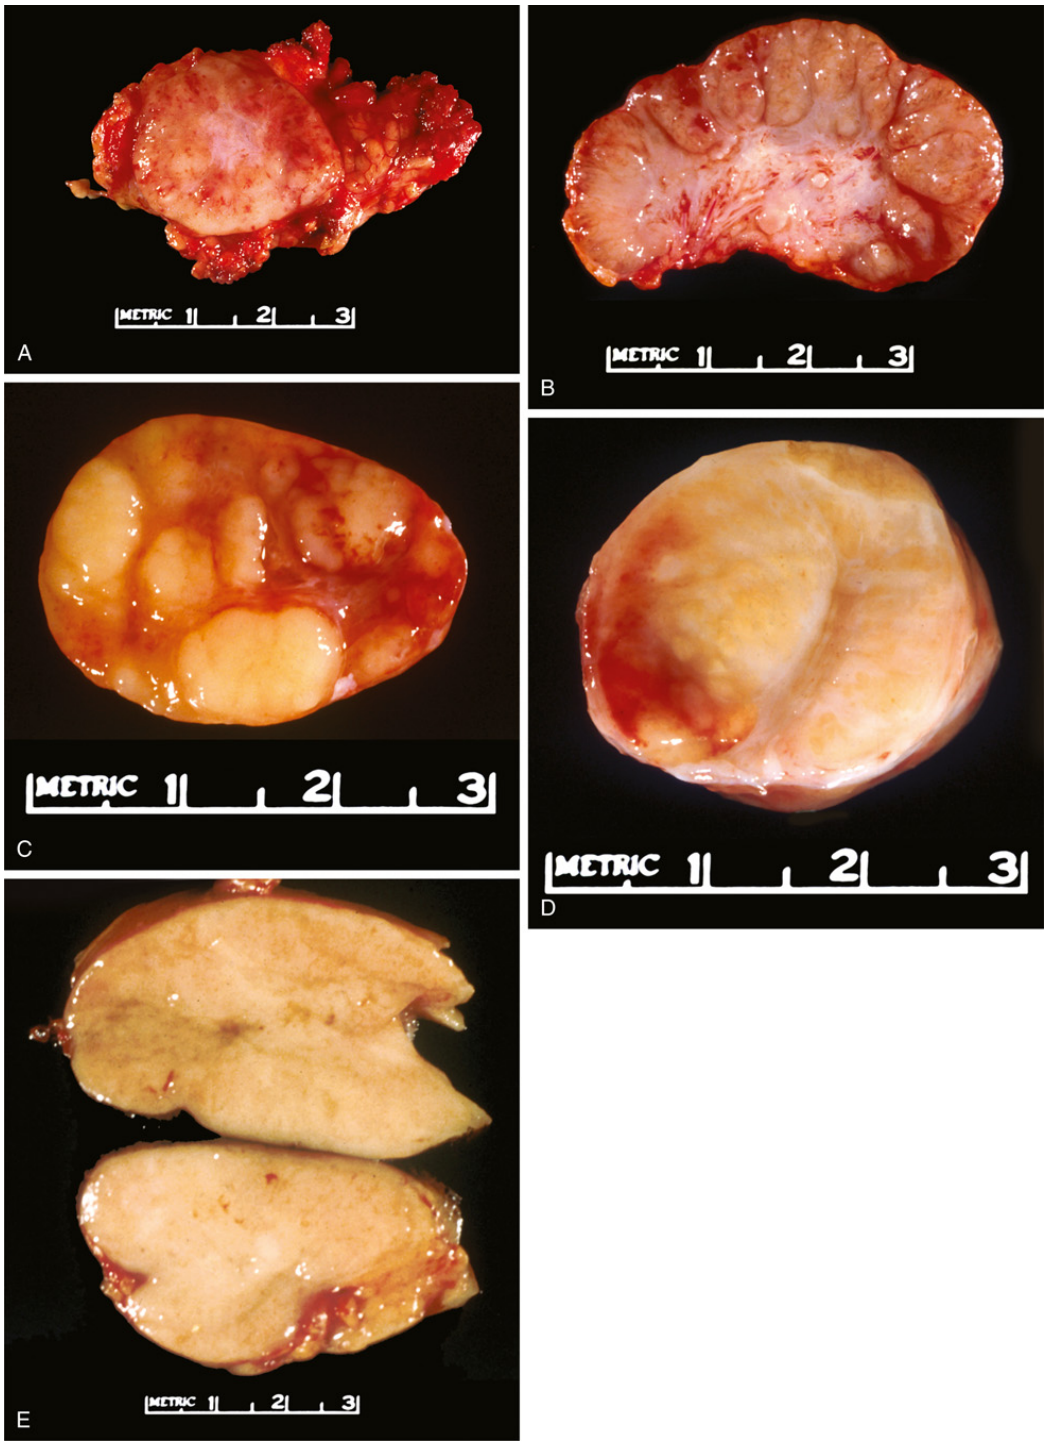

FIGURE 1-3. Gross appearance of lymph nodes involved by a variety of processes.**A,** Intraparotid lymph node with reactive hyperplasia shows preservation of the hilus (gray structure in the

center). **B,** Lymph node with dermatopathic lymphadenitis has a brownish color to the cut surface, possibly reflecting melanin deposition. The hilus is preserved in this lymph node as well, suggesting a reactive process. **C,** Lymph node with both progressively transformed germinal centers and nodular lymphocyte predominant B-cell lymphoma has an obviously nodular architecture on cut section. **D,** Lymph node containing nodular sclerosis classic Hodgkin lymphoma has fibrous bands traversing the cut surface. **E,** Lymph node involved by follicular lymphoma has a homogeneous, fleshy cut surface with obliteration of the hilus, which is typical of lymphomatous involvement.

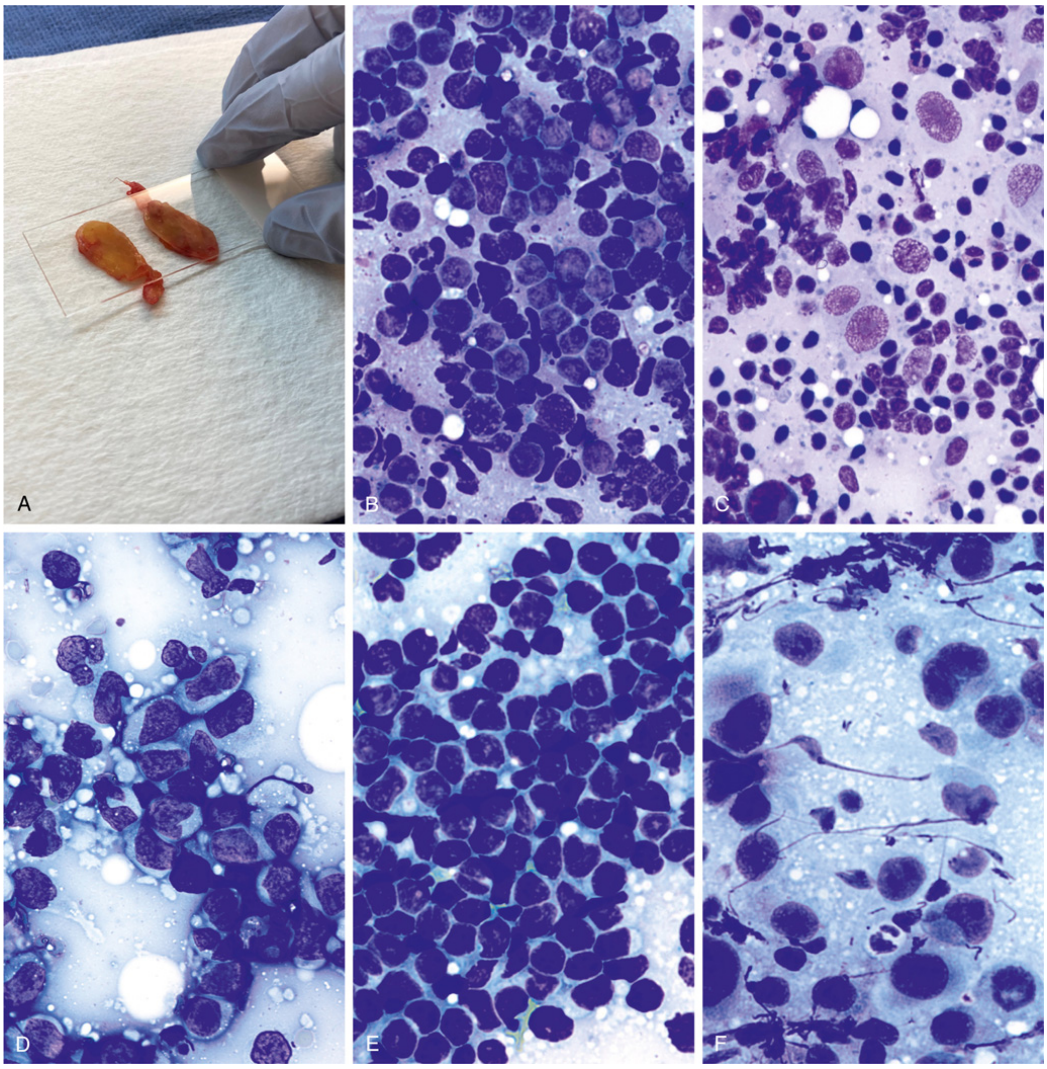

FIGURE 1-4. **A,** Example of touch imprint technique.**B,** Microscopic images of B-lymphoblastic lymphoma. **C,** Classic Hodgkin lymphoma. **D,** Diffuse large B-cell lymphoma. **E,** Follicular lymphoma. **F,** Metastatic poorly differentiated carcinoma of unknown primary site.

A Wright-Giemsa or Diff-Quik stain is best for identifying and characterizing cells of the hematopoietic system and tumors derived from them, but the Papanicolaou stain is useful for assessing nuclear

details such as membrane irregularity, chromatin configuration, and nucleoli. When necrosis and inflammatory cells are present, a Gram stain can be helpful to highlight bacterial organisms. In general, aspirations of lymph nodes are highly cellular and are characterized by a dispersed cell pattern and lymphoglandular bodies (detached cytoplasmic fragments of lymphoid cells). In aggressive lymphomas, the presence of monotonous sheets of medium-sized to large-sized cells, especially when associated with karyorrhexis and apoptosis, suggests the differential diagnosis of lymphoblastic, Burkitt, or large cell lymphoma (**Fig. 1-4A**). Similarly, imprints can be helpful in highlighting Reed-Sternberg cells (**Fig. 1-4C**) or high-grade cytologic features in diffuse large B-cell lymphoma (**Fig. 1-4D**). Indolent lymphomas composed of predominantly small cells or a mixed cellular milieu are much more difficult to diagnose on cytologic preparations than are aggressive lymphomas. Reactive follicular hyperplasia can be nearly impossible to distinguish from follicular lymphoma (**Fig. 1-3E**) on cytologic imprints, although the presence of a limited range of maturation together with the absence of tingible body macrophages favors a malignant diagnosis. Cytologic preparations can also be useful in the diagnosis of metastatic melanoma and carcinoma (**Fig. 1-4F**) and of non-neoplastic lesions in the lymph node, such as granulomatous and Kikuchi lymphadenitis. Lesions associated with significant sclerosis seldom yield sufficient material for cytologic preparations.

Sectioning

The two most important initial steps in the processing of a lymph node specimen are sectioning (blocking) and fixation. Blocking

should be performed promptly and should precede fixation, because an intact lymph node capsule is impervious to fixation. In addition, touch and scrape imprints are best obtained fresh. The objective of good lymph node sectioning is to provide an undisrupted section that maintains the overall architecture of the tissue and is thin enough to yield significant cytologic detail. Sections should also preserve the relationship between the capsule and the remainder of the lymphoid compartments (**Fig. 1-5**). The best cross-section of a lymph node results from sectioning perpendicular to the long axis of the node with a sharp knife in one continuous sweep. This technique facilitates excellent preservation of the nodal architecture. For lymph nodes less than 1 cm in diameter, a single cut along the long axis is recommended; such small specimens may be crushed when attempting to perform cross-sections perpendicular to the long axis. The entire specimen should be sectioned in 2- to 3-mm slices and then placed promptly in fixative. Portions of lymph nodes should never be left unfixed or fixed without slicing. Because the fibrous tissue in the capsule may contract when exposed to fixatives, scoring of the capsule by introducing small cuts with a sharp scalpel blade may prevent distortion during processing (**Fig. 1-5A**). When lymph node specimens are fixed whole or when the central portion of the section is too thick, uneven fixation results (**Fig. 1-6**). This may lead to autolysis of the central areas or retraction of the tissue, causing erosion or cracking of the sections upon cutting with a microtome blade.

Thin slices of 2 to 3 mm should be placed in shallow plastic cassettes (used in most modern surgical pathology laboratories) to allow adequate penetration by fixation and processing reagents.

Thorough—if not complete—sampling of the lymph node specimen is essential. This practice prevents sampling errors in disorders that may only partially involve the lymph node, such as NLPBL in patients with progressive transformation of germinal centers and in cases of grade variations or focal progression of a low-grade lymphoma (e.g., follicular lymphoma). Under most circumstances, once portions of the lymph node specimen have been removed for ancillary studies, the specimen is small enough to be submitted entirely in a few cassettes. When multiple lymph nodes are submitted or when a lymph node is so large that 10 or more cassettes are required to submit the entire specimen, knowledge of the clinical differential diagnosis and good gross examination skills are helpful. Multiple sections at 2- to 3-mm intervals should be made throughout the specimen, and sections from various portions should be submitted. It is always preferable to err on the side of submitting too much adequately fixed tissue rather than not having enough to establish a definitive diagnosis or perform ancillary studies. In any lymph node biopsy in which microscopic examination of the initially submitted sections does not yield a definitive diagnosis, all the remaining tissue should be promptly submitted for microscopic examination.

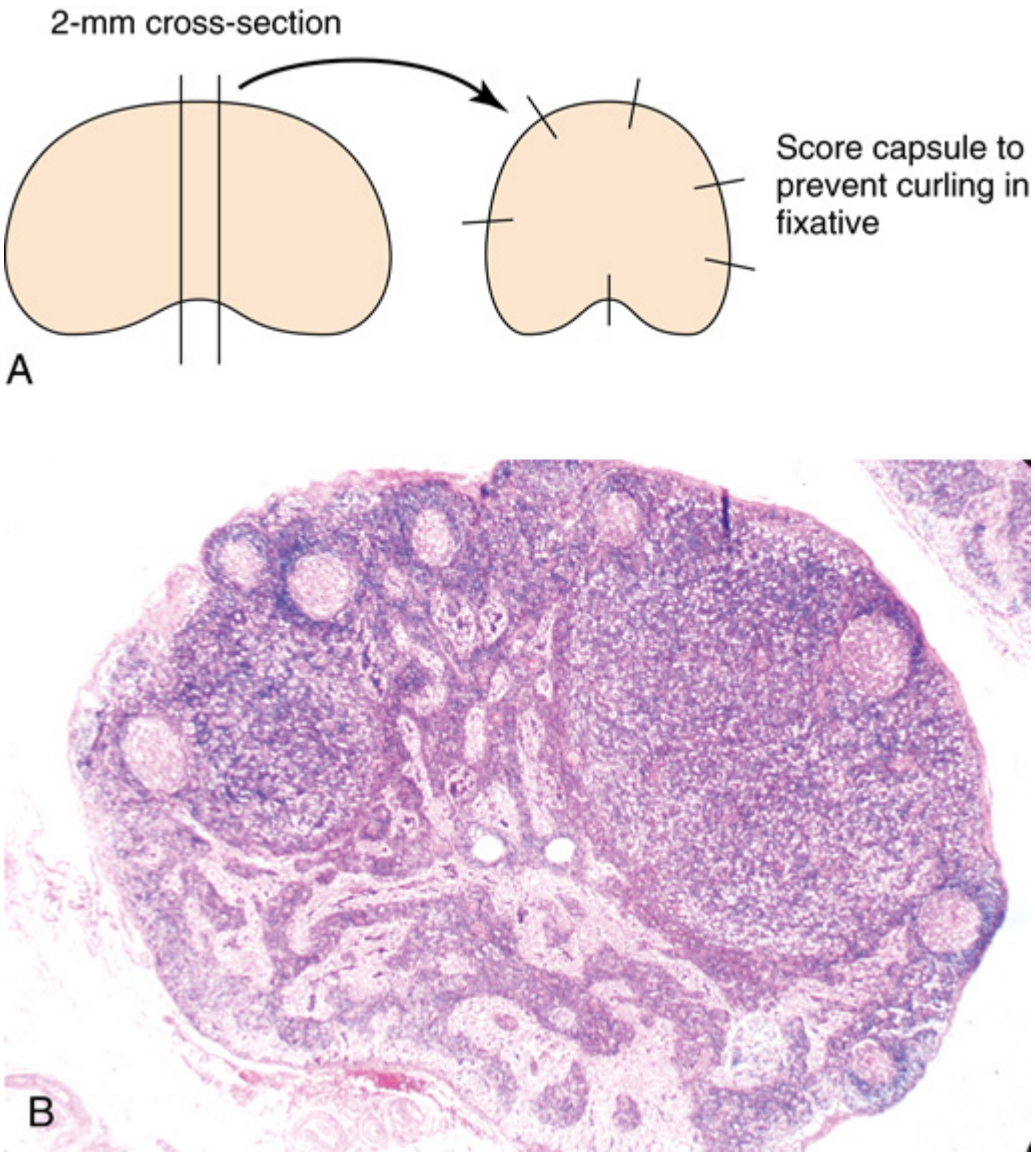

FIGURE 1-5. Lymph node sectioning.Lymph nodes should be sectioned to provide a complete cross-section that allows an appreciation of architecture. **A,** Schematic diagram shows that the lymph node is cut perpendicular to the long axis of the node (best for specimens >1 cm in diameter). The lymph node capsule can be scored with several small cuts before placing the section in fixative; this prevents curling as the capsule

retracts on exposure to fixative. **B,** Low-power photomicrograph of a properly oriented lymph node section shows the capsule, cortex, paracortex, and medulla.

Fixation

Fixation is the point of no return in the processing of a lymph node specimen. Although subsequent steps, including infiltration, clearing, and dehydration, can be repeated, if necessary, inadequate fixation cannot be reversed. Inadequate fixation may lead to a significant delay in patient care if attempts are made to reprocess a poorly fixed specimen, ancillary studies fail, or the poorly processed specimen is sent for expert consultation to avoid a repeat biopsy.

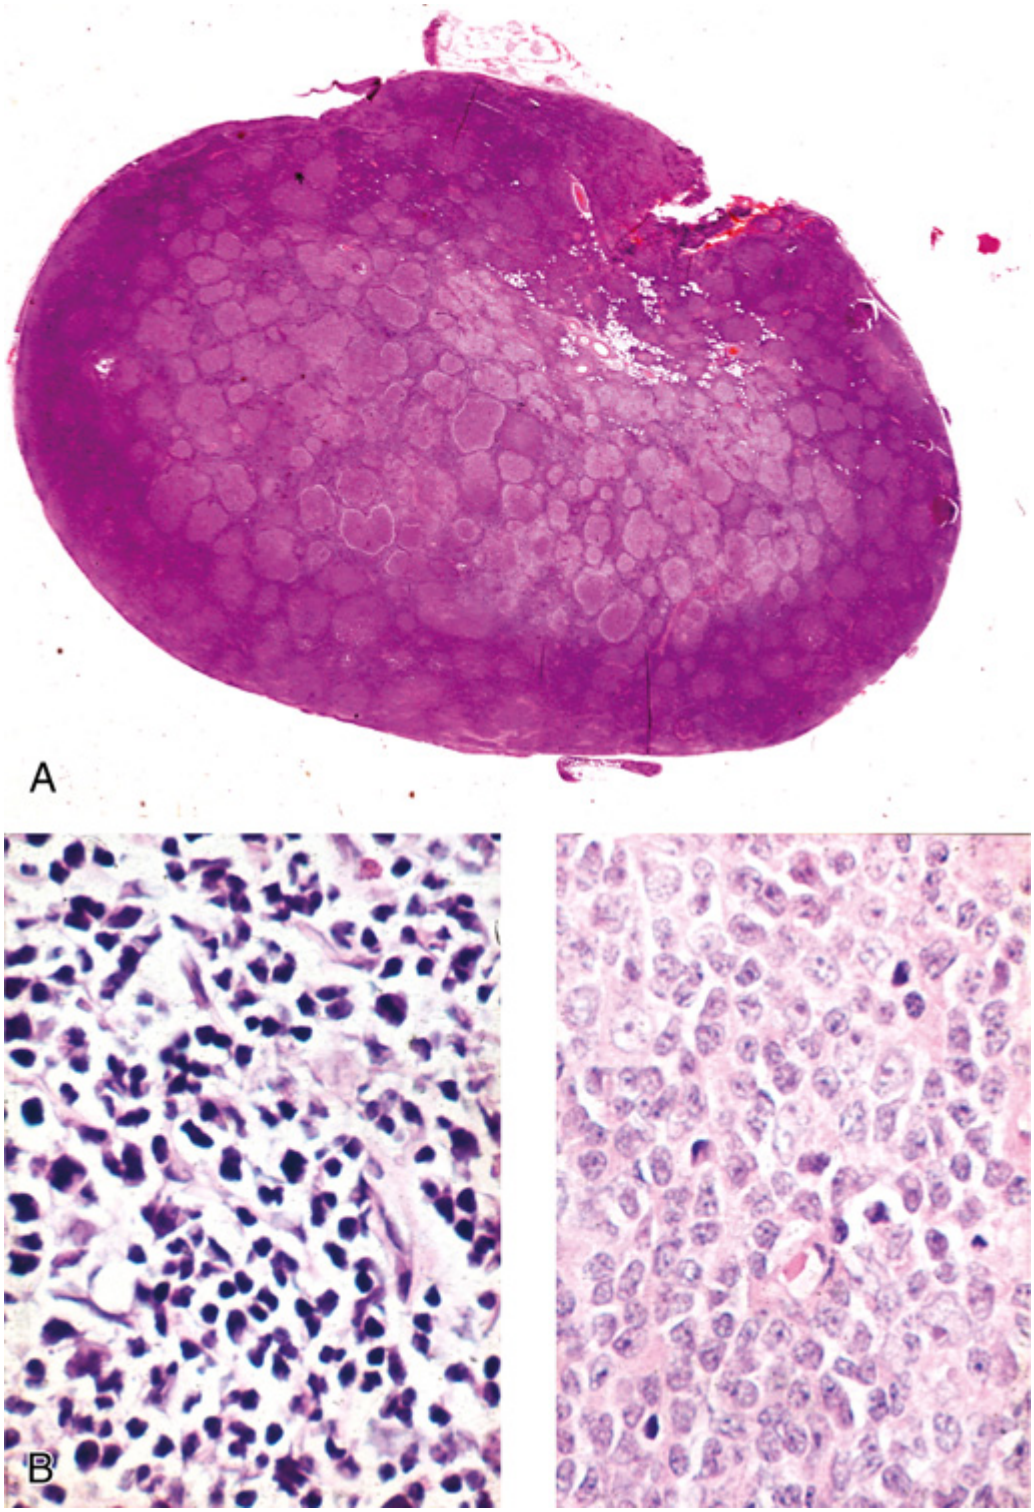

FIGURE 1-6. Lymph node fixation.This lymph node was placed in fixative without first cutting thin sections. **A,** Only the outer 1.0 mm of this

paraffin section stained with hematoxylin and eosin is well fixed and stained; the center shows fainter staining and evidence of cell retraction. **B,** At high magnification, the center of the node *(left)* is autolyzed, with suboptimal cellular detail; the periphery *(right)* shows good cellular detail.

Excellent-quality slides can be prepared from lymph node specimens using a number of different fixatives as long as the proper volume and strength of fixative are used and, most importantly, adequate time is allowed for fixation.[16] The advantages and disadvantages of the most commonly used fixatives for lymph node specimens are outlined in **Table 1-1**. Neutral buffered formalin has the advantage of both excellent morphologic detail and adequate preservation of antigens for IHC and nucleic acids for in situ hybridization and next-generation sequencing assays. In most laboratories, assays to assess expression of proteins and ribonucleic acid (RNA) and the presence of genetic abnormalities are validated for use in FFPE specimens; therefore fixation in neutral buffered formalin is preferred. Some laboratories may use a combination of neutral buffered formalin and a metal-based fixative; one or two slices are fixed in a metal-based fixative for speed of fixation and optimal morphology, and the remainder are fixed in formalin for preservation of DNA and long-term storage. Although pathologists' preferences for metal fixatives vary, B5, neutral Zenker's solution, and zinc sulfate formalin are the most commonly used. Although B5 fixative renders excellent nuclear detail (**Fig. 1-7**), several factors make its routine use problematic. These include the relatively high cost, the time-sensitive nature of fixation (2–4 hours), and the need

to remove mercuric chloride crystals from the sections and dispose of the mercury, an environmental hazard. Zinc formalin is an alternative to B5 fixative; it offers good nuclear detail, is less costly, and requires no special procedures for handling and disposal as it contains no mercuric chloride. Fixatives that are highly acidic, such as Zenker's, B5, Bouin's, and Carnoy's, are unsuitable for molecular diagnostic studies because they compromise the efficiency of polymerase chain reaction (PCR) amplification by decreasing the ability of the DNA within tissue to function as a template for the amplification of DNA fragments of desirable length.

Table 1-1

* Time is dependent on the size and thickness of the tissue and other factors.

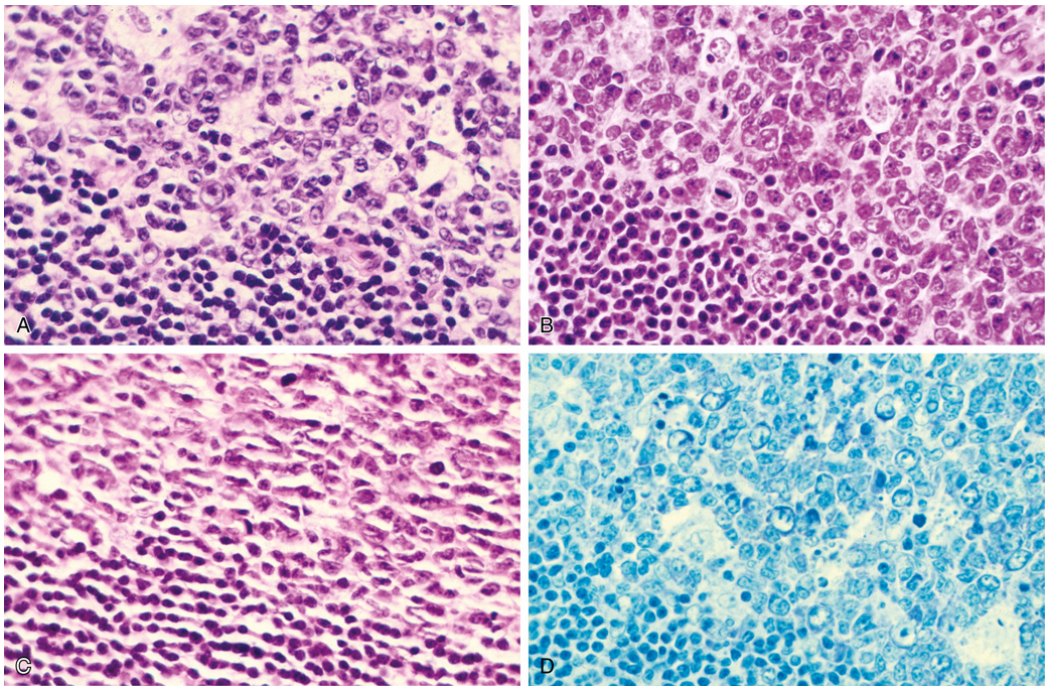

FIGURE 1-7. Lymph node germinal center showing the effects of different fixatives, cutting techniques, and staining.**A,** Specimen fixed in formalin for 24 hours and stained with hematoxylin and eosin (H&E) shows adequate fixation but some cytoplasmic retraction. **B,** Specimen fixed in B5 and stained with H&E shows crisp nuclear detail and better preservation of the cytoplasm. **C,** The same field and paraffin block as in **A** was cut by an inexperienced technician. Marked chatter artifact makes the recognition of cellular detail impossible. The section in **A** was cut by the same technician the next day after reviewing the initial slide with the pathologist. **D,** The same germinal center shown in **B** stained with Giemsa stain. The clear chromatin structure, peripheral nucleoli, and

> cytoplasmic basophilia of centroblasts are now more clearly delineated and contrast with the dispersed chromatin and pale cytoplasm of centrocytes.

We find that 10% neutral buffered formalin offers the best overall results by furnishing excellent morphologic preparations with good preservation of immunoreactivity and suitability for molecular diagnostic studies (**Table 1-2**). The standard use of FFPE tissue has the benefit of being in line with tissue handling and processing and ancillary study validation across the anatomic pathology laboratory. In addition, neutral buffered formalin provides the best method for long-term storage of fixed tissue, a particularly important consideration in storing archival material for research purposes. For good morphology, though, fixation in formalin requires at least 12 hours, with a maximum of about 48 hours for optimal morphology and tissue preservation for IHC.[17]

Contribution of the Histotechnologist

Once thinly sliced tissue sections are well fixed, the subsequent steps, including dehydration, clearing and infiltration by paraffin, and sectioning, depend on the expertise of the histotechnologist. The histotechnologist is responsible for ensuring the quality and combination of solutions used in tissue processors and for changing those solutions frequently enough to avoid dilution or contamination. It is particularly important to dehydrate the specimen without a trace of moisture before clearing with xylene and infiltration by paraffin. Blocks can be difficult to section if these steps

are inadequately performed, resulting in cracking of the blocks, disintegration, or wrinkling of sections in the water bath.

Well-fixed and well-processed paraffin-embedded lymph node tissue should be cut at no more than 3- to 4-µm sections for microscopic slides. The best cytologic details are obtained when lymph node sections are uniformly one cell layer thick. Such sections provide remarkable details regarding the texture of the chromatin, the irregularities of the nuclear membrane, the presence or absence of nucleoli, and other features that enhance diagnostic capability. A sharp microtome blade, maintenance of the water bath at the optimal temperature, addition of appropriate detergents, and good mounting techniques are some of the key elements in obtaining a perfect microscopic section[23] (**Fig. 1-7A** and C). The College of American Pathologists (CAP) and the National Society for Histotechnology (NSH) Committee publish practical and up-to-date guides to specimen handling in surgical pathology that can serve as a histology laboratory resource.[24]

Table 1-2

* Submit under sterile conditions.

+ Suitable; –, unsuitable; ±, suboptimal but acceptable for study because of altered or destroyed antigens, with limited success using selected probes or antibodies. *FISH,* fluorescence in situ hybridization; *PCR,* polymerase chain reaction.

Whole Slide Imaging

Whole slide imaging (WSI) is at the core of the move to digital pathology and, in many ways, improves downstream workflows by increasing access to microscopic images and facilitating review of current and historic cases for second opinions and clinical and educational conferences.[25,26] WSI has good performance characteristics for primary lymphoma diagnosis, but it has limitations related to resolution (e.g., not optimal for detection of microorganisms), a fixed z-plane (inability to focus up and down), and differences in the ease and speed of slide manipulation, all of which can cause occasional diagnostic discrepancies compared with glass slide review.[27] Processing of the lymph node biopsy, including section thickness and staining characteristics, should be optimized as part of the WSI validation process, as it can have significant downstream effects on the quality of the scanned image.[28] The CAP recommendations for validation of WSI stress the importance of validating the entire process in a manner as similar as possible to real-world clinical use, including using at least 60 sample cases per general application (such as H&E-stained fixed tissue) and an additional 20 cases for additional applications (such as IHC and special stains).[29]

ROUTINE HISTOLOGIC, HISTOCHEMICAL, AND SPECIAL STAINS

H&E-stained sections are sufficient for the assessment of many lymphoid lesions. The Giemsa stain highlights nuclear features such as chromatin texture, nucleoli, and cytoplasmic granules, especially in myeloid and mast cells, and demonstrates cytoplasmic basophilia

in cells such as centroblasts, immunoblasts, and plasma cells (**Fig. 1-7D**). Periodic acid–Schiff (PAS) stain is helpful in highlighting mucin, glycogen, and the basement membrane of blood vessels, and it is particularly useful in assessing the architecture of the spleen, where it highlights the fenestrated basement membrane of the sinuses. Cytoplasmic and nuclear immunoglobulin (Ig) inclusions, particularly IgM and IgA, which are rich in carbohydrate moieties, also stain with PAS. Enzyme histochemical stains have been largely replaced by more specific and reliable immunohistologic and flow cytometric immunophenotyping methods in the diagnosis of lymph node specimens.

Microbiological Evaluation of Fixed Lymph Node Tissue

On H&E-stained sections, if necrosis or granulomas are identified, special stains for pathogenic organisms are routinely undertaken and correlated with microbiological cultures. Even dispersed histiocytic infiltrates may be a subtle sign of an infectious process in the setting of a blunted immune response, as in the setting of adult-onset immunodeficiency associated with neutralizing anti-interferon-gamma autoantibodies, which can mimic AITL, classic Hodgkin lymphoma, and other malignant and nonmalignant hematolymphoid processes.[30,31] PCR-based methods are highly sensitive and specific for detection and speciation of various microorganisms, even on FFPE tissue, and should be considered depending on the clinical setting and histologic findings. For necrotizing granulomatous processes, we routinely use Grocott-Gomori methenamine silver (GMS) and acid-fast bacillus (or Fite) stains to rule out fungal

organisms and acid-fast bacilli; we also use PAS stain, which is helpful in the diagnosis of Whipple disease and for the identification of fungi. Of note, when fungal elements are identified and concomitant fungal cultures are not available, PCR-based methods should be used to identify the genus and species of the fungus. Similarly, sensitive PCR-based techniques can allow identification and speciation of mycobacterial organisms in FFPE tissue.[32,33]

In necrotizing lymphadenitis, a modified Gram stain (Brown and Hopps) can be used to detect gram-positive organisms. When an infectious gram-negative organism, such as *Bartonella henselae* (cat scratch disease), or a spirochete is suspected, a silver stain such as Steiner or Warthin-Starry stain can highlight the organisms; however, interpretation is difficult as a result of scant organisms and common confounding precipitate, which may lead to false positives. An immunohistochemical stain is also available for *B. henselae,* but it is likely less sensitive than PCR on FFPE tissue.[34] Gram-negative organisms of the *Brucella* genus may be visualized using McCullum-Goodpasture or Giemsa stain and can be identified and speciated in FFPE tissue with PCR.[35]

Table 1-3

Role of Immunohistochemistry, In Situ Hybridization, and Flow Cytometry Immunophenotyping in the Lymph Node Workup

Ancillary Study	Target	Roles
Immunohistochemistry	Proteins in fixed tissue	Therapeutic targets (e.g., CD30[37]) Expression of normal and aberrant antigens (B, T, NK, myeloid) Prognostication (e.g., Ki67 in mantle cell lymphoma[38])
In situ hybridization	mRNA in fixed tissue	Diagnosis (e.g., EBER for PTLD[39]) Highly sensitive detection of low-level mRNA for diagnosis (e.g., HTLV-1 integration in ATLL[40])

Ancillary Study	Target	Roles
Flow cytometry immunophenotyping	Proteins in fresh tissue	Expression of normal and aberrant antigen expression (B, T, NK, myeloid) Minimal residual disease studies (usually in BM or PB specimens) Quantitation of antigen expression to predict response to therapy (e.g., CD19 for CAR-T[41] therapy)

ATLL, Adult T-cell leukemia/lymphoma; *BM,* bone marrow; *CAR-T,* chimeric antigen receptor T-cell; *EBER,* Epstein-Barr virus–encoded small RNA; *HTLV-1,* human T-cell leukemia virus type I; *mRNA,* messenger ribonucleic acid; *PB,* peripheral blood; *PTLD,* posttransplant lymphoproliferative disorder.

Immunohistochemistry, In Situ Hybridization, and Flow Cytometry Immunophenotyping

Lymph node diagnoses benefit from multiple complementary approaches (**Table 1-3**) allowing for characterization of protein or

mRNA expression patterns either on the slide (IHC and in situ hybridization) or in disaggregated fresh cells (flow cytometry immunophenotyping). Though the number of immunohistochemical stains used in clinical laboratories can number from 1 to 200, in situ hybridization markers are more limited. Commonly used examples of in situ hybridization stains include markers for Epstein-Barr virus (EBV) and kappa and lambda light chains. IHC and in situ hybridization performed on unstained slides cut from FFPE tissue allow interpretation of protein or mRNA expression in the context of a counterstain highlighting the nuclei of tissue cells. A large number of immunohistochemical stains for membrane, cytoplasmic, and nuclear antigens are in routine clinical use and, in combination with histologic features, can support the diagnosis and correct classification of many common lymphomas and lymphadenopathies.

Flow cytometry is recommended when sufficient fresh tissue is available and is particularly helpful in demonstrating light chain restriction in B-cell lymphomas and in identifying immunophenotypic aberrancies in potentially neoplastic T-cell populations.[36] When there is a need to quantitate the number of cells stained or the antigen density within a population, for example, in measuring the level of expression or the percent of lymphoma cells expressing a potential therapeutic target, flow cytometry is the technique of choice. In addition, flow cytometry provides a means of analyzing multiple antigens simultaneously and of assessing small samples, which is particularly helpful for the measurement of minimal residual disease and for fine-needle aspirates. Because flow cytometry studies can be completed within a few hours from the time of tissue procurement, this method is preferred when rapid diagnosis

of a suspected hematolymphoid lesion is needed. For sections to be generated for immunohistologic staining on FFPE tissue, an overnight step in the tissue processor is often necessary, although more rapid processors are coming into use at some institutions.

Occasionally, the diagnosis may necessitate a particular type of study that is best achieved with either flow cytometry or the use of FFPE tissue. For example, for the definitive diagnosis of mantle cell lymphoma, immunoreactivity for cyclin D1 is best assessed by paraffin-section IHC, because flow cytometry for cyclin D1 and other nuclear antigens is less than optimal. In suspected posttransplant or other immunodeficiency-related disorders or extranodal NK/T cell lymphoma, nasal type, demonstration of EBV by EBV-encoded small RNA (EBER) in situ hybridization is helpful for diagnosis. In the case of some small B-cell lymphomas that do not aberrantly co-express CD5 or CD10, diagnosis on FFPE tissue alone may be challenging because of the suboptimal ability to distinguish light chain restriction by IHC.

Cytogenetic and Molecular Studies

The roles of cytogenetic and molecular studies in diagnosis, prognosis, and treatment planning are summarized in **Table 1-4**. Cytogenetic studies—including routine karyotyping of cultured cells, FISH, and chromosomal microarrays—assess for changes in the location, arrangement, and copy number of segments of chromosomes. Molecular genetic studies assess for qualitative and/or quantitative changes in DNA. Examples include allele-specific PCR, T-cell receptor or Ig gene rearrangement testing by multiplex PCR or next-generation sequencing (NGS), somatic

mutation panel testing by NGS, and RNA sequencing to detect mutations and gene fusions. Many of these assays are discussed in detail in **Chapter 6**. If lymphoblastic lymphoma or myeloid neoplasia is suspected, retention of a portion of fresh tissue for cytogenetic studies is highly desirable, as karyotyping of cultured cells is still the gold standard. Furthermore, FISH panels are often validated for metaphase cultures and not for interphase FISH on FFPE tissue. Likewise, molecular assays applicable to acute leukemias may not be validated for FFPE tissue. Most FISH tests and other molecular tests applicable to mature lymphoma can, by contrast, be performed on either fresh or fixed tissue.

The choice of assays is large and the pace of change in the sensitivity, speed, and scope of the various technologies is rapid. Nevertheless, more is not necessarily better; not only may low-yield testing deplete precious material that may be needed at a later point for other targeted testing as new treatment options or clinical trials become available, but also unexpected or false-positive results may lead to delays in diagnosis, additional unnecessary testing, and even misdiagnosis. The choice of cytogenetic and molecular studies should focus on rendering a definitive diagnosis and on providing the additional prognostic and therapeutically relevant information appropriate to the patient based on the clinical setting and evidence-based guidelines. Communication with the treating oncologist is key in prioritizing the choice of ancillary studies to ensure efficient and appropriate patient management.

Table 1-4

Role of Cytogenetic and Molecular Studies in Diagnosis, Prognosis, and Treatment Planning

Ancillary Study	Role
Karyotype	Lymphoblastic lymphoma or myeloid neoplasia classification and risk stratification
FISH	Specific rearrangements, fusions, or deletions (e.g., *CCND1* rearrangement in mantle cell lymphoma)
Chromosomal microarray	Variable, nonreciprocal cytogenetic abnormalities (e.g., large cell lymphoma with 11q aberration)
Allele-specific PCR	Specific somatic mutations (e.g., $BRAF^{V600E}$ mutation in hairy cell leukemia)
T-cell receptor[42] or immunoglobulin gene[43] rearrangement	Distinguishes lymphoma from reactive proliferations; favors T versus B lineage; assessment for recurrent disease
NGS somatic mutation panels	Aid in diagnosis (e.g., $RHOA^{G17V}$ in AITL[44]) and subclassification (e.g., $MYD88^{L265P}$ in LPL)[45]

Ancillary Study	Role
	and identify targetable mutations
RNA sequencing	Combined detection of mutations and gene fusions[46]; does not replace FISH[47]

AITL, Angioimmunoblastic T-cell lymphoma; *FISH,* fluorescence in situ hybridization; *LPL,* lymphoplasmacytic lymphoma; *NGS,* next-generation sequencing; *PCR,* polymerase chain reaction; *RNA,* ribonucleic acid; *RT-PCR,* reverse transcription PCR.

REPORTING THE LYMPH NODE BIOPSY

The diagnosis of lymphoid malignancies uses a multiparameter approach that includes many ancillary studies that contribute to a comprehensive definitive diagnosis. Although the histopathologic findings, together with the immunophenotypic results, may be available within 1 or 2 days after a biopsy procedure, FISH, cytogenetic, and molecular genetic studies may not be available for 1 to 2 weeks. In these cases, a preliminary diagnosis based on the information at hand should be rendered, with ancillary studies reported in the form of an addendum to the original report. However, when the ancillary studies are necessary for even a preliminary diagnosis, the clinician treating the patient should be informed of the situation, and the report may be delayed until the results of ancillary studies are available.

The final lymph node biopsy report should include all relevant information for a comprehensive and complete diagnosis, including

the results of all pertinent ancillary studies, such as IHC, cytogenetic, and molecular studies. There are several advantages to this practice. First, such a report facilitates continuity of care when patients are seen in follow-up or when relapses of disease occur. Second, it permits easy comparison of prior and subsequent immunophenotypic and molecular data in the detection of posttreatment minimal residual disease. When ancillary studies are performed in multiple specialized laboratories or sent off site, the issuing of multiple addenda when these results become available may be cumbersome. An accurate and efficient data-management system that allows easy access to ancillary test results may be a reasonable alternative to an integrated pathology report. It is imperative that the pathologist ensure that a system is in place to link the results of ancillary studies to the original specimen and to provide an interpretation that relates to the original diagnosis.

Increasingly, core needle biopsies with or without fine-needle aspiration are being used both for initial assessment of adenopathy and in the setting of known lymphoma with adenopathy concerning for residual or transformed disease. Such biopsies are often convenient, fast, cost-efficient, and minimally invasive, making them ideal for fast-moving patient-centered care. Nevertheless, the limited sample volume can cause false-negative results from a lack of diagnostic material and can also raise the risk of misclassification of entities for which architecture plays a role in diagnosis and/or for which diagnostic features are rare, such as in NLPBL.[10] Though these small samples are frequently diagnostic, care must be taken to communicate the need for repeat biopsy if there is a discrepancy between the clinical suspicion and pathologic diagnosis. In addition,

a low threshold for recommending a larger biopsy is warranted for cases in which there is concern that the small biopsy will not be representative or sufficient for diagnosis.

Pearls and Pitfalls

Before the biopsy

- Communicate need for fresh tissue for flow immunophenotyping.

During the intraoperative consultation

- Attempt touch preparation first to preserve tissue for morphology and flow cytometry immunophenotyping.

In the gross room

- If received fresh, make touch preparation.
- Fresh material should be set aside in RPMI medium for possible flow cytometry.
- Formalin fixation is preferred to preserve nucleic acids.

In the histology lab

- Consider cutting unstained slides up front for small/core needle biopsies.

At the microscope

- Triage studies in view of all ancillary studies are required for clinical decision-making.
- Steward tissue so that material is left in block for future needs (e.g., clinical trial eligibility).

LIMITATIONS OF FINE-NEEDLE ASPIRATION

ROLE OF CORE NEEDLE BIOPSY IN LYMPHOMA DIAGNOSIS

Fine-needle aspiration (FNA) of superficial and deep-seated lymph nodes is a well-established and safe method for assessing lymphadenopathy in adult and pediatric patients.[1-14] Patients with primary or recurrent lymphoma frequently undergo FNA, and this diagnostic modality is even more common in suspected reactive or metastatic lymphadenopathy. Using FNA as a first-line procedure has obvious benefits, such as rapid turnaround time, low cost, and low morbidity. The cytomorphologic diagnosis is relatively straightforward in the majority of cases of reactive lymphadenopathy and non-hematopoietic metastatic disease. The diagnostic accuracy of FNA in lymphoma cases is variable and dependent on lymphoma type and concurrent use of ancillary studies.[4,8-11,13,15-26] The latter significantly enhances diagnostic sensitivity and specificity beyond that obtained with cytomorphologic evaluation alone.[22,26] Nevertheless, the inability to assess architectural features and limited immunohistochemistry (IHC) can be challenging. Therefore, the application of FNA to establish a primary diagnosis of lymphoma is controversial.[15,17,18,27] With few exceptions, FNA has been used predominantly as a screening tool with a final diagnosis and lymphoma classification often requiring lymph node excision or biopsy.[17,27] The Sydney system for cytopathologic evaluation of lymphadenopathy has shown high sensitivity, specificity, and positive predictive value and slightly lower negative predictive value.[28,29] This proposed system combines clinical information, imaging findings, cytopathological features, and ancillary techniques

with the goal of standardizing the cytopathologic diagnosis and reporting of lymph nodes and provides an algorithm for patient management. Nevertheless, in clinical practice, a final diagnosis of lymphoma is rarely solely based on FNA, with the exception of cases in which excision or incisional biopsy is medically contraindicated. FNA without a follow-up biopsy is more commonly used for diagnosis of progression, transformation, or recurrent disease in patients with a previously documented history of lymphoma and to procure fresh material for specialized studies such as genetic testing for targeted therapy.

The effectiveness of FNA as a diagnostic procedure in hematopoietic neoplasms is dependent on a dedicated multidisciplinary team of highly specialized experts in cytopathology and hematopathology, and experienced aspirators. This integrated approach will ensure the procurement of an adequate FNA specimen and analysis by appropriate cytomorphologic, immunophenotypic, and molecular techniques. When core needle biopsy (CNB) is procured concurrently with FNA, correlating results obtained from both samples is strongly recommended. A detailed clinical history should be reviewed at the time of FNA. An on-site evaluation provides information regarding the cellularity of a sample, guides selection of additional testing, and in cases with scant cellularity, allows one to prioritize ancillary studies. If an adequate sample is available and there is suspicion of a lymphoproliferative process, material should be reserved for flow cytometry (FCM) and cell block for IHC or molecular studies. When a definitive diagnostic immunophenotype is not provided by FCM or other ancillary studies,

such as immunocytochemistry (ICC)/IHC, a lymph node excision is recommended.

This chapter focuses on the cytomorphologic diagnoses of the most common reactive and neoplastic lymphoid proliferations as seen on FNA smears. Cell block preparations are referenced primarily when IHC is discussed as a diagnostic aid; however, for a complete discussion of immunophenotypic and genetic features, the reader is referred to the chapters discussing individual lymphoma entities. We provide a brief guide for the optimal processing and evaluation of cytologic samples obtained by FNA of lymph nodes (**Table 2-1**). A role of CNBs in lymphoma diagnosis is also discussed, as these biopsies are frequently procured at the time of FNA to provide a more robust assessment of architectural and cytomorphologic features. Nevertheless, CNBs did not provide as complete an evaluation as lymph node excisions,[30] and an excision remains the gold standard in lymphoma diagnosis.

Table 2-1

Approach to Lymphoma Diagnosis Using Fine-Needle Aspiration: Recommendations and Limitations

Process	Recommendations/Limitations
Sample collection	On-site evaluation of specimen adequacy by a pathologist or cytotechnologist is highly recommended. If on-site evaluation is not available, perform additional passes until solution is cloudy. Perform multiple passes (>3) from different parts of lymph node. Prepare cell block for immunocytochemistry (critical in cases with rare neoplastic cells that may be difficult to immunophenotype by FCM, such as cHL).
Case sign-out	Correlate cytomorphology with ancillary studies. Consider possibility of false-positive and false-negative results of ancillary studies. In challenging cases or in cases with discrepant results, discuss

Process	Recommendations/Limitations
	cytomorphology with flow cytometrist, who may prompt additional gating. If cytologic findings do not correlate with clinical presentation, recommend lymph node excision or biopsy.
Evaluation of high-grade B-cell lymphoma and high-grade transformation*	Large lymphocyte count >20% is highly predictive of large cell lymphoma (in practice, >25%). If large cell count is >25% but <50%, correlate cytomorphology with clinical and immunophenotypic findings. Biopsy/excision may be required in discrepant cases.

cHL, Classic Hodgkin lymphoma; *FCM,* flow cytometry.

* High-grade B-cell lymphomas include entities with blastoid morphology.

SPECIMEN COLLECTION AND PROCESSING

The proper handling and processing of a lymph node aspirate is imperative for an accurate diagnosis. In general, at least three separate passes should be executed.[31] Nonaspiration technique, performed using only a needle or a needle attached to a syringe

without a plunger (to minimize bleeding and sample mixing with peripheral blood), can be applied for cytologic evaluation of lymph nodes. On-site Coulter counters can be used to ensure collection of a minimum of 10 million cells for adequate FCM.[15] An on-site assessment for specimen adequacy should be performed by a pathologist or a cytotechnologist. This is most easily accomplished with a Wright's-Giemsa–type stain (usually a Diff-Quik [DQ]) carried out on an air-dried smear, which allows a detailed visual evaluation of the cytoplasm and nuclei of the lymphoid cells; this is imperative for classification. Although DQ stain, comparable to the Romanowsky and Giemsa stains used in clinical hematology laboratories, is generally preferred for cytologic evaluation, some authors believe alcohol-fixed slides stained with Papanicolaou (Pap) stain should also be prepared to provide enhanced nuclear detail. Techniques that use alcohol fixation with Pap staining, including monolayer technologies, are insufficient for demonstration of cytoplasmic features and should not be used as the only stain when hematopoietic processes are evaluated. If desired, these approaches can be used in addition to air-dried Giemsa-stained material. Air-dried Giemsa-stained cytospins may be particularly helpful because the cell morphology on the cytospin may be superior to that on the smear owing to the flattening and enlarging effect of cytocentrifugation (**Fig. 2-1**). Sample collection for monolayer preparations is easy and may be a viable alternative,[32] especially when on-site assessment is not available. Liquid-based cytology has been shown to perform well while using the Sydney system.[33] However, such preparations are known to increase the risk of false-

negatives and should not be used without accompanying FNA smears.[34]

Once a differential diagnosis is formulated based on cytomorphology and clinical history, a portion of a sample should be placed in cell culture media such as RPMI (Roswell Park Memorial Institute) medium to assure preservation of cell viability. From this aliquot, cells can be submitted directly for FCM and molecular diagnostics. A cell block prepared from tissue fragments embedded in paraffin[35] or a cytospin can be used for ICC/IHC, fluorescence in situ hybridization (FISH), or in situ hybridization for Epstein-Barr virus (EBV) with the EBV-encoded small RNA (EBER) probe.

ANCILLARY STUDIES

Immunocytochemistry

ICC can be performed on air-dried cytospins or smears on charged slides that have been stored desiccated and refrigerated, and are postfixed in acetone before staining. The staining protocols used for air-dried cytospins are similar to those used for frozen section material (see **Chapter 4**). Cell block sections can also be used for immunohistochemical studies with a staining protocol similar to that used for tissue sections.[19,34,36] If cellular material is limited, it may be preferable to prepare cytospins rather than attempting a cell block with potentially insufficient material. Of note, alcohol fixation may affect the performance of some lymphoid markers.

ICC on cytospins may be as effective as FCM for the immunophenotyping of cytologic specimens and may be particularly suited for samples with an insufficient number of cells for FCM analysis.[37,38] One distinct benefit of ICC on cytospins is the detailed

visualization of cell size in conjunction with immunophenotypic staining patterns, particularly with mixed cell populations.

Flow Cytometry

FCM is an indispensable ancillary technique that significantly enhances the sensitivity and specificity of lymphoma diagnosis in cytologic material.[26,27,39-41] The combination of FCM and cytomorphology can lead to a specific lymphoma classification with a rapid turnaround time of less than 24 hours. Commonly available multiparameter FCM instruments analyze numerous markers simultaneously and allow comprehensive immunophenotyping of a wide variety of samples, including paucicellular specimens. This obviates the need to prioritize markers on the basis of a cytomorphologic triage. Optimally, several million cells are needed to analyze an expression of 10 to 20 antigens. In scant samples, immunophenotyping can be performed on as few as 50,000 cells, provided the cell viability is not compromised. In these cases and in those with a suspicion of rare types of lymphoma, close communication between the cytopathologist and the hematopathologist performing the FCM may help design a more specific antibody panel and facilitate incorporation of FCM results in the cytomorphologic diagnosis.

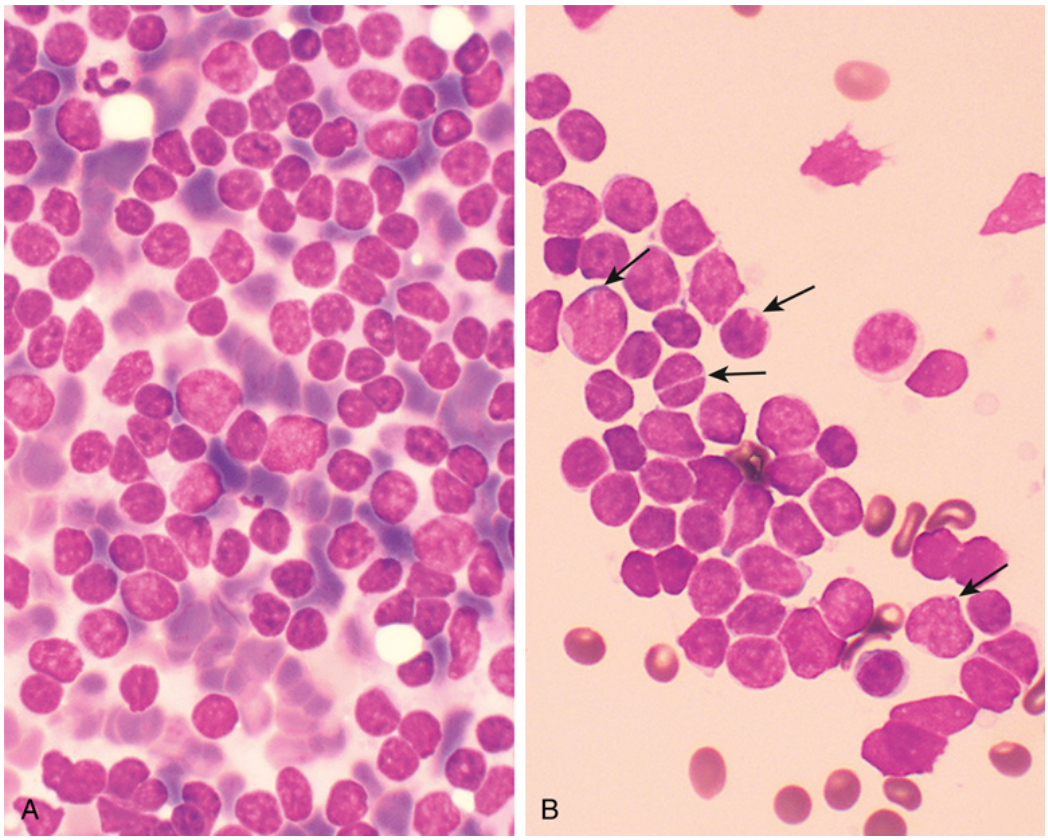

FIGURE 2-1. **A,** Smear of chronic lymphocytic leukemia/small lymphocytic lymphoma showing mostly small, atypical lymphoid cells with scant cytoplasm and round, slightly irregular nuclei with occasional nuclear clefts. **B,** Cytospin preparation for the same case showing the flattening and enlarging effect of atypical lymphoid cells, accentuating the nuclear irregularity and clefts *(arrows)* (Diff-Quik).

Sample type and processing can significantly influence cellular yield and viability. In our experience, FNA yields a superior material for FCM in comparison with CNBs, which are often procured at the same time.[42] Some advocate obtaining cell suspensions using a rinse

technique and have reported it provides FCM material comparable to an FNA or disintegrated CNB.[43] The FCM sample should be placed in RPMI medium with 10% fetal bovine serum immediately after procurement and stored at 4° C. Samples of select, highly proliferative lymphomas will deteriorate rapidly, even if stored in a protective media; thus, a specimen should be stained promptly whenever possible to avoid cell loss. If rapid analysis is not feasible, a stained sample can be fixed and analyzed the next day.

Results of FCM must be interpreted within the context of cytomorphology and clinical information because of the possibility of false-negative or false-positive results.[40] A false-negative immunophenotype occurs most commonly in limited paucicellular samples because of necrosis and fibrosis or cell loss during processing. It may also be challenging to identify a malignant clone in cases in which neoplastic cells are accompanied by a rich reactive background or aggregating with reactive lymphocytes, as seen in classic Hodgkin lymphoma (cHL). False-positive results may be encountered in reactive lymphoid processes with a skewed kappa-lambda light chain ratio, which is primarily seen in follicle center lymphocytes or in cases with an abnormal T-cell immunophenotype. An interpretation of atypical T-cell immunophenotype has become easier as a result of FCM evaluation of T-cell receptor constant beta chain-1 (TRBC1), which allows confirmation of the clonality of T-cell proliferation.[44] Of note, minor immunophenotypic abnormalities should not be interpreted as evidence of a neoplastic process unless supported by cytomorphologic findings and clinical presentation. Additional studies may be warranted when a false-negative or false-positive result is suspected.

When a definitive diagnostic immunophenotype is not provided by FCM and other ancillary studies (such as ICC or IHC) are not conclusive, a lymph node excision is recommended as the gold standard for lymphoma diagnosis. The latter may also be required in cases in which there are discrepancies among clinical presentation, cytomorphology, and FCM immunophenotype. When a lesion is not easily accessible, such as in deep-seated lymph nodes, CNBs may be attempted.

Molecular Studies

In the past, molecular studies were most commonly performed in FNA cases in which a conclusive diagnosis could not be reached with a combination of cytomorphology and immunophenotyping. As the number of lymphomas defined by molecular genetic abnormalities increases, molecular genetic studies are routinely used for lymphoma classification.[45,46]

The majority of molecular studies can be performed on fresh or archival FNA samples.[47,48] Alcohol-fixed, air-dried, and stained FNA slides can be used to scrape off material to extract DNA and RNA using the method of choice.[49] Similar to FCM, the results of the molecular studies should be interpreted in the context of morphologic findings and clinical data because of potential false-positive and false-negative assays.

Interphase FISH has added tremendously to the diagnostic specificity of FNA. Numerous commercially available probes allow for interrogation of lymphoma-associated rearrangements, and a few are specific for certain lymphoma subtypes.[16,22,50-56] Cytospins or smears prepared from FNA material are ideally suited for FISH

because scoring of fluorescent signals is easier in a cell population dispersed as a monolayer.[54] Both fresh, ethanol-fixed, and archival (Pap-stained and DQ-stained) slides can be used. The adequacy of hybridization varies in published reports, with the highest success rates at approximately 95%. FISH with lymphoma type-specific probes is predominantly used for the classification of lymphoid neoplasms.[55,56] Of note, only select translocations (e.g., *IG::CCND1* for mantle cell lymphoma and *NPM1::ALK* for anaplastic large cell lymphoma [ALCL]) are specific for a particular entity and allow for a definitive classification in the context of appropriate cytomorphology and immunophenotype. Many other genetic alterations can occur in several histologically and immunophenotypically defined entities and thus are not diagnostic of a specific lymphoma type. A demonstration of these genetic abnormalities by FISH can still be used as a proof of clonality and can support a diagnosis of lymphoma in cases with equivocal cytomorphology and/or immunophenotyping.

The importance of saving additional unstained smears for molecular assays has been emphasized by some cytopathologists, and the triage of FNA material based on on-site evaluation has been proposed.[14,55,56] It remains to be seen whether FNA with stepwise application of ancillary techniques, including molecular studies, is the most accurate and cost-effective approach to diagnose and classify lymphomas at the time of initial diagnosis, particularly in cases involving peripheral lymph nodes that are amenable to excision.

NON-NEOPLASTIC ASPIRATES

Lymph node enlargement can be secondary to lymphadenitis, an inflammatory or infectious process or reactive lymphoid hyperplasia secondary to a variety of immune stimuli. Lymphadenitis is broadly divided into acute and chronic (granulomatous and nongranulomatous).[57] The inflammatory or infectious processes can be readily identified in aspirated samples based on the composition of the cellular population. In such instances, FNA can also be procured for additional studies, including microbiology studies. The presence of atypical lymphoid cells in an otherwise inflammatory background, however, raises the possibility of lymphoma.

Aspirates of reactive hyperplasia are diverse and diagnostically challenging (**Fig. 2-2**). The pattern and distribution of the lymphoid population vary according to the stage of the reactive process and the primary lymph node compartment affected by it—lymphoid follicles or paracortex. Paracortical hyperplasia is characterized by a polymorphous population of lymphoid cells, ranging from small lymphocytes to immunoblasts, and other inflammatory cells including plasma cells, histiocytes, and eosinophils. Follicular center cells associated with tingible body macrophages and follicular dendritic cells (FDCs) predominate in follicular hyperplasia. The lymphoid cells are frequently seen in aggregates, embedded in a meshwork formed by the FDCs and their processes.[58] The FDC aggregates are composed of large cells with ovoid to coffee-bean shaped nuclei with small central nucleoli, fine nuclear membranes, and clear cytoplasm. Some lymphomas are associated with a polymorphous background and may mimic an inflammatory process. High proliferative activity favors lymphoma but can also be seen in some reactive conditions, such as infectious mononucleosis.[59]

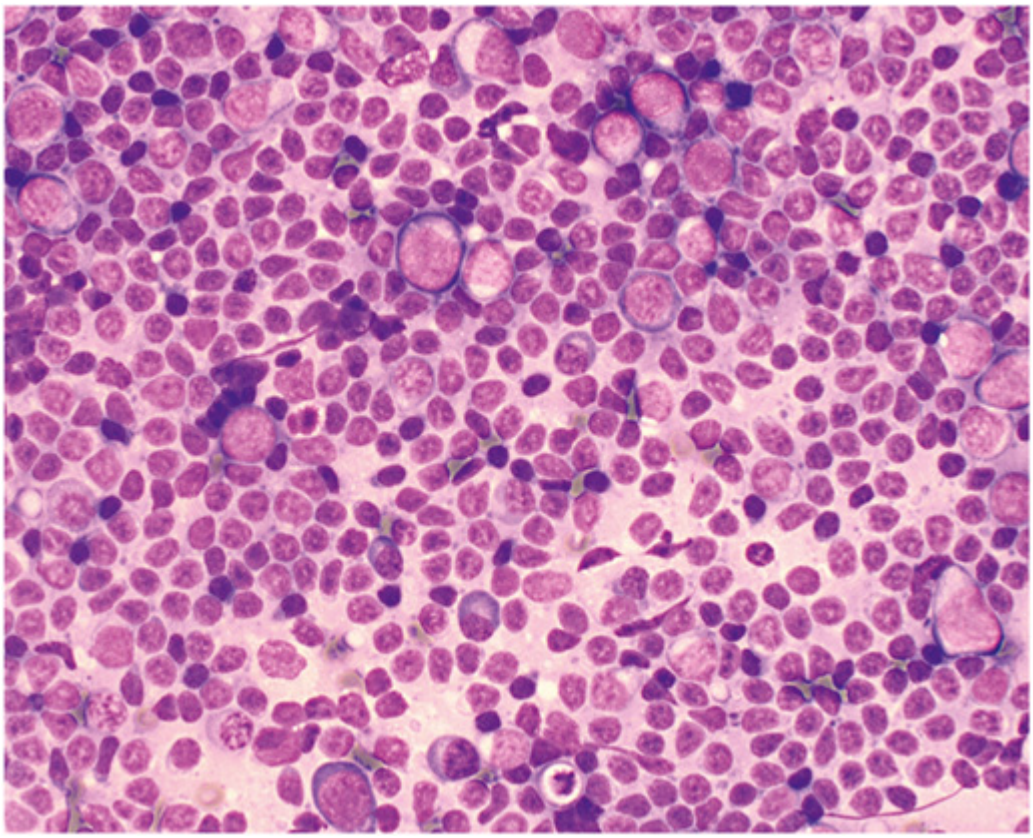

FIGURE 2-2. Reactive lymphoid hyperplasia.Polymorphous population of lymphocytes composed of numerous small mature lymphocytes, centrocytes, and centroblasts. Background shows rare plasma cells, lymphoglandular bodies, and scattered red blood cells (Diff-Quik, smear).

ASPIRATES OF LYMPHOID NEOPLASMS

The World Health Organization (WHO) classification and International Consensus Classification include a wide variety of B-cell, T-cell, and histiocytic-dendritic–cell neoplasms.[45,46,60] Reviewing the cytologic features of all tumor types is beyond the

scope of this chapter. Our goal is to focus on the cytomorphologic features of the most common types of B-cell and T-cell lymphomas encountered in clinical practice (**Table 2-2**).

Mature B-Cell Neoplasms

The most common cell types seen in B-cell lymphomas include centrocytes, centroblasts, and immunoblasts (**Fig. 2-3**). The range of cytologic appearances is exceedingly broad and reflects the spectrum of B-cell differentiation. Immunophenotypic and molecular features useful in differential diagnosis are listed in the chapters reviewing individual disease entities, and this information will not be duplicated here unless unique to cytologic preparations.

Table 2-2

Cytomorphologic Features of Common Types of Lymphoma

Lymphoma Diagnosis	Cytomorphologic Features
Chronic lymphocytic leukemia/small lymphocytic lymphoma	The majority of neoplastic lymphocytes are small with round to oval nuclei, coarsely clumped chromatin, occasional nucleoli, and scant cytoplasm. Admixed prolymphocytes are larger with round nuclei with a vesicular chromatin, prominent nucleoli, and a moderate to abundant amount of cytoplasm. A monomorphic population of large transformed lymphoid cells is consistent with Richter transformation.
Marginal zone lymphoma	Intermediate-sized lymphoid cells with mild atypia including slightly irregular nuclei, condensed chromatin, indistinct nucleoli, and moderate to abundant cytoplasm. Plasmacytoid features and typical plasma cells may be present.
Follicular lymphoma	Heterogeneous population of centrocytes and centroblasts in

Lymphoma Diagnosis	Cytomorphologic Features
	varying proportions, dependent on histologic grade. Centrocytes are medium sized with irregular nuclear outlines, condensed chromatin, and scant cytoplasm. Centroblasts are large with oval to round nuclei, dispersed chromatin, several nucleoli, and moderate cytoplasm. Follicular dendritic cell meshworks are apparent with adherent lymphocytes.
Mantle cell lymphoma	Classic variant: a monotonous population of small to medium-sized lymphoid cells with delicate nuclear clefts, finely stippled chromatin, inconspicuous nucleoli, and distinct pale or basophilic cytoplasm. Blastoid variant: intermediate-sized to large lymphoid cells with slightly irregular nuclei, evenly distributed chromatin, small nucleoli, and scant pale blue cytoplasm (Diff-Quik). Pleomorphic variant: Large lymphoid cells with

Lymphoma Diagnosis	Cytomorphologic Features
	pleomorphic nuclei with hyperchromasia and moderate cytoplasm.
Diffuse large B-cell lymphoma	Abundant large lymphoid cells, frequently with centroblast or immunoblast features, and prominent lymphoglandular bodies; pleomorphic nuclei may be seen.
Primary mediastinal large B-cell lymphoma	Scattered medium-sized to large lymphoid cells with round to oval or multilobated nuclei, smooth to irregular nuclear contours, one or more visible nucleoli, and scant to abundant pale blue or basophilic cytoplasm. Vacuoles may be identified. Background may include connective tissue fragments admixed with single lymphocytes or groups of lymphocytes.
Burkitt lymphoma	Medium-size lymphoid cells with round nuclei, finely granular to coarse chromatin, several nucleoli, and abundant, deeply basophilic cytoplasm with small cytoplasmic vacuoles. The background includes

Lymphoma Diagnosis	Cytomorphologic Features
	tingible body macrophages, apoptotic bodies, lymphoglandular bodies, and a watery, basophilic proteinaceous matrix.
Classic Hodgkin lymphoma	Large, pleomorphic, and often binucleated or multinucleated cells (Hodgkin and Reed-Sternberg cells) with prominent nucleoli and abundant cytoplasm in a polymorphous reactive background including small lymphocytes, histiocytes, eosinophils, and plasma cells.
Nodular lymphocyte predominant large B-cell lymphoma	Large pleomorphic lymphoid cells with multilobated nuclei, vesicular chromatin, delicate nuclear membrane, and abundant cytoplasm ("popcorn" cells) in a background rich in small lymphocytes and epithelioid histiocytes.
Peripheral T-cell lymphoma, not otherwise specified	Variable cell size and cytomorphology, from small to large with nuclear pleomorphism. Hodgkin-like cells can be seen. Background can include epithelioid histiocytes,

Lymphoma Diagnosis	Cytomorphologic Features
	eosinophils, plasma cells, and fragments of vessels.
Follicular helper T-cell lymphoma, angioimmunoblastic-type	Small and medium-sized atypical lymphoid cells with abundant clear cytoplasm on a background of small lymphocytes, histiocytes, plasma cells, B immunoblasts, follicular dendritic cells, and fragments of vessels. Aggregates of lymphocytes associated with follicular dendritic cells can be frequent and are termed *dendritic cell–lymphocyte complexes*.
Anaplastic large cell lymphoma	Cytomorphology dependent on morphologic variant. Most frequently, atypical large pleomorphic lymphoid cells with abundant, variably staining cytoplasm with vacuoles, azurophilic granules, or cytoplasmic blebbing. The nuclei can be horseshoe shaped or wreath-like (“hallmark cells”). Lymphoid cells with multiple nuclei are also seen. Admixed small and medium-sized plasmacytoid

Lymphoma Diagnosis	Cytomorphologic Features
	cells are abundant in the small cell variant. The background contains lymphoglandular bodies, small lymphocytes, histiocytes, and neutrophils.
Lymphoblastic lymphoma	Monotonous population of medium-sized lymphoid cells with round to irregular nuclei with speckled chromatin and scant agranular cytoplasm, which may contain small vacuoles. The background includes variable lymphoglandular bodies, tingible body macrophages, necrosis, and mitotic figures.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Cytomorphology

Aspirates of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) are composed of two cell populations (**Fig. 2-4**). Most cells are small with round to oval nuclei, coarsely clumped chromatin, occasional nucleoli, and scant cytoplasm (**Fig. 2-1**). Prolymphocytes are fewer in number and are larger with round nuclei, a vesicular chromatin pattern, prominent nucleoli, and a moderate to abundant amount of cytoplasm.[4,61] A uniform population of large transformed cells suggests Richter

transformation.[62-64] Other cytologic features suggestive of progression are an increased number of intermediate-sized or plasmacytoid cells, mitotic figures, the presence of apoptotic bodies and necrosis, and a myxoid and dirty background.[62] The latter features are also more frequently observed in the accelerated phase; however, a definitive cytomorphologic definition of accelerated CLL/SLL remains to be determined. In rare cases of Hodgkin lymphoma (HL) (Richter) transformation, isolated large bilobated or multilobated cells on a background of histiocytes and poorly formed granulomata are identified.[65] The cytologic appearance should be correlated with clinical features indicative of transformation.

Ancillary Studies

The cytomorphologic diagnosis requires confirmation by immunophenotyping, most commonly by FCM. FISH studies can be performed on FNA material; however, they are of limited diagnostic value and are typically used for a prediction of prognosis in individual patients.[22] There is accumulating evidence that Richter transformation includes clonally related and unrelated (de novo) lymphoid neoplasms, a distinction that has prognostic significance.[66] FNA is an excellent tool to obtain diagnostic material to study clonal relationships at the time of progression.

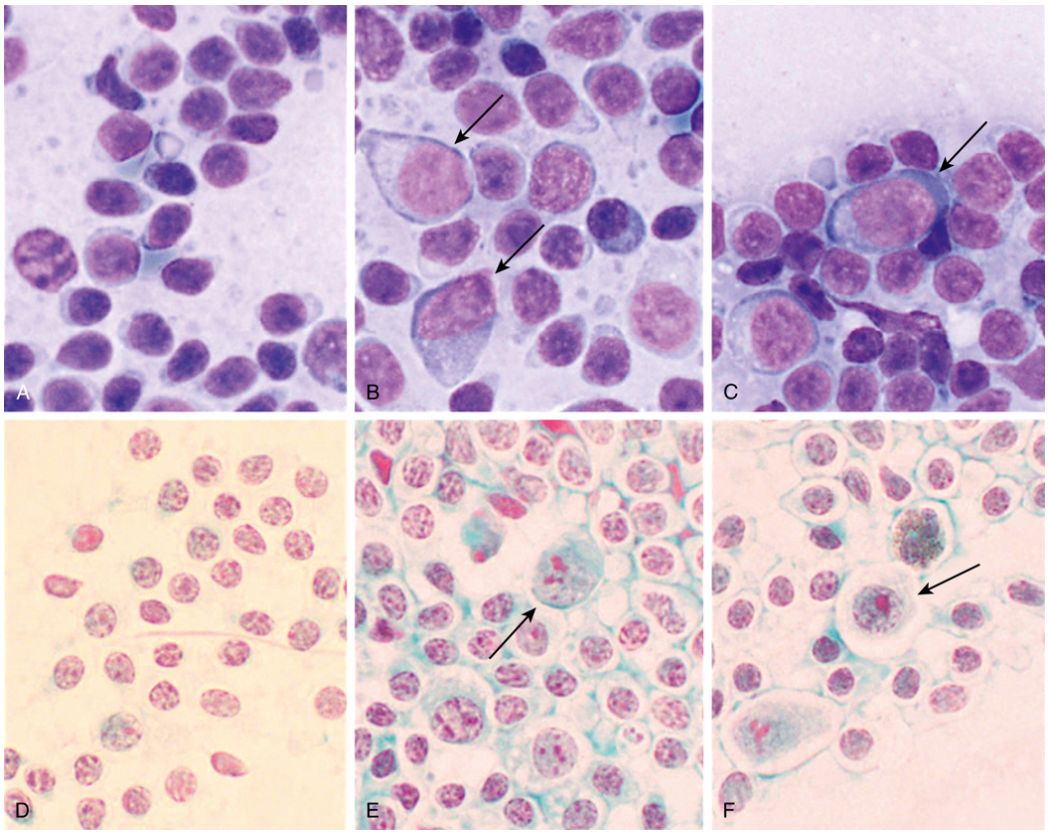

FIGURE 2-3. Common cellular components of B-cell lymphomas.**A,** Centrocytes with clumped chromatin and scant cytoplasm (Diff-Quik, smear). **B,** Centroblasts *(arrows)* with enlarged round nuclei, visible nucleoli, and moderate amounts of basophilic cytoplasm (Diff-Quik, smear). **C,** Immunoblast *(arrow)* shows an enlarged round nucleus, a single prominent nucleolus, and a deep blue cytoplasm (Diff-Quik, smear). **D,** Centrocytes with round nuclei, coarsely clumped chromatin, and scant cytoplasm (Pap smear). **E,** Large centroblast *(arrow)* in a background of small centrocytes. The centroblast shows an enlarged nucleus, dusty chromatin, and

a moderate amount of cytoplasm (Pap smear). **F,** Immunoblast *(arrow)* with an enlarged round nucleus, a prominent eosinophilic nucleolus, and dense cytoplasm (Pap smear).

Differential Diagnosis

The differential diagnosis includes reactive lymphoid hyperplasia, follicular lymphoma, mantle cell lymphoma, marginal zone lymphoma, and lymphoplasmacytic lymphoma. Differentiation of these entities is relatively straightforward based on immunophenotype. On the contrary, a tissue-based monoclonal B-cell lymphocytosis with CLL/SLL immunophenotype is challenging to diagnose without lymph node excision.[67,68] Similarly, an accelerated phase of CLL/SLL has been primarily defined on lymph node histology, and careful attention to detail is required to avoid diagnosis of large cell transformation when evaluating histologic progression in CLL/SLL.

Marginal Zone Lymphoma

Cytomorphology

Aspirates of nodal marginal zone lymphoma and extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma) usually display a population of numerous intermediate-sized lymphoid cells with mild atypia (round to slightly irregular nuclei, condensed chromatin, and indistinct nucleoli) (**Fig. 2-5**).[61,69,70] The cytoplasm is moderate to abundant. Neoplastic cells may have a plasmacytoid appearance.[71-73] The background contains

small lymphocytes, plasmacytoid lymphocytes, plasma cells, and occasional immunoblasts.[71,74] These heterogeneous features can make marginal zone lymphoma difficult to distinguish from a reactive process.[70]

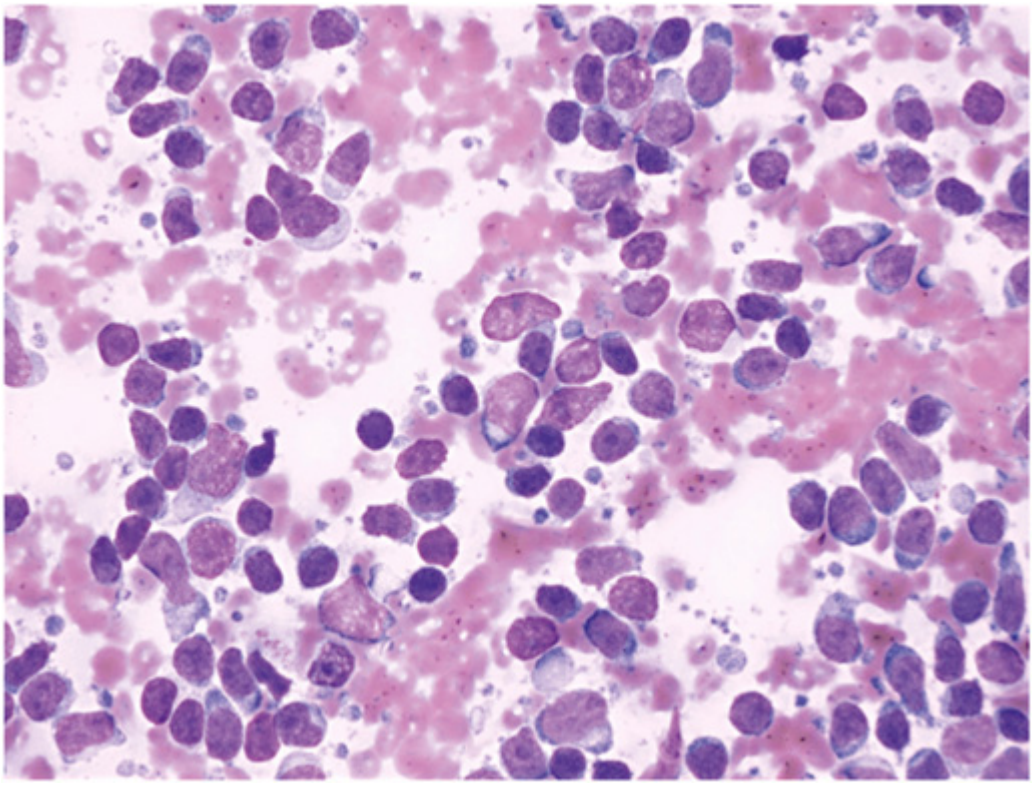

FIGURE 2-4. Small lymphocytic lymphoma.Numerous small, atypical lymphoid cells with mostly round nuclei, coarsely clumped chromatin, and scant amounts of cytoplasm. Scattered larger prolymphocytes with open chromatin, nucleoli, and basophilic cytoplasm are also shown (Diff-Quik, smear).

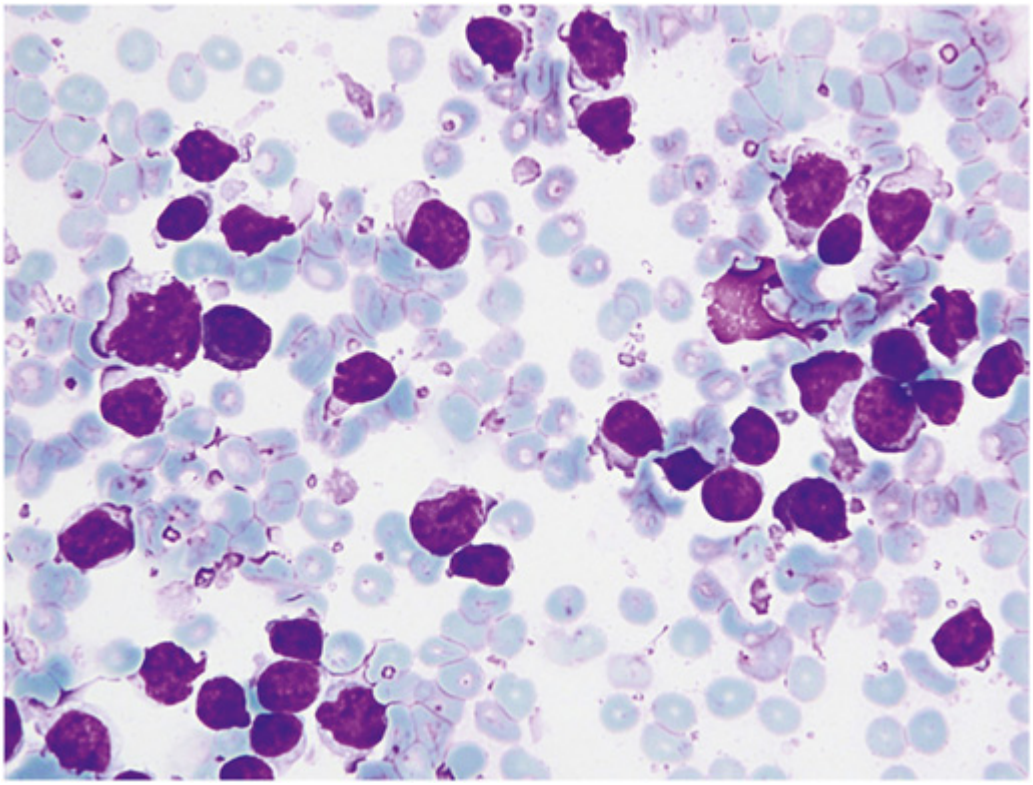

FIGURE 2-5. Marginal zone lymphoma.Atypical small to intermediate-sized lymphoid cells with slightly enlarged irregular nuclei and variable amounts of basophilic cytoplasm. Isolated benign centrocytes and a plasma cell are also shown (Diff-Quik, smear).

Ancillary Studies

Nodal marginal zone lymphoma is often a diagnosis of exclusion because of a lack of specific immunophenotypic or cytogenetic features. An addition of CD43, NMDA and IRTA1 antigens may be helpful along with negative markers, which are typically specific in other B-cell lymphomas, such as cyclin D1, SOX11, follicular center cell markers, CD5, and LEF1.[75] The nodal marginal zone lymphoma

shows no recurrent gene rearrangements, however, t(11;18)(q12;q21) is frequently detected in pulmonary and gastric MALT lymphomas, and rearrangement of *MALT1* can be detected by interphase FISH with break-apart probe on cytospin preparations.[22,71] Specific translocations are not detected in nodal marginal zone lymphoma.[22] The reported mutations also differ among nodal variants and individual sites of extranodal marginal zone lymphoma.[76]

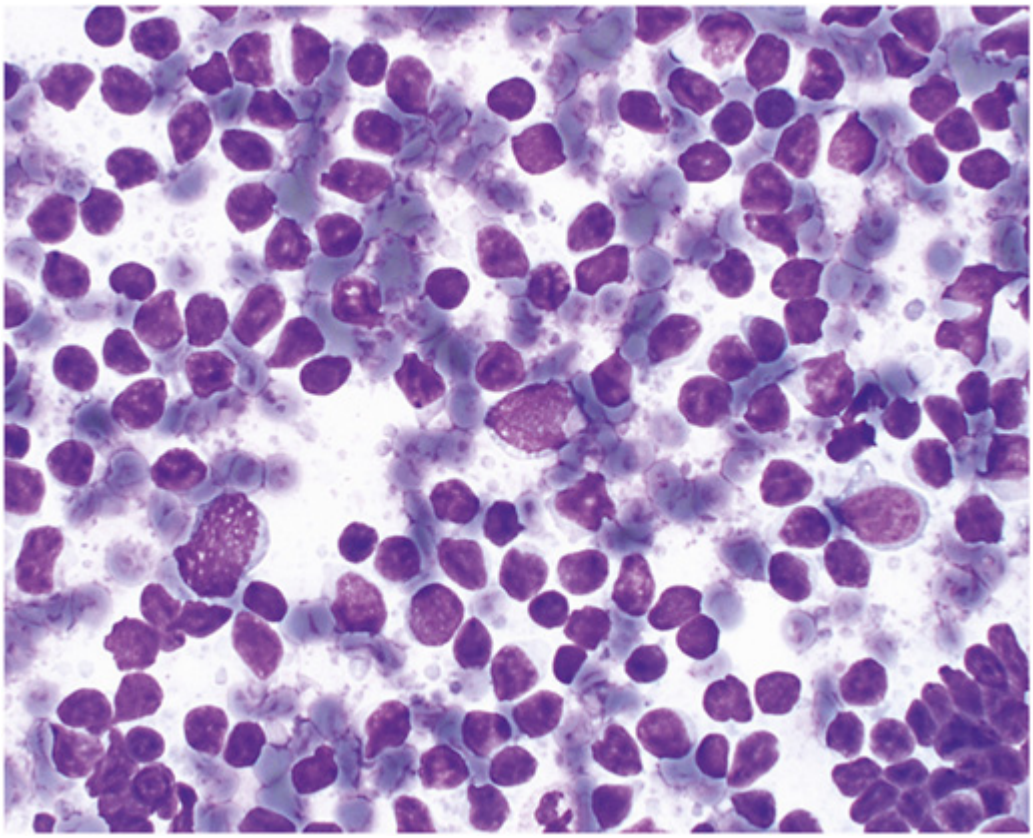

FIGURE 2-6. Follicular lymphoma.Follicular lymphoma (grade 1 to 2) composed predominantly of small to intermediate-sized atypical centrocytes and a few atypical centroblasts simulating a polymorphous lymphoid population seen in a reactive process (Diff-Quik, smear).

Differential Diagnosis

The differential diagnosis includes reactive hyperplasia, follicular lymphoma, mantle cell lymphoma, lymphoplasmacytic lymphoma, and small lymphocytic lymphoma. In cases with extreme plasma cell differentiation, a distinction from plasmacytoma may be difficult on cytologic material.

Follicular Lymphoma

Cytomorphology

Follicular lymphoma aspirates contain a mixed population of centrocytes and centroblasts in varying proportions (**Fig. 2-6**).[61,77] It is important not to confuse centroblasts with FDCs, which are normal occupants of lymphoid follicles. FDCs have oval to coffee-bean shaped nuclei, with smooth nuclear membranes and indistinct cytoplasm (**Fig. 2-7**).[77] The atypical lymphoid cells may be seen in tight clusters, in fragments of follicles, or adherent to the FDCs. Follicular structures may also be seen in reactive hyperplasia. Occasionally, tingible body macrophages are seen, but they are less frequent than in reactive lymph nodes.[78]

Grading

Although architectural assessment cannot be achieved on aspirates, grading of FNA samples using the counting method of Mann and Berard on entire smears or solely on follicular structures has been the subject of investigation using Pap-stained or Pap/DQ-stained cytologic material.[77,79-82] The investigators agree that the discrimination of large centrocytes from centroblasts is facilitated by use of the Pap stain. Discrimination of centroblasts from FDCs is particularly important, as it can lead to erroneous grade assignment.[83] Although Sun and coworkers[84] were able to discriminate intact follicular structures in smears and use them for a centroblast count, Young and colleagues were unable to make this discrimination reliably on any material other than cell blocks and used the entire smear for centroblast counting.[80]

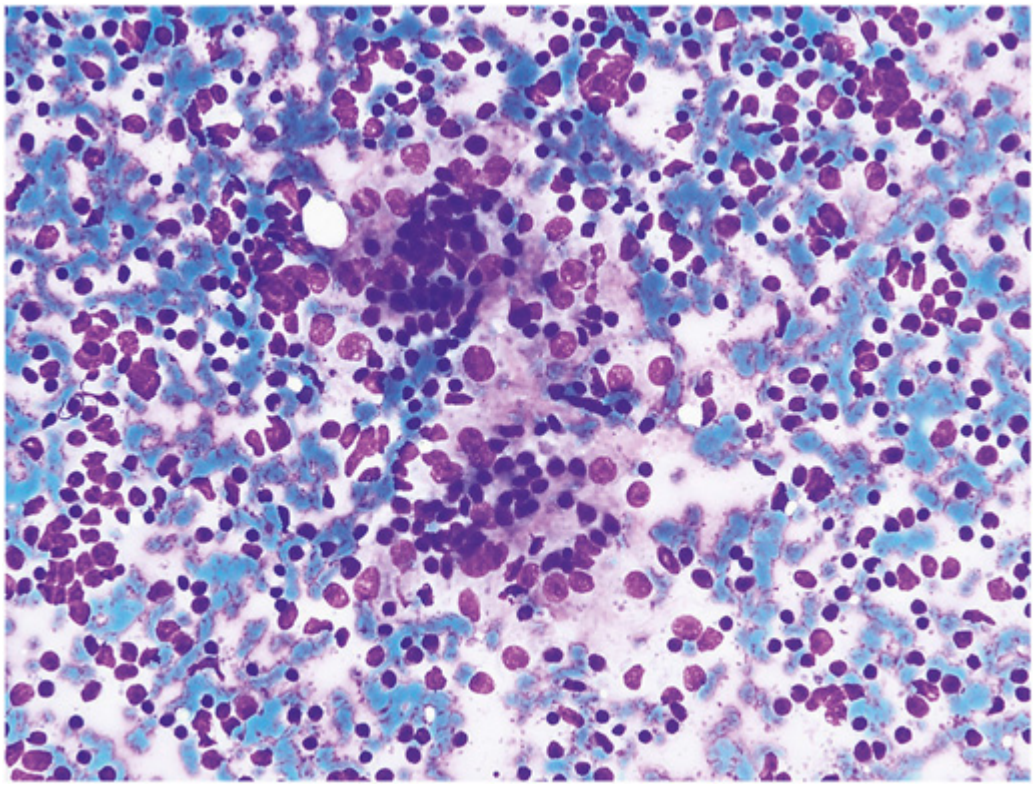

FIGURE 2-7. Follicular lymphoma.Lymphoid fragments with numerous follicular dendritic cells and aggregates of lymphocytes. Follicular dendritic cells have abundant syncytial cytoplasm and histiocyte-like nuclei. Note the paucity of tingible body macrophages (Diff-Quik, smear).

The 2016 WHO classification did not require the distinction of grades 1 and 2, which historically was challenging in both tissue sections and cytologic preparations.[82] In the 2004 study by Sun and coworkers,[84] a minimum of 200 cells was counted in 6 to 10 intact lymphoid follicular structures at 40× magnification. The number of large cells or centroblasts was expressed as a percentage of the total number of cells counted within the follicles and graded accordingly. In grade 3, they identified 48.4 ± 7.5% centroblasts, which is readily

distinguished from significantly fewer centroblasts in grades 1 and 2 (9.7 ± 2.9% and 24.7 ± 5.6%, respectively). Brandao and coworkers were able to grade follicular lymphoma on Pap-stained monolayer preparations by counting the number of centroblasts in 300 lymphoid cells or 10 high-power fields.[85] The most recent edition of the WHO classification abandoned morphologic grading on histologic material as a result of the debatable clinical differences between grade 1 to 2 and grade 3A.[45] The histologic grading has remained in use in the International Consensus Classification, with emphasis on distinction of the grade 3B, which seems to be the most clinically relevant.[46] The distinction between grades 3A and 3B has not been studied by cytomorphology and may be challenging considering a lack of architecture assessment. Similarly, discrimination between grade 3B and diffuse large B-cell lymphoma (DLBCL) is not feasible without the context of nodal architecture seen on histology.

Ancillary Studies

Both FCM and interphase FISH for *IG::BCL2* rearrangement can be used to support a diagnosis of follicular lymphoma in cytologic preparations. The sensitivity and specificity of FCM in detecting a neoplastic population varies depending on the assay and can approach 94% to 100%.[26] Similarly, Richmond et al. showed 81% sensitivity and 100% specificity for detection of the *IG::BCL2* rearrangement on archival Pap-stained cytologic smears.[53] Of note, t(14:18)(q32;q21) can also be detected on Giemsa-stained smears by PCR-based techniques; however, it is generally less sensitive than the FISH-based approach.[22] Of note, a small proportion of follicular

lymphomas, including those involving both nodal and cutaneous sites, and pediatric follicular lymphomas are negative for *BCL2* rearrangement, as are some grade 3 cases. Therefore, lack of t(14:18)(q32;q21) does not exclude a follicular lymphoma diagnosis. Some translocation-negative cases may contain rearrangements of *BCL6,* which can also be assessed. In addition, FISH for *IRF4/MUM1* rearrangement may be indicated to exclude large B-cell lymphoma with *IRF4* rearrangement.

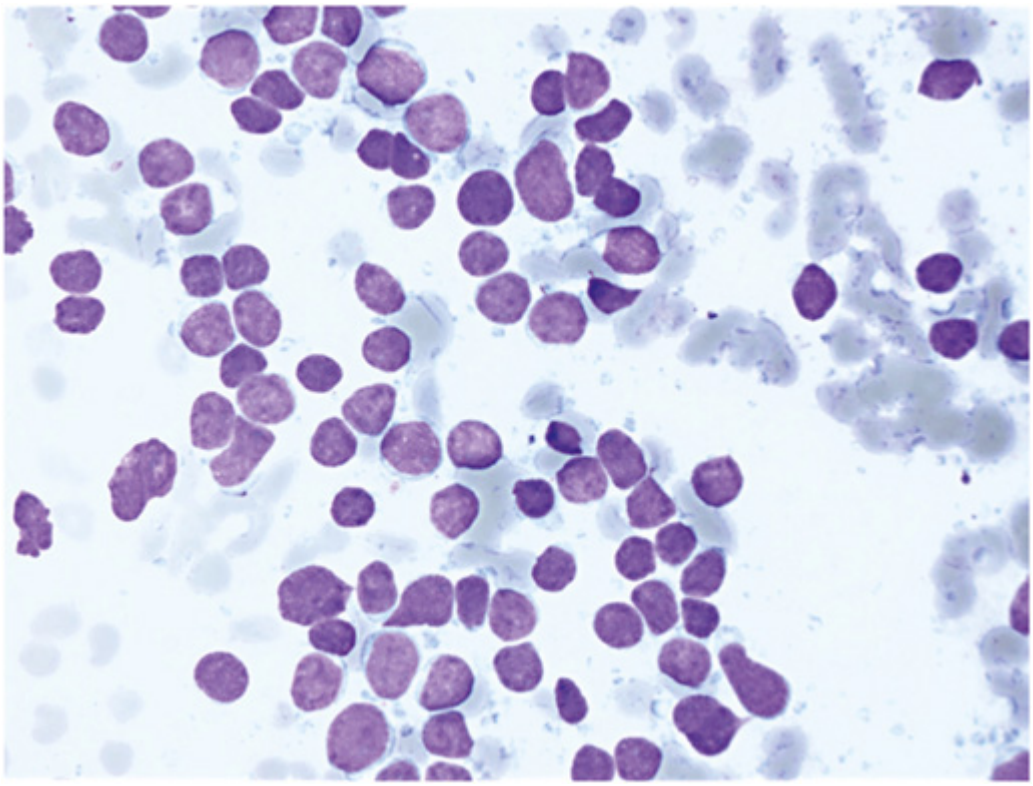

FIGURE 2-8. Mantle cell lymphoma.Monotonous population of atypical small to intermediate-sized lymphocytes with slightly enlarged nuclei, dispersed chromatin pattern, scattered nuclear clefts, and scant pale cytoplasm (Diff-Quik, smear).

Differential Diagnosis

Included in the differential diagnosis are variants of follicular lymphoma such as diffuse and pediatric follicular lymphoma, large B-cell lymphoma with *IRF4* rearrangement, reactive hyperplasia, mantle cell lymphoma, marginal zone lymphoma, small lymphocytic lymphoma, and DLBCL, not otherwise specified. A diagnosis of in situ follicular neoplasia requires correlation with histology.

Mantle Cell Lymphoma

Cytomorphology

Mantle cell lymphoma aspirates often show a monotonous population of small to intermediate-sized lymphoid cells with delicate nuclear clefts, dispersed or finely stippled chromatin, inconspicuous nucleoli, and distinct pale or basophilic cytoplasm (**Fig. 2-8**).[61,86-88] Two variants of mantle cell lymphoma—blastoid and pleomorphic—have potential clinical significance. The blastoid variant exhibits intermediate-sized to large lymphoid cells with enlarged, slightly irregular nuclei, evenly distributed chromatin, and small nucleoli (**Fig. 2-9**). The cytoplasm on DQ-stained material is scant and pale blue. Apoptotic and lymphoglandular bodies may be present in the background.[87] In the pleomorphic or anaplastic variant, the atypical lymphoid cells are larger, with more nuclear irregularity and hyperchromasia.[61]

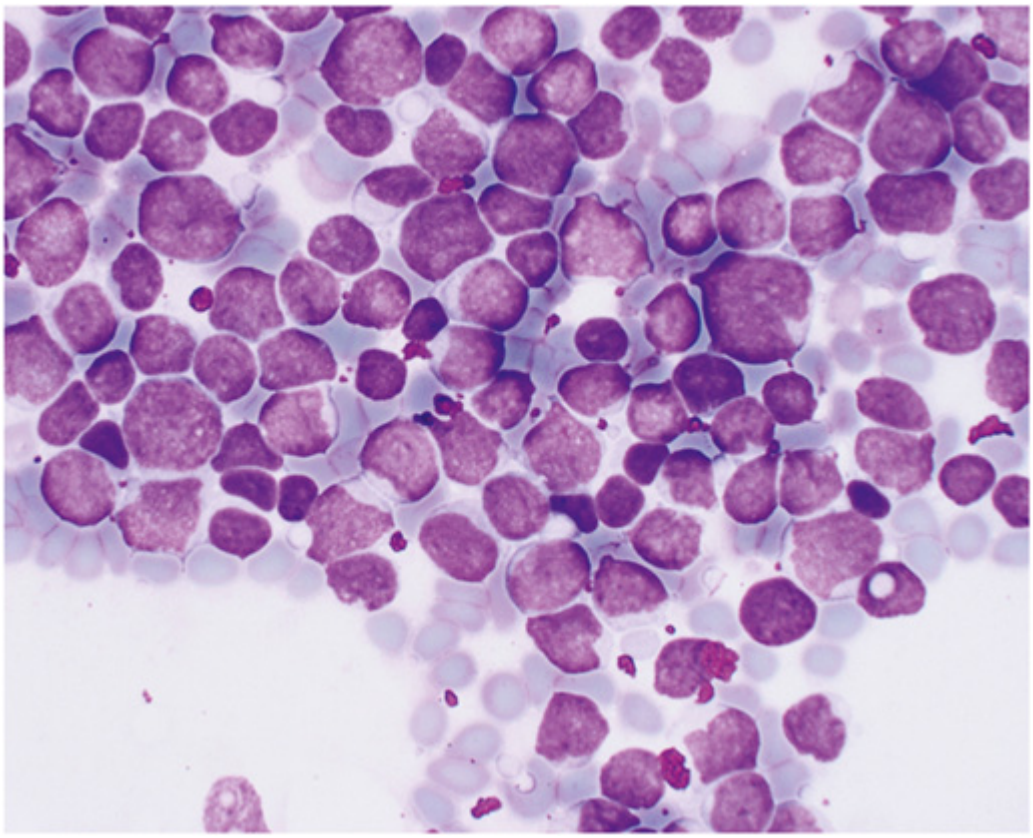

FIGURE 2-9. Blastoid variant of mantle cell lymphoma.Atypical intermediate-sized to large lymphocytes with enlarged irregular nuclei and small amounts of pale blue cytoplasm (Diff-Quik, smear).

Ancillary Studies

The t(11;14)(q13;q32) is present in the vast majority of cases and can be detected by FISH on cytospins of FNA material.[22,50] ICC/IHC for SOX11 may be informative in cases negative for *IG::CCND1* rearrangement.[22] A confirmation of *CCND2* and *CCND3* rearrangements by FISH or sequencing is recommended in these cases, as they should be classified as mantle cell lymphoma.[89]

In addition, the National Comprehensive Cancer Network (NCCN) recommends assessing the proliferative activity by Ki67 immunostain and evaluating the *TP53* status, preferably by sequencing, both of which are used for prognostication and therapy assignment.[90]

Differential Diagnosis

The differential diagnosis includes reactive hyperplasia, follicular lymphoma, marginal zone lymphoma, small lymphocytic lymphoma, and lymphoblastic lymphoma. A diagnosis of in situ mantle cell neoplasia requires correlation with histology.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Cytomorphology

DLBCL is characterized by the presence of a significant number of discohesive large lymphoid cells (**Figs. 2-10** and **2-11**). Smear preparations showing cohesive clusters of large lymphoid cells mimicking carcinoma cells may also be seen.[91] Cytoplasmic fragments, so-called *lymphoglandular bodies,* are usually abundant (**Figs. 2-10** and **2-11**). The majority of cells on FNA smear preparations are centroblasts. These cells have a vesicular chromatin pattern, distinct nuclear membranes, prominent nucleoli, and basophilic cytoplasm. The immunoblastic variant of DLBCL shows a predominance of lymphoid cells (immunoblasts) with large round nuclei, single prominent nucleoli, and abundant plasmacytoid or clear to pale cytoplasm.[4,61,74] Atypical large cells may display pleomorphic multilobated nuclei, similar to ALCL. In cell block preparations, the presence of “sheets” of large lymphoid cells may be

an indication of a primary diagnosis of large cell lymphoma or transformation of a small cell lymphoma.[61]

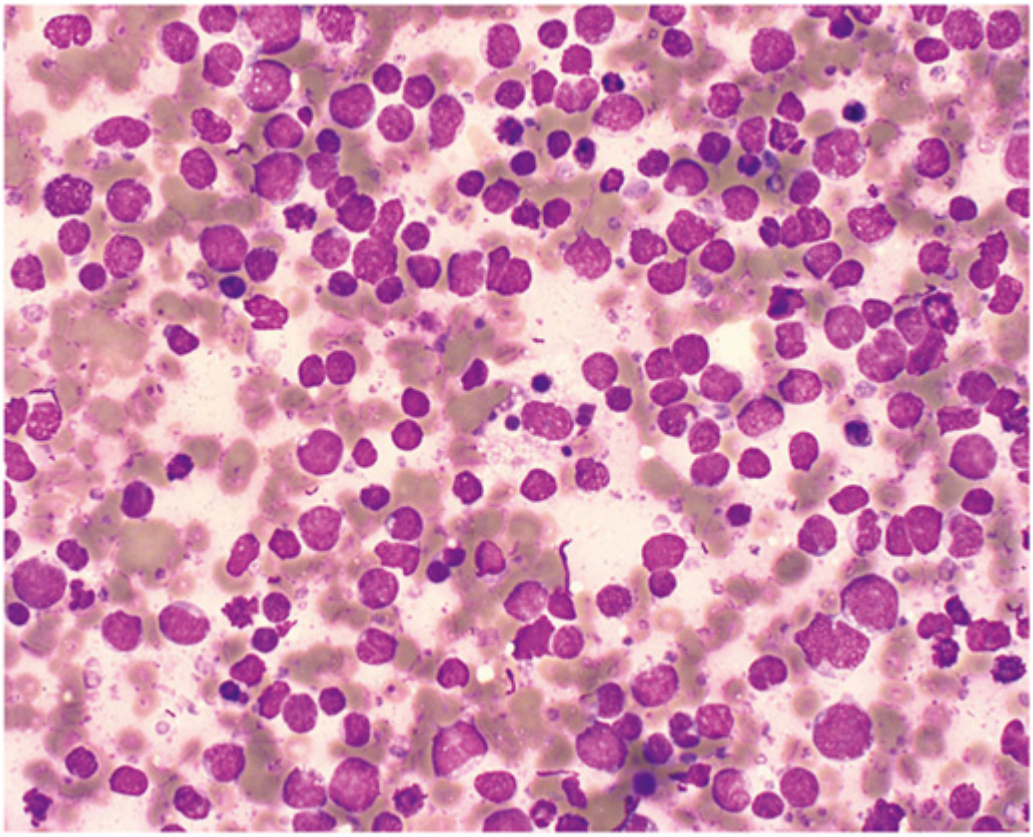

FIGURE 2-10. Diffuse large B-cell lymphoma, not otherwise specified.Predominant population of large atypical centroblasts with basophilic cytoplasm admixed with benign centrocytes and centroblasts, lymphoglandular bodies, and a single tingible body macrophage. Apoptotic cells are noted (Diff-Quik, smear).

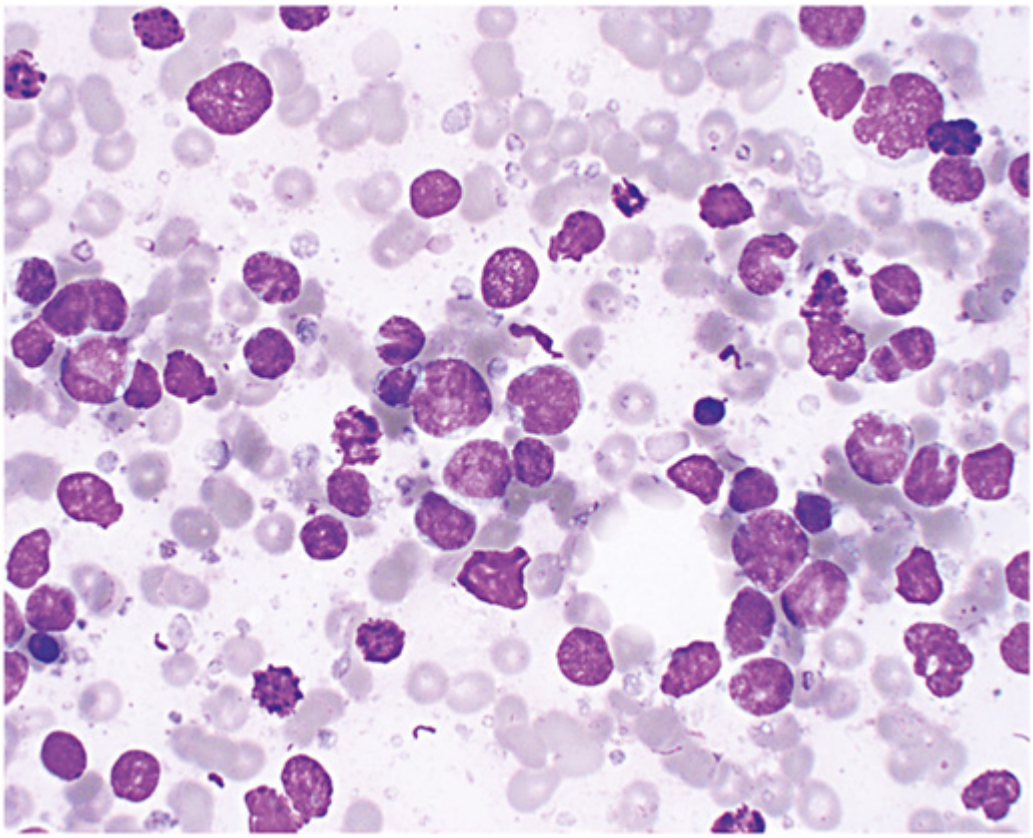

FIGURE 2-11. Diffuse large B-cell lymphoma, not otherwise specified.Large atypical centroblasts with enlarged nuclei, prominent nucleoli, and basophilic cytoplasm. Some atypical centroblasts display irregular nuclear membranes. The background contains a few benign centrocytes and centroblasts and lymphoglandular bodies (Diff-Quik, smear).

Differential Diagnosis

The differential diagnosis includes, but is not limited to, grade 3 follicular lymphoma, large B-cell lymphoma with *IRF4* rearrangement, HL, Burkitt lymphoma, histiocytic sarcoma, myeloid sarcoma, malignant melanoma, seminoma, and metastatic

carcinoma. Distinctive cytologic features of nonlymphoid malignancies include:

- Metastatic carcinoma—presence of atypical cells in clusters and absence (usually) of lymphoglandular bodies in the background

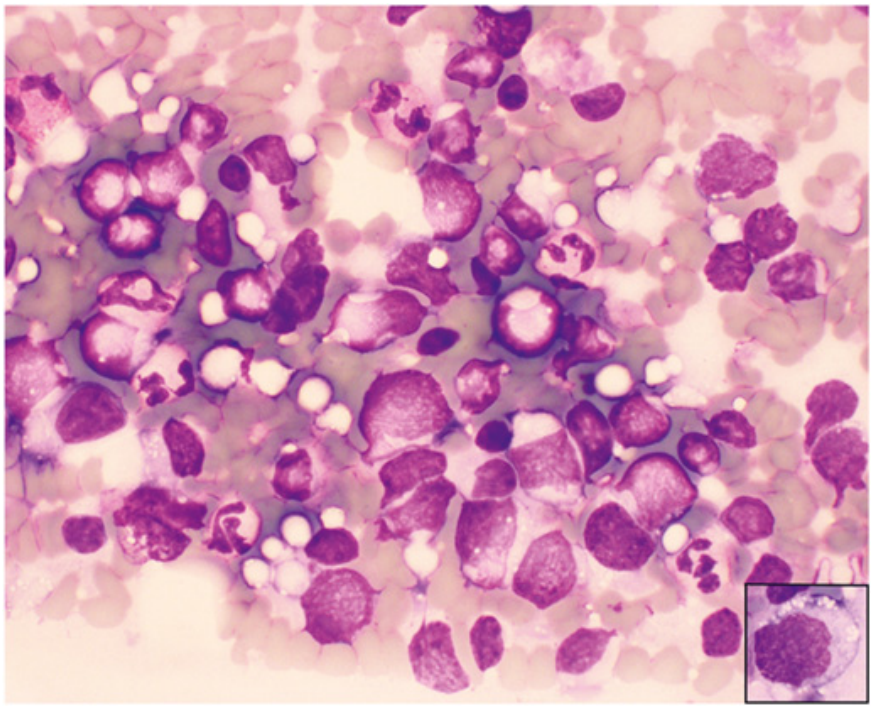

FIGURE 2-12. Primary mediastinal (thymic) large B-cell lymphoma.Large atypical lymphoid cells with enlarged round to irregular nuclei and variable amounts of cytoplasm in a background of mostly red blood cells. Inset shows a large, atypical lymphocyte with moderate amounts of basophilic cytoplasm and small vacuoles (Diff-Quik, smear).

- Metastatic melanoma—presence of pigment and intranuclear cytoplasmic inclusions
- Seminoma—presence of a “tigroid” background on DQ with scattered small, mature lymphocytes; there may be multinucleated giant cells

- Myeloid sarcoma—lack of lymphoglandular bodies; cytoplasmic granules may be present, including Auer rods (rarely); nuclear chromatin is finely distributed, with prominent and usually central nucleoli in blasts; myeloid maturation may be present.

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

Cytomorphology

Aspirates of primary mediastinal large B-cell lymphoma show predominantly single, medium-sized to large lymphoid cells with round to oval nuclei, smooth to irregular nuclear contours, one or more visible nucleoli, and scant to abundant cytoplasm (**Fig. 2-12**). In some cases, the atypical lymphoid cells show markedly lobulated nuclei.[92-94] The cytoplasm is pale blue or deeply basophilic (DQ-stained slides), and vacuoles may be identified.[94] The background may contain connective tissue fragments admixed with single or groups of lymphocytes. These lymphocytes may have a distorted or elongated morphology as a result of fibrosis.[93] Some aspirates may show scant cellularity with a few atypical lymphoid cells.[88]

Ancillary Studies

The confirmation of B-cell origin and presence of associated markers such as CD23, MAL (myelin and lymphocyte), CD200, cREL, TRAF1, TNFAIP2 and pSTAT6 by FCM or ICC are helpful in a differential diagnosis.[95] The majority of primary mediastinal large B-cell lymphomas do not express surface immunoglobulins, which, by definition, are atypical and indicative of a lymphoma diagnosis.[92]

Cytomorphologic diagnosis can also be supported by rearrangements of *CIITA (C2TA)* and abnormalities of the *JAK2/PDCD1LG2/CD274* locus at 9p24.1.[95]

Differential Diagnosis

The differential diagnosis of tumors in this anatomic location includes cHL, lymphoblastic lymphoma, thymoma, and poorly differentiated carcinoma. Distinctive cytologic features of these most common differential diagnoses include:

- cHL—presence of classic Reed-Sternberg cells in a background of lymphocytes, plasma cells, and eosinophils
- Lymphoblastic lymphoma—presence of intermediate-sized atypical lymphoid cells with finely dispersed chromatin and inconspicuous, small nucleoli; cytoplasm is sparse (in contrast to primary mediastinal large B-cell lymphoma)
- Thymoma—presence of epithelial cells and lymphocytes; keratinaceous debris may be present if there is cystic degeneration
- Poorly differentiated carcinoma—atypical cells are cohesive, and lymphoglandular bodies are often absent.

Burkitt Lymphoma

Cytomorphology

The lymphoid cells in Burkitt lymphoma are intermediate in size with round nuclei, a finely granular to coarse chromatin pattern, several nucleoli, and abundant, deeply basophilic cytoplasm with small cytoplasmic vacuoles (**Fig. 2-13**).[96,97] The background shows

tingible body macrophages, apoptotic bodies, lymphoglandular bodies, and a watery, basophilic proteinaceous matrix.[61,96,97] Usually, there are only a few reactive lymphocytes in the background. Similar cytomorphology with slightly more pleomorphic neoplastic lymphoid cells can be encountered in large B-cell lymphoma with 11q aberration (synonym: high-grade B-cell lymphoma with 11q aberrations). The tingible body macrophages seen in the latter entity show numerous coarse apoptotic bodies (**Fig. 2-12**).[98]

Ancillary Studies

ICC and FCM can be helpful in distinguishing Burkitt lymphoma from CD10-positive DLBCL; however, the definitive confirmation of the diagnosis requires a demonstration of *MYC* translocation in the absence of other common genetic abnormalities, such as rearrangements of *BCL2* and *BCL6*.[22] The t(8;14)(q24;q32) and variant translocations of the *MYC* gene can be detected by FISH on cytospins and cell block sections of FNA material.[97]

Differential Diagnosis

The differential diagnosis includes DLBCL, myeloid sarcoma, lymphoblastic leukemia/lymphoma, and other subtypes of high-grade B-cell lymphomas.

Hodgkin Lymphoma

Diagnosis of both cHL and nodular lymphocyte predominant B-cell lymphoma (synonym: nodular lymphocyte predominant Hodgkin lymphoma) can be challenging on cytologic material alone. The paucity of neoplastic cells, rich polymorphous background, cytomorphologic features overlapping with other lymphomas, and

difficulties in immunophenotyping by FCM limit the utility of FNA for the initial diagnosis of HL. In the majority of cases, a follow-up biopsy or lymph node excision are recommended. In patients with a prior history of HL, FNA may be helpful in confirmation of a recurrent disease.

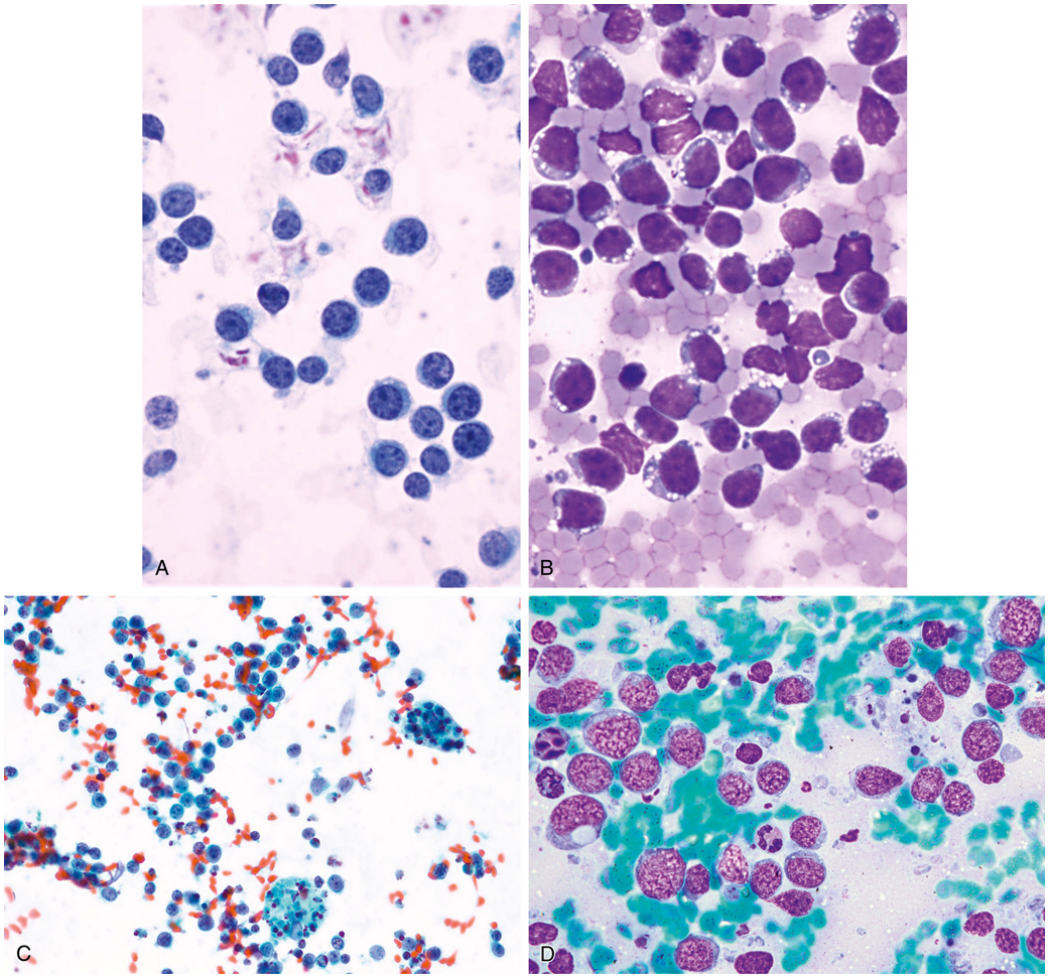

FIGURE 2-13. Burkitt lymphoma and large B-cell lymphoma with 11q aberration.Burkitt lymphoma shows uniform population of atypical lymphoid cells of intermediate size with enlarged round nuclei, coarse chromatin, prominent nucleoli, and homogeneous, well-defined cytoplasm. Some atypical cells display small vacuoles in the cytoplasm. **A,** Pap smear. **B,** Diff-Quik smear. **C, D,** Large B-cell lymphoma with 11q aberration shows more pleomorphic lymphoid cells and tingible body macrophages

with prominent coarse apoptotic debris (**C,** Pap smear. **D,** Diff-Quik smear).

Classic Hodgkin Lymphoma

Cytomorphology

FNA smears of cHL show large pleomorphic and Hodgkin and Reed-Sternberg (HRS) cells in a polymorphous reactive background including small lymphocytes, histiocytes, eosinophils, and plasma cells (**Fig. 2-14**).[99-101] The HRS cells, pathognomonic for cHL, are binucleated with prominent nucleoli and abundant cytoplasm. Hodgkin cells and their variants can be mononuclear or multinucleated, with abundant cytoplasm and nucleoli ranging from small, single, and inconspicuous to large, multiple, and prominent. It has been suggested that a number of neoplastic cells encountered in FNA smears and a type of non-neoplastic component correspond to specific types of cHL. For example, nodular sclerosis cHL frequently shows paucicellular smears with HRS cells, fibroblasts, eosinophils, and fibrous strands.

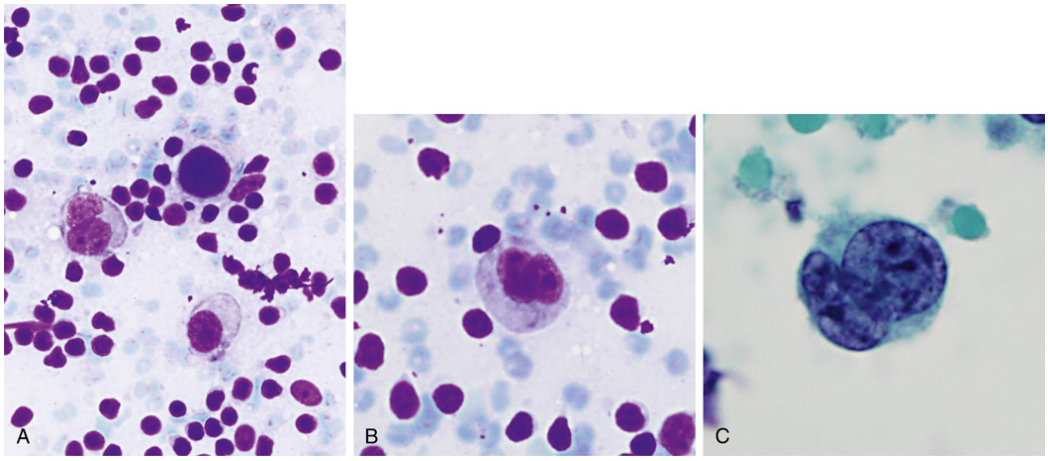

FIGURE 2-14. Classic Hodgkin lymphoma.**A,** Reed-Sternberg cell, mononuclear Hodgkin cells, and numerous small lymphocytes in the background (Diff-Quik, smear). **B,** Classic binucleated Reed-Sternberg cell with prominent nucleoli and abundant pale cytoplasm (Diff-Quik, smear). **C,** Reed-Sternberg cell seen in Pap smear.

Ancillary Studies

Immunophenotyping can be performed on smears/cytospins or cell blocks; however, in clinical practice, the definitive diagnosis of cHL relies on tissue histology supported by IHC whenever possible.

Differential Diagnosis

Because of the overlapping cytomorphology of neoplastic cells and polymorphous inflammatory background, the differential diagnosis of cHL is broad and includes a number of reactive conditions such as infectious mononucleosis, granulomatous lymphadenitis, and suppurative lymphadenitis. Infectious mononucleosis, ALCL, and T-

cell/histiocyte-rich large B-cell lymphoma can be distinguished from cHL only with the help of ICC/IHC. Differential diagnosis also includes metastatic poorly differentiated carcinoma, melanoma, and germ cell tumors.

Nodular Lymphocyte Predominant B-Cell Lymphoma (Synonym: Nodular Lymphocyte Predominant Hodgkin Lymphoma)

Cytomorphology

Neoplastic cells of nodular lymphocyte predominant B-cell lymphoma have a multilobated nucleus with complex folds ("popcorn" cells). The "popcorn" morphology is best appreciated in histologic sections. The chromatin is vesicular with a delicate nuclear membrane, multiple small nucleoli, and scant cytoplasm.[102] The cytology of neoplastic cells may vary, however, and may include cells more closely mimicking HRS cells and their variants. The background is rich in small lymphocytes and epithelioid histiocytes.[102]

Ancillary Studies

Ancillary studies are marginally helpful, as this lymphoma displays a B-cell immunophenotype similar to other large B-cell lymphomas. Definitive diagnosis requires lymph node excision because it is predominantly based on architectural features.

Differential Diagnosis

Given the rarity of neoplastic cells in the reactive background, the cytologic diagnosis is challenging, and the differential diagnosis is

similar to that of cHL.

Mature T-Cell Neoplasms

Diagnosis and classification of T-cell lymphomas can be challenging because of polymorphous cytomorphology, commonly a non-specific immunophenotype, and a low index of suspicion resulting from the low frequency of these disorders. A significant admixture of cells typically seen in reactive lesions such as macrophages, epithelioid histiocytes, plasma cells, eosinophils, and a few small background lymphocytes may suggest reactive lymphadenopathy. We discuss here the cytomorphologic and ancillary features of the most common T-cell lymphomas.

Peripheral T-Cell Lymphoma, Not Otherwise Specified

Cytomorphology

Aspirates of lymph nodes involved by peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) are typically highly cellular and show a spectrum of cytomorphology (**Fig. 2-15**).[103,104] The atypical lymphoid cells range from small to large. The small lymphoid cells are larger than a mature small lymphocyte and show more abundant cytoplasm. There is variable nuclear irregularity with indentations and protrusions and coarse chromatin, which are better visualized on Pap stain. The nucleoli can be inconspicuous or prominent. Large lymphoid cells have round to irregular nuclei, finely granular chromatin, and prominent nucleoli. Large pleomorphic cells resembling Hodgkin cells can be seen; however, binucleated or multinucleated forms are uncommon. Cases with a polymorphous cytomorphology, including medium-sized to large lymphoid cells, are

not infrequent. Epithelioid histiocytes, eosinophils, plasma cells, and fragments of vessels can be seen in a background of neoplastic cells. These heterogeneous cytologic features coupled with a low frequency of PTCL, NOS make a conclusive diagnosis and classification challenging, even when supported by ancillary studies.

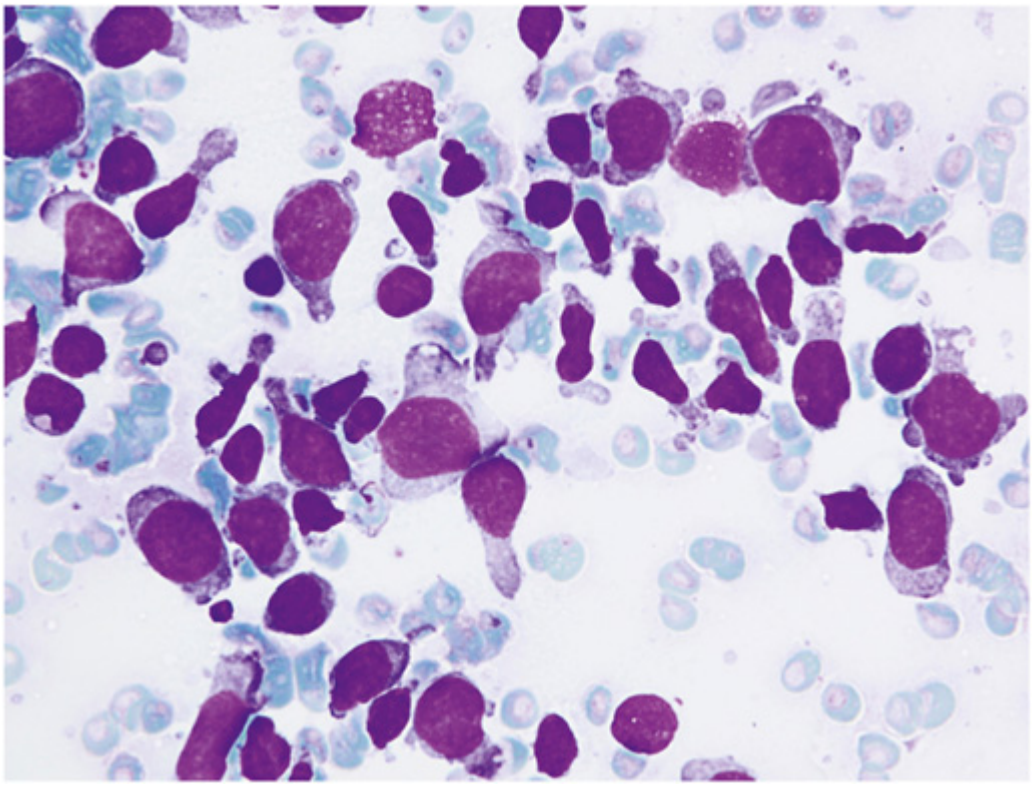

FIGURE 2-15. Peripheral T-cell lymphoma, not otherwise specified.Medium-sized to large atypical lymphocytes with irregular nuclear outlines and scant cytoplasm (Diff-Quik, smear).

Ancillary Studies

The atypical immunophenotype includes a loss of various T-cell markers, most commonly CD7, and is best seen by FCM. A simplified

method to detect T-cell clonality by FCM based on the T-cell receptor (TR) constant beta chain-1 can also be applied.[44] TR gene rearrangement studies by PCR or sequencing can also be performed on cytologic preparations; however, the definitive confirmation of the PTCL, NOS diagnosis is best performed on a lymph node excision.[48,55]

Differential Diagnosis

A differential diagnosis based on cytomorphology alone is broad and includes reactive lymphoid hyperplasia, follicular lymphoma, marginal zone lymphoma, and DLBCL. In select cases with large pleomorphic cells, HL, poorly differentiated carcinoma, and melanoma should be excluded based on the results of flow cytometric immunophenotyping, ICC, or IHC, if a cell block is available.

Follicular Helper T-Cell Lymphoma, Angioimmunoblastic-Type (Synonyms: Nodal T-Follicular Helper Cell Lymphoma, Angioimmunoblastic-Type; Angioimmunoblastic T-Cell Lymphoma)

Cytomorphology

Similar to PTCL, NOS, the cytomorphology of angioimmunoblastic T-cell lymphoma (AITL) is heterogeneous because of a significant component of non-neoplastic small lymphocytes, histiocytes, plasma cells, B immunoblasts, FDCs, and fragments of vessels.[105,106] Small and medium-sized atypical lymphoid cells are found in all reported cases. Lymphoid cells with abundant clear cytoplasm, similar to those seen in histologic sections, have been reported. The

lymphocytes are often found associated with aggregates of FDCs, an arrangement termed *dendritic cell-lymphocyte complexes*. FDCs have an amphophilic cytoplasm with ragged outlines, an oval nucleus, a thin nuclear membrane, and a small nucleolus. Vessels can be seen in tissue fragments on FNA smears or on cell block sections. The heterogeneous population described earlier and the absence of tingible body macrophages, follicle center cells, and Reed-Sternberg cells can suggest a diagnosis of AITL in patients with typical clinical presentation.

Ancillary Studies

Multiparameter FCM confirms the presence of a neoplastic T-cell population in both lymph node and peripheral blood.[107,108] Utilization of markers associated with follicular helper T cells, such as PD1 (CD279), ICOS, CXCL13, CD10, and BCL6, is required. Clonal TR gene rearrangements can be accompanied by clonal IG gene rearrangements, and therefore are best interpreted in the context of histologic evaluation of a lymph node excision.[109,110]

Differential Diagnosis

Differential diagnosis includes reactive lymphoid hyperplasia, especially mixed lymphoid hyperplasia, paracortical hyperplasia, or dermatopathic lymphadenopathy, which are characterized by paracortical expansion and vascular proliferation. Cytomorphology in conjunction with clinical information serves as a screening tool to exclude cases of reactive lymphadenopathy and, if suspicious, to recommend lymph node excision. HL and T-cell/histiocyte-rich large B-cell lymphoma are also included in the differential diagnosis

because of the presence of a polymorphous background cell population.

Anaplastic Large Cell Lymphoma

Cytomorphology

FNA smears of ALCL are variably cellular and show a discohesive population of cells. Cytomorphology is dependent on the histologic variant, and in the most common variant, it includes numerous atypical large pleomorphic lymphoid cells with abundant, variably staining cytoplasm (**Fig. 2-16**).[111-113] Vacuoles, azurophilic granules, or cytoplasmic blebbing can be seen. The nuclei are often horseshoe shaped or wreath-like and correspond to nuclei of "hallmark cells." Lymphoid cells with multiple nuclei are also seen. Nuclei show finely condensed chromatin, well-defined, irregular membranes, and centrally or eccentrically placed prominent nucleoli. Small and medium-sized plasmacytoid cells are admixed.[111,112] The latter are particularly abundant in the small-cell variant. The background may contain lymphoglandular bodies, small lymphocytes, histiocytes, and neutrophils.

Ancillary Studies

The cytologic diagnosis requires confirmation by immunophenotyping. The most useful is demonstration of the classical strong membranous and paranuclear dot pattern of CD30 by IHC, coupled with the absent B-cell and non-hematopoietic antigens. ALK positivity and/or FISH demonstrating rearrangement of the *ALK* gene are useful in ALK-positive ALCL.

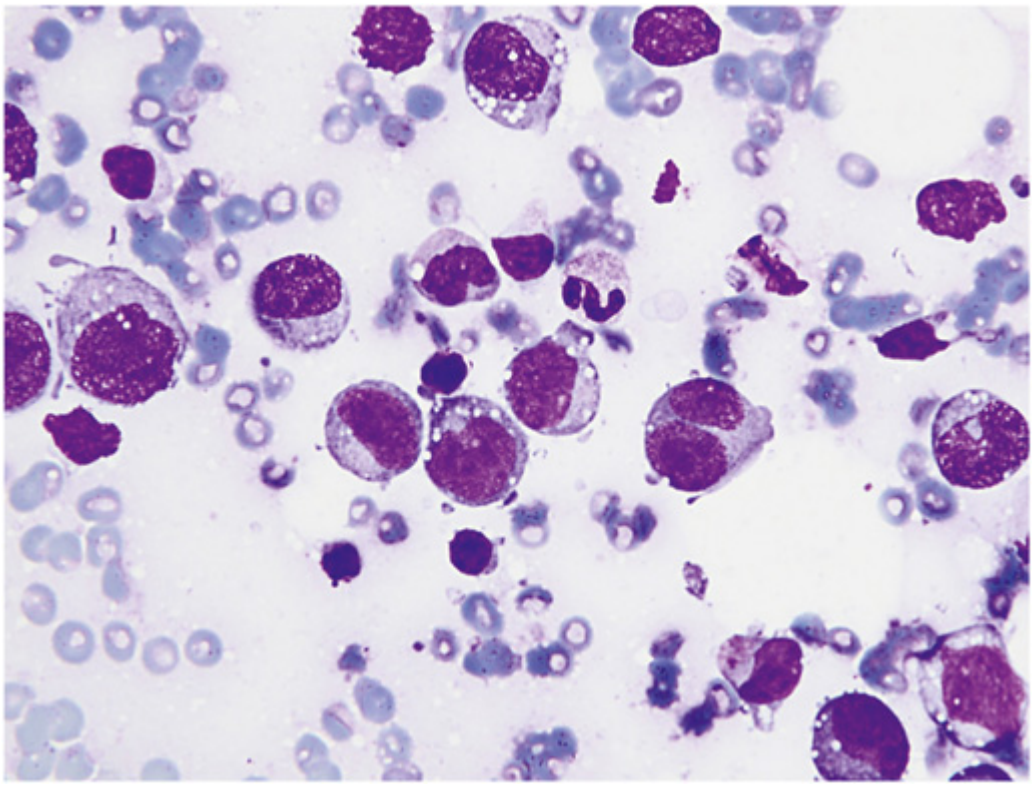

FIGURE 2-16. Anaplastic large cell lymphoma.Large atypical lymphoid cells with pleomorphic nuclei, occasional binucleation, and pale basophilic cytoplasm. Background shows rare small lymphocytes, red blood cells, and debris (Diff-Quik, smear).

Differential Diagnosis

The differential diagnosis includes HL, histiocytic sarcoma, DLBCL, poorly differentiated carcinoma, malignant melanoma, and sarcoma. The erroneous diagnosis of HL has been reported as one of the common major discrepancies between cytology-based and histology-based diagnoses.[114] Certain cytomorphologic features, such as abundant eosinophils and neutrophils seen in cHL or melanin

pigment in melanoma, can help in differentiating ALCL from other entities; however, the definitive diagnosis is based on adequate IHC/ICC. In the absence of a convincing immunophenotype, lymph node excision is recommended.

Lymphoblastic Leukemia/Lymphoma

Cytomorphology

FNA samples of lymphoblastic leukemia/lymphoma (LBL) of either B-cell or T-cell origin show similar features (**Fig. 2-17**). The aspirates contain a monotonous population of immature lymphoid cells that are frequently larger than a small mature lymphocyte and have a high nuclear-to-cytoplasmic ratio.[115] The cytoplasm is scant, agranular, and may contain small vacuoles. Nuclei can be round or irregular, with nuclear clefts and convolutions. The chromatin is finely dispersed, similar to other immature cells, and may be more condensed than that of myeloid blasts. The background shows variable amounts of lymphoglandular bodies, tingible body macrophages, and necrosis.[116] Mitoses may be frequent.

Ancillary Studies

A definitive diagnosis requires immunophenotyping, preferably by FCM, to confirm a homogeneous population of immature T cells or B cells and to exclude rare cases of mixed-phenotype acute leukemia, which can also involve lymph nodes and is challenging to diagnose using IHC. Thymocytes in thymic hyperplasia or thymoma show an immunophenotype consistent with a spectrum of maturation.

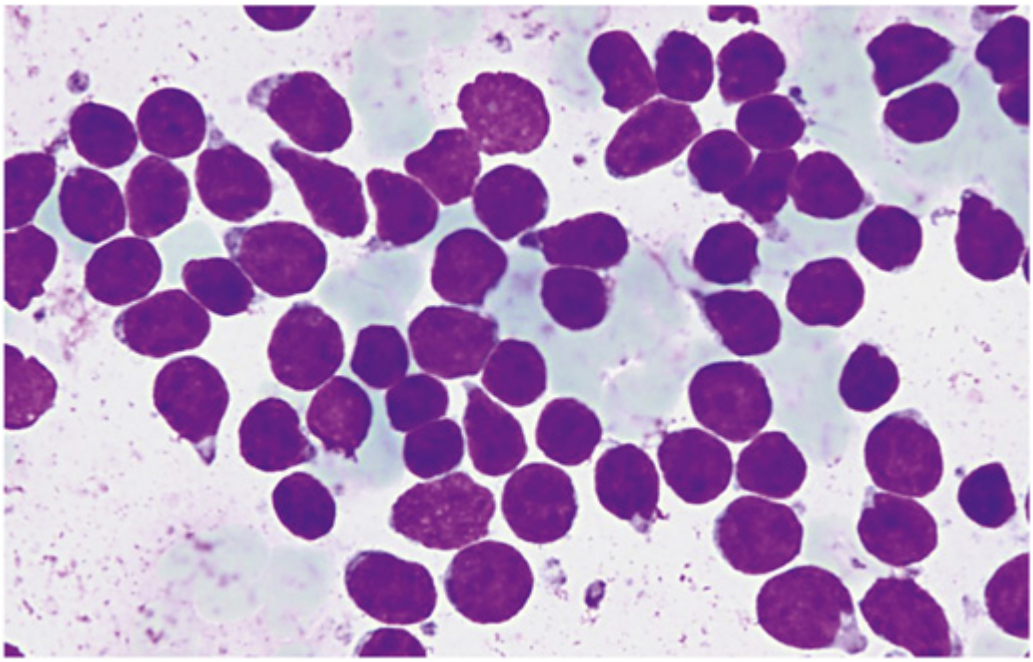

FIGURE 2-17. Lymphoblastic lymphoma.Monotonous population of atypical lymphoid cells (twice the size of small benign lymphocytes) with enlarged, round to oval nuclei, high nuclear-to-cytoplasmic ratio, and scant amount of pale basophilic cytoplasm (Diff-Quik, smear).

Differential Diagnosis

The differential diagnosis includes lymphomas composed of small and medium-sized lymphocytes, including mantle cell lymphoma (blastoid variant). Other neoplasms presenting as mediastinal mass, such as thymoma and small cell carcinoma, should be considered. Myeloid sarcoma occasionally involves lymph nodes and can have a cytomorphology similar to that of LBL.

LIMITATIONS OF FINE-NEEDLE ASPIRATION

Limitations of lymph node FNA are related to technical issues associated with the procedure itself or are intrinsic to entities that are difficult to diagnose based on cytomorphology without the context of architectural features. Poor sampling resulting in a paucicellular specimen that is insufficient for ancillary studies and sampling error are procedure-related problems that are also encountered in FNA of other organs. Missing a lymph node or FNA of a highly fibrotic lesion can result in low or no cellularity. Similarly, inadequate sampling with only a few passes may yield a sample that is not representative of a disease process when a lymph node is partially involved by lymphoma or shows focal transformation. Entities characterized by a rich reactive background with only a few neoplastic cells, such as HL and T-cell/histiocyte-rich large B-cell lymphoma, are also a potential diagnostic challenge.[114,117] These two entities and other lymphomas with a polymorphous population of cells, such as select T-cell lymphomas, are most confidently diagnosed within the context of nodal architecture. Similarly, a follicular or diffuse growth pattern cannot be evaluated in cytology preparations other than a cell block section in some cases. The ability to determine follicular architecture is clinically significant in grade 3 follicular lymphoma versus DLBCL of follicle center cell origin. CNBs (see discussion in next section) accompanying aspiration may partially mitigate some of these limitations; however, in difficult cases, the threshold to recommend lymph node excision should be low.

It is generally agreed that FNA can be used with confidence to distinguish between benign/reactive and malignant lymphoid processes and for the diagnosis of recurrent disease or staging.[27,118,119] However, there is no consensus regarding use of FNA for primary lymphoma diagnosis.[27] Reported diagnostic sensitivity varies greatly, and precise classification can be achieved in less than 80% of cases.[17,27,120] This is partially related to the FNA limitations discussed in the previous paragraph and is also dependent on a variable level of expertise in the diagnosis and current classification of hematologic neoplasms among the cytopathology community. Cytopathologists must be familiar not only with the cytomorphologic evaluation of lymphoid neoplasms; they must also integrate the results of a variety of highly specialized ancillary studies, such as FCM and molecular assays. These studies are typically performed by hematopathologists and molecular pathologists; therefore, effective communication among the team testing individual FNA samples is critical. Close communication with an attending clinician is also important because the knowledge of the clinical context is essential both for an on-site evaluation and at the time of sign-out. The more challenging cases, at least, should be thoroughly discussed within the team before a final cytology diagnosis is issued. Whenever the cytomorphologic diagnosis is inconsistent with the clinical presentation or results of ancillary studies, a lymph node excision or multiple CNBs for inaccessible sites are advised.

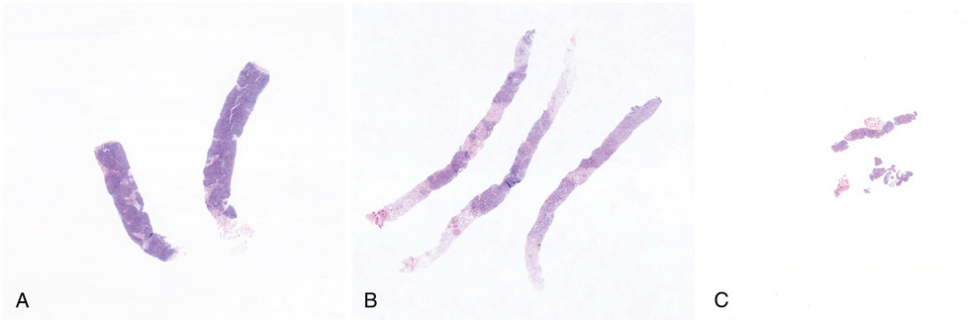

FIGURE 2-18. Examples of core needle biopsies performed with different gauge needles.**A,** 14-gauge core needle biopsy (CNB) of axillary lymph node. **B,** Optimal CNB sample including several tissue fragments procured with 18-gauge needle. **C,** CNB inadequate for evaluation because of small, fragmented sample (20-gauge needle).

ROLE OF CORE NEEDLE BIOPSY IN LYMPHOMA DIAGNOSIS

CNBs are increasingly procured at the time of FNA in an attempt to improve diagnostic sensitivity and provide additional material for ancillary studies. Because of the ease of procurement and low morbidity associated with the procedure, there have been suggestions that CNB can supplement or replace FNA or even lymph node excision in the evaluation of lymphadenopathy. The reported accuracy of CNB in the diagnosis of lymphoma appears superior to FNA alone.[121,122] A modest improvement in accuracy has been reported when CNB is added to FNA.[123,124] The advantage of adding CNB was most pronounced in cases involving DLBCL and cases in

which FNA material was not sufficient for diagnosis. Small B-cell lymphomas showed similar diagnostic accuracy when evaluation was based on FNA alone and FNA accompanied by CNB.

It is challenging to determine whether CNB can replace lymph node excision and become a diagnostic standard. The NCCN and European Society of Medical Oncology guidelines recommend excision or incisional biopsy for lymphoma diagnosis.[90,125-127] Nevertheless, the number of CNBs increases each year owing to the low morbidity of the procedure, ease of performance, and decreased expense.[121,122,128-130] In large multi-institutional series or in the referral lymphoma network setting, CNB can provide a definitive diagnosis in 70% to 90% of cases.[30,42,131] The diagnostic accuracy may differ depending on the regional versus referral setting, use of ancillary studies, and a primary versus recurrent diagnosis.[131,132] Nevertheless, the number of cases with nondefinitive diagnoses is higher for CNB than for lymph node excisions. A comparison of CNB and paired excision samples showed a major diagnostic discrepancy in approximately 10% of cases. This number may be higher when excisions are specifically requested after diagnostic difficulties encountered on preceding CNBs. Specifically, diagnostic challenges related to CNB are common in PTCL and especially angioimmunoblastic T-cell lymphoma, for which the evaluation of architectural features is paramount. In addition, HL, nodular lymphocyte predominant large B-cell lymphoma, T-cell/histiocyte-rich large B-cell lymphoma, and nodal marginal zone lymphoma can be challenging to diagnose based on CNB. Studies have shown that approximately 20% of CNBs yield material insufficient for diagnosis. One multi-institutional study reported significant differences in

aggregate core length among institutions.[42] Not surprisingly, longer cores and larger needle gauges were associated with a definitive diagnosis on CNB and fewer diagnostic discrepancies.[42] The standardization of CNB and quality control may improve diagnostic yield. Obtaining several cores with needles that are 18-gauge or larger may provide reasonable material for an initial diagnosis, at least in select subtypes of lymphoma (**Fig. 2-18**). It is questionable whether CNB samples will be sufficient for potential future ancillary studies such as molecular genetic testing, evaluation of tumor microenvironment, and other tests required for clinical trial qualification and novel therapies. Therefore, lymph node excision or incisional biopsy remains the standard for lymphoma diagnosis.

Pearls and Pitfalls

- Diagnostic accuracy of FNA in lymphoma cases is variable and is significantly increased by the use of ancillary studies such as FCM, ICC, and molecular testing.
- Standardized protocol for the collection and processing of FNA samples is recommended to procure sufficient material and eliminate delays in ancillary studies.
- On-site evaluation, including a detailed review of clinical history, guides the selection of additional testing and, in cases with scant cellularity, allows one to prioritize ancillary studies.
- Addition of air-dried Giemsa-stained cytospins may be helpful, as the cell cytology is superior on cytospins because of the flattening and enlarging effect of cytocentrifugation.

- Alcohol fixation with Pap staining, including monolayer technologies, is insufficient for demonstration of cytoplasmic features, may increase the risk of false-negative diagnoses, and should not be used as the only stain when evaluating hematopoietic processes.
- In our experience, FNA yields superior material for FCM when compared with CNBs, which are often procured at the same time.
- Results of FCM must be interpreted within the context of cytomorphology and clinical information because of the possibility of false-negative or false-positive results.
- When a definitive diagnostic immunophenotype is not available in cases with cytomorphologic features of lymphoma, a lymph node excision is recommended.
- Cytomorphologic diagnosis of lymphoma is challenging in cases with polymorphous populations of cells, including cells typically seen in reactive lesions such as macrophages, epithelioid histiocytes, plasma cells, and eosinophils. Such cases are most confidently diagnosed within the context of nodal architecture.
- Evaluation of growth pattern (follicular vs. diffuse) and distinction between grade 3A and grade 3B follicular lymphomas are not feasible in cytologic material. In these cases, the threshold to recommend lymph node excision or biopsy should be low.
- Differential diagnosis of cHL, nodular lymphocyte predominant large B-cell lymphoma, T-cell/histiocyte-rich large B-cell lymphoma, and ALCL may be challenging because

of a polymorphous cell population and frequently noncontributory FCM.

- Close communication with attending clinicians, hematopathologists, and molecular pathologists is critical in cytomorphologic evaluation of cases of suspected lymphoma.
- For a definitive lymphoma classification and whenever the cytomorphologic diagnosis is inconsistent with the clinical presentation or results of ancillary studies, a lymph node excision or incisional biopsy is advised.

Chapter 3: Immunohistochemistry for the Hematopathology Laboratory

Girish Venkataraman, and Karen L. Rech

OUTLINE

INTRODUCTION

BASIC IMMUNOHISTOCHEMISTRY

- **Antigens**
- **Primary Antibodies**
- **Detection Systems**
- **Interpretive Problems**
- **Special Considerations for Immunostaining Bone Marrow Biopsies**

ANTIGENS OF HEMATOPATHOLOGIC INTEREST

Immunohistochemical Characterization of Lymphoid Malignancies

Immunohistochemical Characterization of Myeloid Leukemias, Myelodysplastic Disorders, and Other Myeloproliferative Diseases

Immunohistochemical Characterization of Histiocytic, Dendritic, Mast Cell, and Other Tumor Cell Types

BEYOND DIAGNOSTICS: THE EVOLVING ROLE OF IMMUNOHISTOCHEMISTRY

IN SITU HYBRIDIZATION

APPROACH TO USING IMMUNOHISTOCHEMISTRY

INTRODUCTION

Perhaps in no other subspecialty of pathology does immunohistochemistry (IHC) play as important a role in the accurate diagnosis and definition of disease subtypes as it does in hematopathology. Before the development of this technology, the diagnosis of lymphoproliferative diseases depended on classification systems based solely on morphologic differences. The subjective use of morphologically based classification schemes led to difficulty in defining biologically different entities, and the morphologic categories were often difficult to reproduce, even among expert

hematopathologists. The advent of IHC allowed the objective identification of specific phenotypic characteristics associated with different lymphoid proliferations. Such phenotypic markers provide information about the cell lineage and origin of the hematopoietic neoplasm, the production of characteristic oncogenic proteins, and the proliferative characteristics of the tumor. IHC is increasingly being used to identify underlying molecular alterations to aid in diagnosis and guide therapy decisions. By integrating IHC studies with morphologic characteristics, more reproducible and biologically relevant classification schemes were developed, reaching their current level of sophistication with the most recent iteration of the World Health Organization Classification and International Consensus Classification of myeloid/lymphoproliferative diseases.[1,2] The goal of this chapter is to introduce the reader to the practice of IHC and to the wide range of antigenic targets that have proved useful in hematopathology.

BASIC IMMUNOHISTOCHEMISTRY

In theory, IHC is a simple technology that requires only three basic elements: a cellular antigen of interest, a primary antibody targeting the antigen, and a detection system to visualize the location of the antibody-antigen complex. In actual practice, the production of an optimally immunostained slide is much more problematic and depends on the condition of the tissue antigen; the type, specificity, and affinity of the primary antibody; and the detection system used. The interpretation of IHC stains requires knowledge of and control over these elements and an experienced pathologist.

Antigens

At the heart of IHC is the antigen-antibody reaction; therefore, it is crucial that the antigenic epitopes recognized by the cognate diagnostic antibody maintain their reactive conformation. The specific antigenic epitopes present on any given protein or carbohydrate moiety are subject to enzymatic degradation that begins immediately after biopsy or resection and to further conformational changes resulting from fixation. To ensure preservation of the antigen of interest, rapid tissue fixation is important. Some antigenic epitopes, such as those on keratin proteins and other structural proteins of the cell, are relatively resistant to degradation; other antigens, such as phosphoepitopes on signaling proteins, undergo rapid degradation within minutes to hours.[3,4]

Although prompt tissue fixation is essential to preserve antigenicity, the specific fixative and the fixation process itself can interfere with antigenicity by causing conformational changes in antigenic molecules or by chemically modifying the antigenic epitopes. Traditionally, tissues have been fixed in neutral buffered formalin (pH 7.0) because it is inexpensive, has sterilizing properties, and preserves morphologic features well. The exact chemical reactions that occur in tissues are not well understood, but it is generally assumed that formalin's ability to cross-link aldehyde groups in proteins is responsible for its fixative properties. This mode of action is potentially deleterious to antigenic structure, and although some antigenic epitopes may not be affected significantly by formaldehyde cross-linking, these chemical modifications clearly have an adverse effect on many antigens. As formalin penetrates

tissues slowly and the chemical reactions are complex, the number of modifications that take place is time dependent. In practice, this means that antigens fall into three basic categories: formalin-resistant epitopes, highly formalin-sensitive epitopes, and epitopes with a time-dependent sensitivity to formalin fixation. Although there have been attempts to generate antibodies specific to formalin-resistant epitopes,[5] most of the antibodies found to react with formalin-resistant epitopes have been identified through large-scale screenings of available antibody preparations.

Over the years, there has been great interest in identifying methods to overcome or reverse the deleterious effects of formalin fixation. The earliest attempts to retrieve antigenicity used proteolytic enzymes,[6] which presumably act by breaking formaldehyde-induced methylene cross-links in the antigenic molecules, thereby relaxing some of the conformational constraints on the protein epitopes. Such proteolytic methods continue to be used in many IHC laboratories and are particularly useful for recovering the reactivity of the cytokeratins. Nonetheless, proteolytic methods are difficult to control, and careful attention is needed to optimize their retrieval effect and avoid tissue destruction.

Despite some successes with proteolytic methods, the major breakthrough that brought IHC into widespread use was the development of heat-induced epitope retrieval (HIER) procedures.[7] This technique involves heating fixed tissue sections in buffered solutions at or above 100° C for several minutes to more than 30 minutes. HIER methods vary in terms of the recommended buffer solutions and the mode of heating, but the basic formula of applying wet heat over a period of time is universal.[8,9] The exact mechanism

by which HIER reverses the loss of antigenicity in formalin-fixed tissue is unknown. However, hydrolytic cleavage of formaldehyde-related chemical groups and cross-links, the unfolding of inner epitopes, and the extraction of calcium ions from coordination complexes with proteins are among the hypothesized mechanisms.[10,11]

The advent of HIER methods revolutionized IHC and greatly expanded the number of antibodies that react in formalin-fixed, paraffin-embedded tissue sections.[7,11,12] HIER has also improved the sensitivity of antibodies directed to formalin-resistant epitopes and has enabled the routine assessment of a wide spectrum of antigens in epoxy resin–embedded bone marrow sections.[13] Appropriate antigen retrieval can minimize many of the problems related to preanalytic factors, reducing differences in immunostaining that result from the variations in fixation time in the clinical laboratory.[14]

The major disadvantage of HIER is that the high heat can cause considerable tissue damage, particularly when the tissue is underfixed or has a high collagen content, the antigen-retrieval time is prolonged, and the buffers contain ethylenediaminetetraacetic acid (EDTA) or have a high pH. Tissue damage can be minimized by ensuring tissues are optimally fixed, reducing the antigen-retrieval time, or changing the retrieval buffer. Despite this potential problem, the ability to detect otherwise nondetectable antigens far outweighs the potential for occasional damage of tissue sections.

Primary Antibodies

There are two major categories of primary antibodies used in diagnostic pathology: monoclonal antibodies and polyclonal

antibodies. Polyclonal antibodies are generated by injecting an animal (most commonly a rabbit or goat) with the antigenic preparation of interest and harvesting the animal's serum once an immune response is detected. The serum is subjected to antibody purification and sometimes to differential adsorptions to eliminate unwanted reactivity, but it always contains a spectrum of antibody molecules originating from multiple unrelated antibody-producing cells (hence the term *polyclonal*). The specificity of a polyclonal antibody preparation is highly dependent on the purity of the initial antigenic preparation and how extensively adsorbed it is. Obtaining highly specific preparations is difficult, and background problems can be troublesome, especially when applied to IHC. Further, because the antibody response is variable over time and from one individual animal to another, complete standardization of antibody composition is not possible. Although developments in recombinant DNA and protein synthesis technology have greatly improved the specificity of polyclonal antibodies by providing tools to generate highly purified protein immunogens or even specific immunogenic peptides, polyclonal antibodies may still contain unwanted specificities.

Monoclonal antibodies, in contrast, are the product of a single immortalized antibody-producing cell, thus avoiding most problems related to antibody heterogeneity and specificity inherent in polyclonal antibody preparations. The hybridoma technology pioneered by Kohler and Milstein[15] in the 1970s allows the immortalization of a single antibody-producing mouse plasma cell by fusing it with a mouse plasmacytoma cell line. Individual hybrid mouse cells can be clonally expanded in tissue culture or in mice as

tumors, providing a continuous source of antibody of known composition and reactivity. Because of their high quality and specificity, monoclonal antibodies were rapidly developed as diagnostic reagents in hematopathology and for other clinical applications that require standardized reagents. The specificity advantage of the monoclonal antibody, however, can also be a disadvantage when applied to denatured proteins in tissue sections. Because a polyclonal antibody preparation generally contains a mixture of antibodies reacting to multiple epitopes, it does not matter if some of the epitopes are rendered inactive by the fixation process, as long as one epitope remains in its reactive conformation. However, if the single epitope recognized by a monoclonal antibody is affected by the fixation process, the antibody cannot be used for IHC. A second disadvantage of mouse monoclonal antibodies is that they generally have weaker affinity constants than do comparable polyclonal rabbit antibody preparations. This led to the development of rabbit plasmacytoma cell lines that could be used as fusion partners to generate high-affinity rabbit monoclonal antibodies. These high-affinity rabbit monoclonal antibodies have improved the detection of some antigens, such as cyclin D1, and permitted detection of others that were heretofore unavailable with murine antibodies, such as CD103.

Regardless of which type of antibody is chosen for an IHC procedure, careful control over the development and use of the antibody must be maintained. Although antibody specificity is best demonstrated by immunoblotting or immunoprecipitation, this type of biochemical analysis is required only during the initial development of the antibody by the commercial vendor. However,

before placing any antibody into clinical use, extensive validation of its efficacy and staining characteristics on tissue sections in the individual laboratory is necessary. This should include extensive testing of normal and tumor tissues to assess the specificity and sensitivity of tissue staining. The use of tissue microarrays can be helpful during this stage. Once the antibody has been validated and placed in service, the continued use of positive controls is mandatory with each test sample. The use of on-slide quality control tissue is an optimal practice that uses tissues known to contain the antigen of interest. As an alternative to on-slide quality control tissues, many hematopathology antigens are expressed on internal control cells within most tissues (e.g., cyclin D1 stains endothelial and stromal cells, and CD15 stains granulocytes).

Detection Systems

Detection systems contain an enzyme, a chromogenic substrate, and a link or bridge reagent that brings the enzyme into proximity with the primary labeling antibody. The choice of detection system is of great importance, and each method has its own advantages and disadvantages. Factors influencing the selection of a detection method are related to the type of tissue, the cellular target, its abundance and localization, and laboratory-specific issues (e.g., complexity, time requirements, reagent costs). Detection systems based on avidin-biotin immunoperoxidase complexes (ABC) have been largely replaced by polymer-based detection systems that avoid the possibility of high backgrounds in tissues rich in endogenous biotin.[16,17] As in biotin-based systems, an unlabeled primary antibody is used first, followed by a modified polymer (e.g., dextran)

that is linked to a large number of secondary link antibodies and enzyme (peroxidase) molecules. Thus, one reagent contains both a species-specific secondary anti-immunoglobulin linking antibody and the chromogen developing enzyme. Newer detection systems have also been developed to increase the sensitivity for detecting antigens expressed at very low levels or to improve the detection of low-affinity primary antibodies. These systems involve a tyramide-based signal amplification method known as the *catalyzed reporter deposition (CARD)* or *catalyzed system amplification (CSA)* method.[18,19] All present-day clinical IHC is performed on automated instruments; hence, knowledge of the design of the amplification systems and postprimary options is critical for optimizing immunostains on a day-to-day basis.

Interpretive Problems

It is necessary to distinguish specific and non-specific signals when interpreting IHC. There are many sources of false-positive results, including endogenous biotin or peroxidase, inappropriately high antibody concentrations, poor technique (e.g., excessive antigen retrieval, drying artifacts, prolonged detection), or interpretive errors such as mistaking endogenous pigment for the chromogenic reaction product. Endogenous biotin reactivity can be a serious problem because of its variable occurrence in tumors. This biotin positivity is often amplified by retrieval techniques and presents as a granular pattern that can be difficult to distinguish from other granular cytoplasmic staining.[20] Failure to block biotin can lead to problems with interpretation and the reporting of false-positive results.[21,22] Use of one of the newer polymer-based detection systems that avoids

the use of a biotin-avidin link can eliminate this problem. There are also myriad reasons for false-negative results, the most frequent of which are inadequate antigen retrieval, suboptimally fixed tissue, inappropriate primary antibody, or other technical staining issues.

It cannot be overemphasized that the accurate interpretation of IHC stains requires knowledge of the laboratory's methods, the antibodies used, and the expected staining pattern for each antibody. Different antibody preparations to the same antigen may show various patterns and intensities of non-specific or even specific staining. For instance, monoclonal antibodies targeting different epitopes of the Treg-associated marker FOXP3 have been shown to stain different subpopulations of cells in comparative studies in paraffin sections.[23] As another example, the anti–Ki-67 monoclonal antibody MIB-1 has been reported to stain the cell membrane of some tumor types, whereas other monoclonal antibodies to the same antigen do not show this type of aberrant staining.[24] Knowledge of the subcellular staining location of the targeted antigen is crucial, including nuclear, cytoplasmic, membranous, Golgi, and extracellular compartments and combinations of these stereotypical patterns (**Fig. 3-1**). An unexpected staining localization should immediately raise a red flag and should not be considered positive in any situation. For example, nucleolar staining for CD20 is seen when secondary antibody cross-reacts with nuclear histones, but non-specific staining in neutrophils may be seen for TIA1 in decalcified marrows.

Special Considerations for Immunostaining Bone Marrow Biopsies

Examination of bone marrow trephine biopsies is an integral component of the assessment of hematologic disorders and other diseases affecting hematopoiesis. It is particularly useful for the evaluation of marrow cellularity, cell distribution, and the relationship between different cell types. Its role is critical when evaluating patients with a “dry tap”—that is, when examination of the aspirate is unsuccessful owing to fibrosis or other infiltrative processes.

For tissue morphology to be preserved, the length and type of fixation, tissue processing, sectioning, and quality of staining are crucial. Decalcification procedures represent an additional variable that may influence the staining pattern and affect the preservation of antigenicity in IHC.[25] A variety of fixatives are available, including buffered formalin, mercury-containing solutions such as Zenker’s or B5, or a combination based on acetic acid–zinc–formalin (AZF) as proposed by the Hammersmith protocol[26,27]; the last provides a morphologic quality comparable to B5, but with superior antigen and nucleic acid preservation (if followed by formic acid decalcification).[26] Subsequent to fixation, the bone marrow trephine needs to undergo decalcification with either calcium-chelating agents such as EDTA or acid-based agents. EDTA decalcification usually lasts 48 to 72 hours; with acid-based solutions, the decalcifying time is shorter (1 to 2 hours or up to 6 hours when 10% formic acid and 5% formaldehyde are used). Usually, each laboratory has a standardized procedure whereby bone marrow biopsies are monitored during fixation and decalcification to ensure morphologic preservation and the best conditions for IHC and molecular techniques.

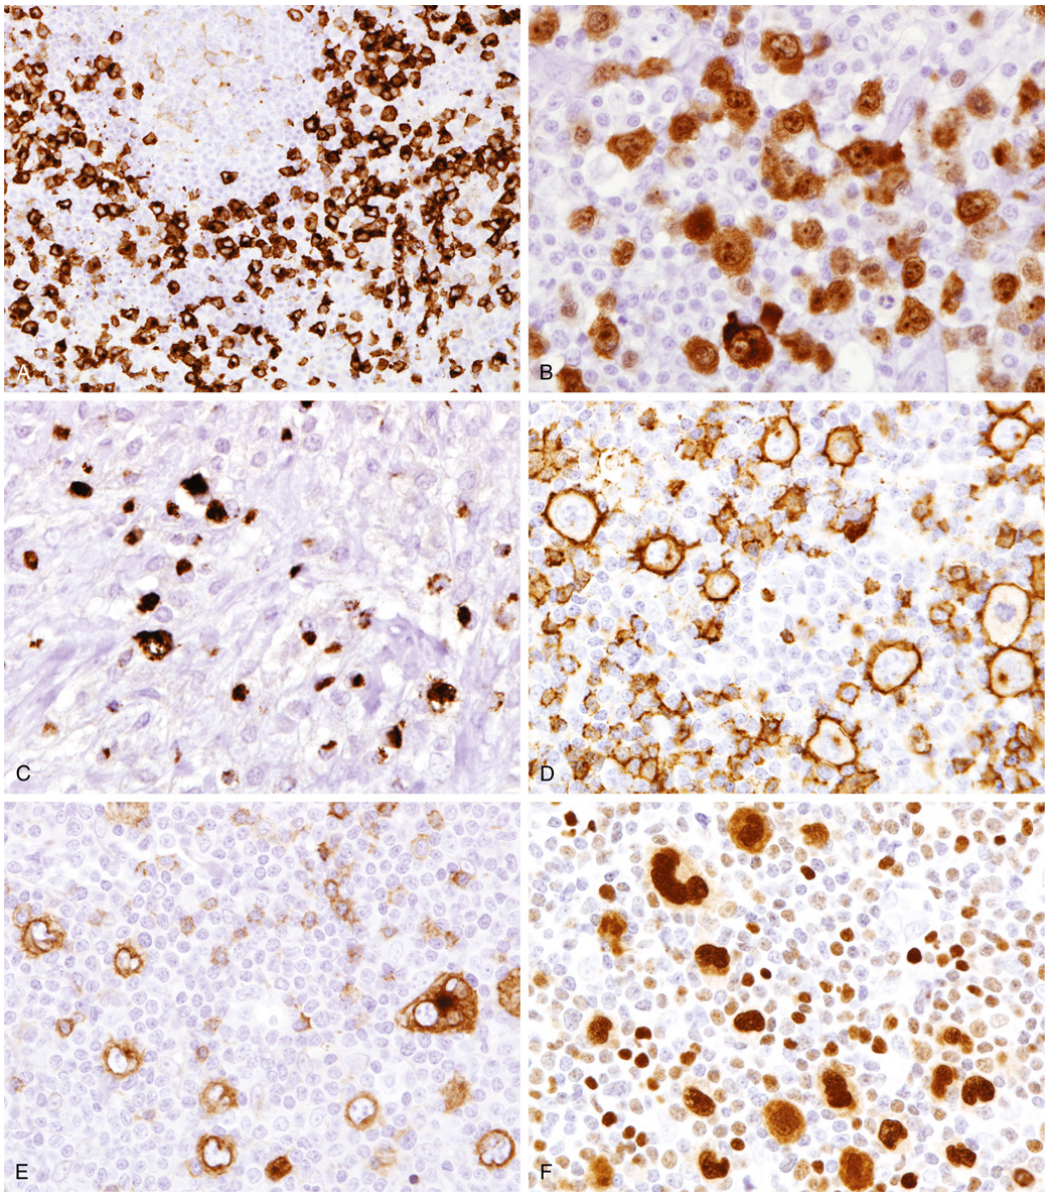

FIGURE 3-1 Representative patterns of cell-associated immunohistochemical staining in different cellular compartments (U-view/DAB detection, Ventana, Tucson, AZ; plus hematoxylin counterstain).A-C, Examples of immunohistochemical targeting of antigen expression in a case of anaplastic lymphoma

kinase (ALK)-positive anaplastic large cell lymphoma. **A,** Membranous and Golgi staining pattern with a monoclonal antibody against CD30. **B,** Nuclear and cytoplasmic staining pattern characteristic of a monoclonal antibody against ALK. **C,** Cytoplasmic granular staining pattern characteristic of a monoclonal antibody against TIA-1. **D,** Membranous staining pattern with a monoclonal antibody against CD20 in nodular lymphocyte-predominant Hodgkin lymphoma. **E** and **F,** Examples of immunohistochemical targeting of antigen expression in a case of nodular lymphocyte-predominant Hodgkin lymphoma (termed more recently as nodular lymphocyte predominant B-cell lymphoma). **E,** Cytoplasmic staining pattern with membranous and perinuclear accentuation with a polyclonal antibody against immunoglobulin D. **F,** Nuclear and cytoplasmic staining with a monoclonal antibody against OCT-2.

Table 3-1

Recommended Immunohistochemistry Panels for Lymph Nodes and Lymphoma Diagnosis

Diagnostic Panel	Antibodies
Small B-cell lymphomas	CD20, CD79a, CD3, CD5, CD10, CD23, CD21, BCL2, BCL6, cyclin D1, IgD, kappa and lambda light chains, Ki-67, LEF1, MUM1, SOX11
Aggressive B-cell lymphomas	CD20, CD3, CD5, BCL2, BCL6, CD10, IRF4/MUM1, MYC, EBER ISH
Plasma cell neoplasms, plasmablastic neoplasms	CD20, CD79a, CD3, kappa and lambda light chains, Ig heavy chains, CD56, CD138, MUM1, ALK, EMA, EBER ISH, HHV8
Classic Hodgkin lymphoma	CD20, CD3, CD30, CD45, CD15, PAX5, OCT2, BOB.1, EBER ISH, LMP1
Nodular lymphocyte-predominant B-cell lymphoma	CD20, CD3, IgD, OCT-2, BCL6, CD21, PD-1
Peripheral T-cell lymphoma (nodal)	CD20, CD3, CD5, CD4, CD8, CD2, CD7, CD10, CD21, CD25, CD30, TIA-1, PD-1, BCL6, CXCL13, ICOS, ALK, EBER ISH

Diagnostic Panel	Antibodies
Peripheral T-cell lymphoma (extranodal)	CD20, CD3, CD5, CD4, CD8, CD2, CD7, CD25, CD30, CD56, TIA-1, granzyme B, β-F1, ALK, TCR delta, EBER ISH

Since the introduction of antigen retrieval and improvements in decalcification, the number of antibodies that can be used on bone marrow trephine biopsies has grown dramatically from a few in the early 1990s to more than 100 today. The staining procedures and detection systems are similar to those already described for other formalin-fixed, paraffin-embedded tissue sections. The vast majority of antibodies used on lymph node biopsies can also be applied to bone marrow biopsies. Each IHC test that will be used on bone marrows should be specifically validated for that specimen type, with changes to optimize the protocol if necessary, prior to using it for clinical testing.

ANTIGENS OF HEMATOPATHOLOGIC INTEREST

The complexity of hematopathologic neoplasms parallels the complexity of the hematopoietic and immune cells from which they derive, and accurate diagnosis frequently requires the assessment of multiple diverse phenotypic markers. Commonly targeted markers include those related to cell lineage, degree of cellular differentiation, cell function, altered gene products associated with lymphomagenesis, and proliferative activity. The sum of this information allows the hematopathologist to categorize diseases in

phenotypic groups that correspond to clinically relevant diagnostic entities. In addition to the characterization of lesional tumor cells, analysis of the microenvironment, which plays an important role during the development and differentiation of hematopoietic and immune cells, can provide diagnostic or prognostic information.

Immunohistochemical Characterization of Lymphoid Malignancies

The use of cell lineage and differentiation markers to assist in making a diagnosis is best illustrated with lymphomas; it has been predicated in large numbers of studies that have validated the concept that the various lymphoma subtypes arise from or at least appear to reflect different stages of normal lymphocyte development. Coordinated and unique programs of gene expression occur during both B-cell and T-cell differentiation, producing unique combinations of stage-specific protein expression that can be exploited by immunologic techniques, including IHC, to characterize these cell populations; these combinations can also be used to assist in the diagnosis of corresponding lymphomas.

In any given case, the panel of targets assessed by IHC should be based on the differential diagnosis formulated after a review of the section stained with hematoxylin and eosin. Successive panels should be ordered in a stepwise fashion to further refine the diagnosis based on initial results. Although this approach may delay the final diagnosis by 1 or 2 days, the process is cost-effective and efficient while still retaining adequate tissue for possible genetic studies (such as clonality studies and next-generation sequencing [NGS] [*MYD88, TP53* mutations] for lymphoplasmacytic lymphoma

or mantle cell lymphoma [MCL], in which this is mandatory in the frontline setting). One should never order an IHC stain without an understanding of how the result will be used or how it will affect the diagnostic decision process. **Table 3-1** outlines some recommended panels for lymph node diagnosis based on common diagnostic questions. The immunophenotypic characteristics of each of the entities are discussed in subsequent chapters; therefore, extensive discussion of the immunoprofiles of individual diseases is deferred.

For many hematopoietic tumors, tumor-associated oncogene products provide unique and sometimes specific targets for IHC interrogation, although their expression may not have diagnostic value; one such gene is *TP53*. *TP53* mutations or deletions have been described in numerous subtypes of mature B-cell and T-cell lymphomas, and they are usually considered a secondary event associated with a more aggressive clinical course. Especially in low-grade lymphomas such as chronic lymphocytic leukemia (CLL) and MCL, there is a critical need to assess *TP53* alterations either via fluorescence in situ hybridization (FISH) or NGS prior to therapy with Bruton's tyrosine kinase (BTK) inhibitors. Deletion of one allele of *TP53* is often associated with mutation in the other allele, resulting in strong P53 detectable by immuhistochemistry.[28,29] The exact thresholds of p53 immunopositivity that correlate with any underlying mutations (often missense mutations) vary across each lymphoma, and one must be aware of this before using binary cutoffs for p53 IHC.

Historically, one of the first examples of a tumor-associated oncogene product that proved useful in hematopathologic diagnosis was BCL2. BCL2 was discovered as a result of its involvement in the

follicular lymphoma–associated t(14;18)(q32;q21) translocation, which juxtaposes the *BCL2* gene to the immunoglobulin heavy-chain locus, resulting in its overexpression.[30] BCL2 resides primarily on the mitochondrial membrane and is the prototypic member of a large family of apoptosis-related proteins.[31] Reactive germinal-center B cells do not express BCL2; therefore, detection of this protein is useful for distinguishing reactive from neoplastic follicles. Certain B-cell lymphomas may harbor mutations in the *BCL2* gene in regions encoding the portions of the protein recognized by the common clone 124. Such cases should be tested using an alternative BCL2 clone such as E17 or SP66 before determining BCL2 IHC to be negative.[32]

Overexpression of cyclin D1 as a result of the t(11;14)(q13;q34) translocation is the hallmark of MCL, involving the immunoglobulin heavy-chain locus and the *CCND1* locus located on 11q13.[33] Most MCL expresses strong cyclin D1 consequent to the translocation, allowing distinction from CLL and marginal zone lymphoma.[34] Cyclin D1 expression can also be detected in multiple myeloma carrying the t(11;14) translocation. Expression is also seen in hairy cell leukemia and Langerhans cell histiocytosis,[35] unrelated to a specific *IGH* translocation but rather consequent to upregulated mitogen-activated protein (MAP) kinase signaling. In addition to cyclin D1, antibodies to LEF1 and SOX11 have been developed and help support diagnoses of CLL and MCL, respectively, in the setting of atypical CD5-positive small to medium B-cell lymphoproliferations.[36]

B-cell lymphomas that have *MYC* gene rearrangements will almost invariably show strong MYC protein expression by IHC.[37] However,

the identification of high-level MYC protein expression does not necessarily reflect an *MYC* rearrangement in all B-cell lymphomas, and it typically does not correlate with an *MYC* translocation in T-cell lymphomas.[38] Programmed death receptor-ligand 1 (PD-L1) amplifications are frequent in classic Hodgkin lymphoma and primary mediastinal large B-cell lymphoma, resulting in overexpression of PD-L1, although immunostaining for PD-L1 is not critical for diagnosis or prognosis in these settings.[39,40]

In contrast to the majority of translocations in B-cell lymphomas, the anaplastic large cell lymphoma (ALCL)–associated translocation involving the anaplastic lymphoma kinase *(ALK)* gene located on 2p23 results in a fusion protein with a variety of partner genes on different chromosomes.[41] The ALK protein is normally expressed only in the brain, so it is a highly specific target for diagnostic application. The most frequent translocation involves the *ALK* gene and the nucleophosmin *(NPM1)* gene encoding for a nucleolar phosphoprotein with a chaperone function. This leads to a fusion protein that contains the amino-terminal portion of *NPM1* fused to the intracytoplasmic portion, including the catalytic domain of the ALK protein. As a result of the t(2;5)(p23;q35) translocation, the ALK protein is expressed in the nucleus and cytoplasm of the malignant ALCL T cells and can be detected by monoclonal antibodies.[42] In cases with variant translocations, the staining pattern of ALK can be cytoplasmic or membranous; the latter staining pattern is usually associated with the t(2;X)(p23;q11-12) translocation involving the moesin *(MSN)* gene. The expression of ALK can also be detected in rare cases of diffuse large B-cell lymphoma with immunoblastic or plasmablastic features, but these

cases usually show a granular cytoplasmic staining, lack CD30, express B-cell markers, and may be IgA positive. In addition, some non-hematopoietic neoplasms such as rhabdomyosarcomas, inflammatory myofibroblastic tumors, and a small subset of lung adenocarcinomas express ALK, but they are easily distinguished morphologically and immunophenotypically from ALCL. Expression of ALK is also prognostically relevant, as ALK-positive ALCLs have vastly superior outcomes with front cyclophosphamide, hydroxydaunorubicin, vincristine, and prednisone (CHOP)-based regimens compared with ALK-negative ALCLs.[43]

Evaluation of the proliferative rate of the lymphoid populations is also diagnostically useful in many settings. Among the proliferation markers, Ki-67 is by far the most widely targeted antigen in pathology. Although the original Ki-67 antibodies were not immunoreactive in formalin-fixed, paraffin-embedded tissue sections, other investigators were successful in generating the now widely used Ki-67 MIB-1 antibody clone. MIB-1 staining can assist in the distinction between follicular hyperplasia and follicular lymphoma; in the former, the reactive germinal centers have a higher proliferative rate with orderly polarization compared with low-grade follicular lymphomas.

Within a particular subtype of lymphoma, an increased number of actively proliferating tumor cells is usually associated with a more aggressive clinical course, although the prognostic significance of Ki-67 staining is not always consistent among studies. There are numerous possible explanations for the lack of concordance among studies, including technical variations and differences in scoring criteria and cutoff values.[44-46] MIB-1 staining is particularly

sensitive to preanalytic factors related to fixation, decalcification (especially in bone marrow biopsies) and the type of antigen-retrieval procedure used. The poor reproducibility in diffuse large B-cell lymphoma is particularly evident in multicenter studies, where interlaboratory variations play a greater role, whereas the Ki-67 index tends to maintain its significance in defining high-risk groups in series published from single institutions.[45] Furthermore, when Ki-67 immunostaining was assessed in the context of the "proliferation signatures" generated by gene-expression studies in MCL, transformed follicular lymphoma, and nodal peripheral T-cell lymphoma, it has generally shown excellent correlation.[47-49] Along these lines, Ki-67 proliferation used in the MCL International Prognostic Index indicates three risk groups based on cut-off points of <10%, 10% to 30%, and >30%.[50]

Immunohistochemical Characterization of Myeloid Leukemias, Myelodysplastic Disorders, and Other Myeloproliferative Diseases

In the diagnosis of acute leukemias, immunophenotyping of bone marrow trephine biopsies is usually complementary to flow cytometry, which uses large panels to characterize the neoplastic populations, identify their lineages, and detect aberrant antigenic expression patterns that can be used in diagnosis and to monitor residual or recurrent disease (see **Table 3-2** for a list of useful panels). The role of IHC in most immature myeloid and lymphoid neoplasms is valuable in two scenarios: (1) testing antigens not widely examined by flow cytometry (such as mutant NPM1, p53 IHC) or (2) to quantitate disease burden in hemodilute marrow aspirate

samples consequent to fibrosis (such as CD34 in fibrotic myeloid neoplasms, CD138 kappa/lambda in myeloma). Another situation arises in patients treated with targeted agents such as anti-CD19 (blinatumomab), anti-CD22 (inotuzumab), and anti-CD38 (daratumumab), when flow antibodies targeting these antigens are unable to detect surface expression of these antigens, thereby necessitating alternate immunostains (CD138, CD79a, kappa, lambda) for detection of minimal disease.

Table 3-2

Recommended Panels for Bone Marrow Immunohistochemistry

Panel	Antibodies
Acute leukemias	CD34, CD117, TdT, CD3, CD19, CD20, CD10, MPO, CD33, CD61 (or CD42b), hemoglobin A, glycophorin A or C, PAX5; also CD123, NPM1, CD68, lysozyme, P53
MDS/MPN	CD34, CD117, CD61, MPO, CD33, mast cell tryptase, hemoglobin A
Plasma cell disorders	CD138, kappa, lambda, CD56, CD20, cyclin D1
Histiocytic (macrophage or dendritic) neoplasms	CD4, CD11c, CD14, CD68, CD163, S100, OCT2, CD1a, CD207 (langerin), lysozyme, BRAF V600E, cyclin D1
Mastocytosis	Mast cell tryptase, CD117, CD25, CD2; also CD34, CD3, CD20

MDS/MPN, Myelodysplastic syndrome/myeloproliferative neoplasms.

The identification of blasts is critical in the characterization of all potential leukemias and myelodysplastic/myeloproliferative disorders, and this is easily achieved with antibodies against CD34

and CD117. However, it should be noted that, in about 25% of cases of acute myeloid leukemia (AML), the blasts do not express CD34. The addition of myeloperoxidase (MPO), glycophorin A or C, hemoglobin, and CD61 is helpful for assessing the distribution and number of different cell types and to identify morphologically abnormal forms such as micromegakaryocytes.

A panel including CD34, TdT, MPO, CD33, CD68 (KP-1 and PGM-1), glycophorin A, CD61, CD20, CD79a, PAX5, CD3, and CD1a is useful to distinguish AML from lymphoblastic leukemia. In cases with monocytic differentiation, additional markers include CD11c, CD14, CD64, CD4, CD163, and lysozyme. In AML, immunophenotyping can be used to identify specific subgroups. Typically, AML with the t(8;21)(q22;q22) translocation is characterized by expression of CD34, CD13, CD33, MPO, and human leukocyte antigen (HLA)-DR and often aberrantly co-expresses CD56 and the B-cell markers PAX5, CD79a, and CD19, whereas AML with the t(15;17)(q22;q12) translocation typically expresses myeloid antigens, MPO, CD13, and CD33; lacks expression of HLA-DR; shows negative to weak CD34; and may aberrantly coexpress CD2, particularly in the microgranular variant.[51] Aberrant co-expression of CD2 can also frequently be seen in AML with the inv(16) or t(16;16) translocation and thus is not specific to a particular AML subtype. Immunostains for p53 and mutated NPM1 are becoming relevant as reliable surrogates of entities with underlying mutations in the respective genes, *TP53* and *NPM1*.[52,53]

Immunohistochemical Characterization of Histiocytic, Dendritic, Mast Cell, and Other Tumor Cell Types

The neoplastic cells of histiocytic sarcoma may express macrophage or dendritic cell antigens such as CD68, CD163, CD11c, CD14, lysozyme, CD4 and PU.1.[54,55] As many of these markers are not lineage specific, expression of at least two markers is recommended to confirm a histiocytic phenotype. Several markers are useful in the differential diagnosis of Langerhans cell proliferations (CD1a, CD207 [langerin], BRAF-V600E, and cyclin D1)[35] and follicular dendritic cell sarcoma (CD21, CD35, CXCL13, clusterin).[56]

All mast cell proliferations can be identified by IHC with an antibody against mast cell tryptase (also effective on bone marrow specimens), irrespective of their degree of maturation.[57] However, CD117 on bone marrow biopsies is particularly useful to identify early erythroid precursors, promyelocytes, and mast cells (which stain rather strongly). Most cases of systemic mastocytosis can be picked up using an initial CD117, but additional CD25 helps confirm neoplastic phenotype in mast cells.

The tumor cells of the blastic plasmacytoid dendritic cell neoplasm express CD4, CD43, and CD56 in addition to CD123 and TCL-1/TCF4.[58]

BEYOND DIAGNOSTICS: THE EVOLVING ROLE OF IMMUNOHISTOCHEMISTRY

Until recently, IHC had primarily been a tool for pathologists to assist in the differential diagnosis of specific disease entities. However, the role of IHC has been evolving and its application is becoming much broader. The information the IHC laboratory provides now extends well beyond diagnostics, contributing

prognostic and predictive information and informing therapeutic decision-making. These newer roles of IHC have been created by rapid advances in three areas: (1) progress in our understanding of molecular mechanisms that underlie tumor cell biology, including host tumor interactions, (2) identification of cancer-associated mutations in critical genes involved in cell growth, and (3) rapid development of targeted cancer therapies. We now know many of the genes implicated in the majority of human cancers and the precise molecular aberrations affecting those genes. We have a much better understanding of the intricate molecular mechanisms used by tumors to evade the immune response. This increase in our understanding of cancer biology has provided a foundation for the rapid development of targeted cancer therapies. Precise identification of the specific cellular lesions is required in each instance for selection of the correct drug. IHC has a major role in meeting this requirement, whether it is identifying a mutated oncogene, a cell surface molecular target for a therapeutic antibody or cytotoxic T cell, or a critical molecule involved in suppression of immune responses.

Rituximab (anti-CD20) was the first widely applied antibody-directed targeted therapy used for lymphoma. Although hematopathologists initially used anti-CD20 antibodies as a diagnostic tool to identify B-cell lymphomas, verification of CD20 expression soon became a requirement for treatment with the therapeutic antibody. Today, multiple cell surface antigens have been targeted by antibodies in B-cell and T-cell neoplasias, with varying degrees of success, including CD20, CD22, CD19, CD138, CD2, CD3, CD4, CD52, CD25, CD30, and CD194 (CCR4).[59-61] In some cases, the

therapeutic antibodies are “naked” or unconjugated (e.g., rituximab), but in other cases, the antibodies may be structurally modified to activate effector functions (e.g., anti-CCR4) or conjugated to a radiochemical or toxin (e.g., antibodies to CD22, CD25, and CD30) to elicit target-cell killing. In addition to the cell-lineage–specific or B-cell/T-cell–restricted antigens, antibodies to markers such as CD123[62] and CD30 have been developed and are currently in clinical trials. Trials with toxin-conjugated antibodies to CD30 (brentuximab vedotin) in both Hodgkin lymphoma and T-cell neoplasms such as ALCL and ATL have shown promising results.[63,64]

Similarly, genetically engineered T-cell transfer immunotherapy using chimeric antigen receptor (CAR) is becoming more common, and protocols targeting CD19 and CD22 have been developed for the treatment of B-cell neoplasms expressing these antigens.[65] In particular, data from CD19 CAR T-cell trials in B-cell acute lymphoblastic leukemia (B-ALL) and CLL have been encouraging.[66] Similar trials targeting the plasma cell antigen B-cell maturation antigen (BCMA) have shown promising results thus far in multiple myeloma and other plasma cell neoplasms.[67] As serum BCMA is easily measured prior to trial enrollment, immunostaining for BCMA has not gained traction.

New research into the immune checkpoints (ICs) that control the reactivity of cytotoxic T cells against self-antigens coupled with the concurrent development of therapeutic antibodies that interfere with these IC proteins has provided pathologists with a completely different set of antigenic targets to evaluate. Programmed death receptor-1 (PD-1) and its ligand (PD-L1) are two checkpoint proteins that have gained attention.[68] Especially for PD-L1, several antibody

clones have been developed and received U.S. Food and Drug Administration approval as companion diagnostic tests. Testing for PD-L1 via IHC and quantitation of tumor and immune cell expression of PD-L1 has been critical for solid tumors, including lung and bladder cancer, where there is a significant linear correlation between expression and response to IC inhibitors. In the realm of hematopathology, many B-cell lymphomas have been shown to harbor PD-L1 alterations, including classic Hodgkin lymphoma and primary mediastinal large B-cell lymphoma. Pembrolizumab and nivolumab are two widely used IC inhibitors that have shown promising results for relapse and even as front-line treatment.[69] Testing for PD-L1 via IHC is not critical to determine eligibility for IC inhibitor therapy in most lymphomas. However, data indicates that PD-L1 addicted non-germinal center diffuse large B-cell lymphoma (DLBCL) (detected via IHC) may benefit from adding IC inhibitors to an R-CHOP backbone.[70]

Knowledge of the molecular pathways and genetic lesions responsible for tumor cell growth provides investigators and oncologists with yet a different set of signaling pathways and proteins to inhibit, and for pathologists, another set of targets to evaluate. There are clinically useful antibodies that are commercially available and capable of identifying mutations in several genes (*BRAF* V600E is a notable one). *BRAF* V600E mutations occur in nearly all cases of hairy cell leukemia and in over 50% of cases of Langerhans cell histiocytosis and Erdheim-Chester disease. The IHC laboratory can play a critical role in identifying the presence of this mutation. The BRAF inhibitor, vemurafenib, has shown durable response in Langerhans cell histiocytosis, Erdheim-Chester disease,

and hairy cell leukemia.[71,72] Antibodies to *IDH1* R132H are also available and can be used to identify cases of AML known to carry this mutation.[73] Newer antibodies to less common IDH1 variants and to *IDH2* R172 mutations, common in both AML and in angioimmunoblastic T-cell lymphoma (AITL), have already been reported in the literature (**Fig. 3-2**).[74] Other common mutations that are potentially amenable to IHC targeting include the *JAK2* V617F mutation, which is common in a variety of myeloproliferative diseases, and the *MYD88* L265P mutation, which is characteristic of lymphoplasmacytic lymphoma (LPL) and a fraction of marginal zone lymphomas and the activated B-cell subtype of DLBCL.

IN SITU HYBRIDIZATION

Although this chapter's focus is IHC, a few words regarding the role of in situ hybridization (ISH) in hematopathology are warranted. These technologies have similarities in that they both interrogate targets in situ—that is, on frozen or paraffin-embedded tissue sections—and they have similar detection systems. The type of target and the chemistry of its identification are the major differences. ISH is a simple and sensitive technique that permits direct assessment of DNA or RNA targets within tissue sections (both frozen and formalin-fixed), single-cell suspensions, and cytogenetic preparations, whereas IHC targets proteins.

The application of ISH in hematopathology is particularly useful when antibodies are not available, have limited sensitivity, or are associated with high background staining (e.g., kappa and lambda light chain immunostains).[75] It may also be indicated when proteins are rapidly secreted and are not stored within cells or when nucleic

acids are more abundant than proteins. The major technical limitations are related to the abundance and preservation of target sequences within cells; thus, preanalytic factors such as fixation and tissue processing can have a significant effect on target-sequence detection by ISH.

Similar to IHC, a primary incubation is performed, substituting DNA or RNA probes instead of a primary antibody. Reactivity (hybridization) is based on complementarity between the sequence of interest and the designed probe, rather than on antigen-antibody recognition. Detection of the annealed products was originally based on the use of radiolabeled probes, which were visualized by slide emulsion autoradiography. Currently, especially in the clinical setting, radioisotopes have been replaced by nonisotopic detection methods. In chromogen-based ISH (CISH), a biotin-labeled or digoxigenin-labeled probe is detected with a secondary antibody and a chromogenic detection system similar to that in IHC. In FISH techniques, signals are detected with a fluorophore-labeled probe in a darkfield setting. These methods offer significant advantages over radioisotope-based ISH, including improved probe stability without waste-disposal issues (other than DAB), shortened assay time, excellent sensitivity, superior tissue preservation, and more accurate subcellular localization.

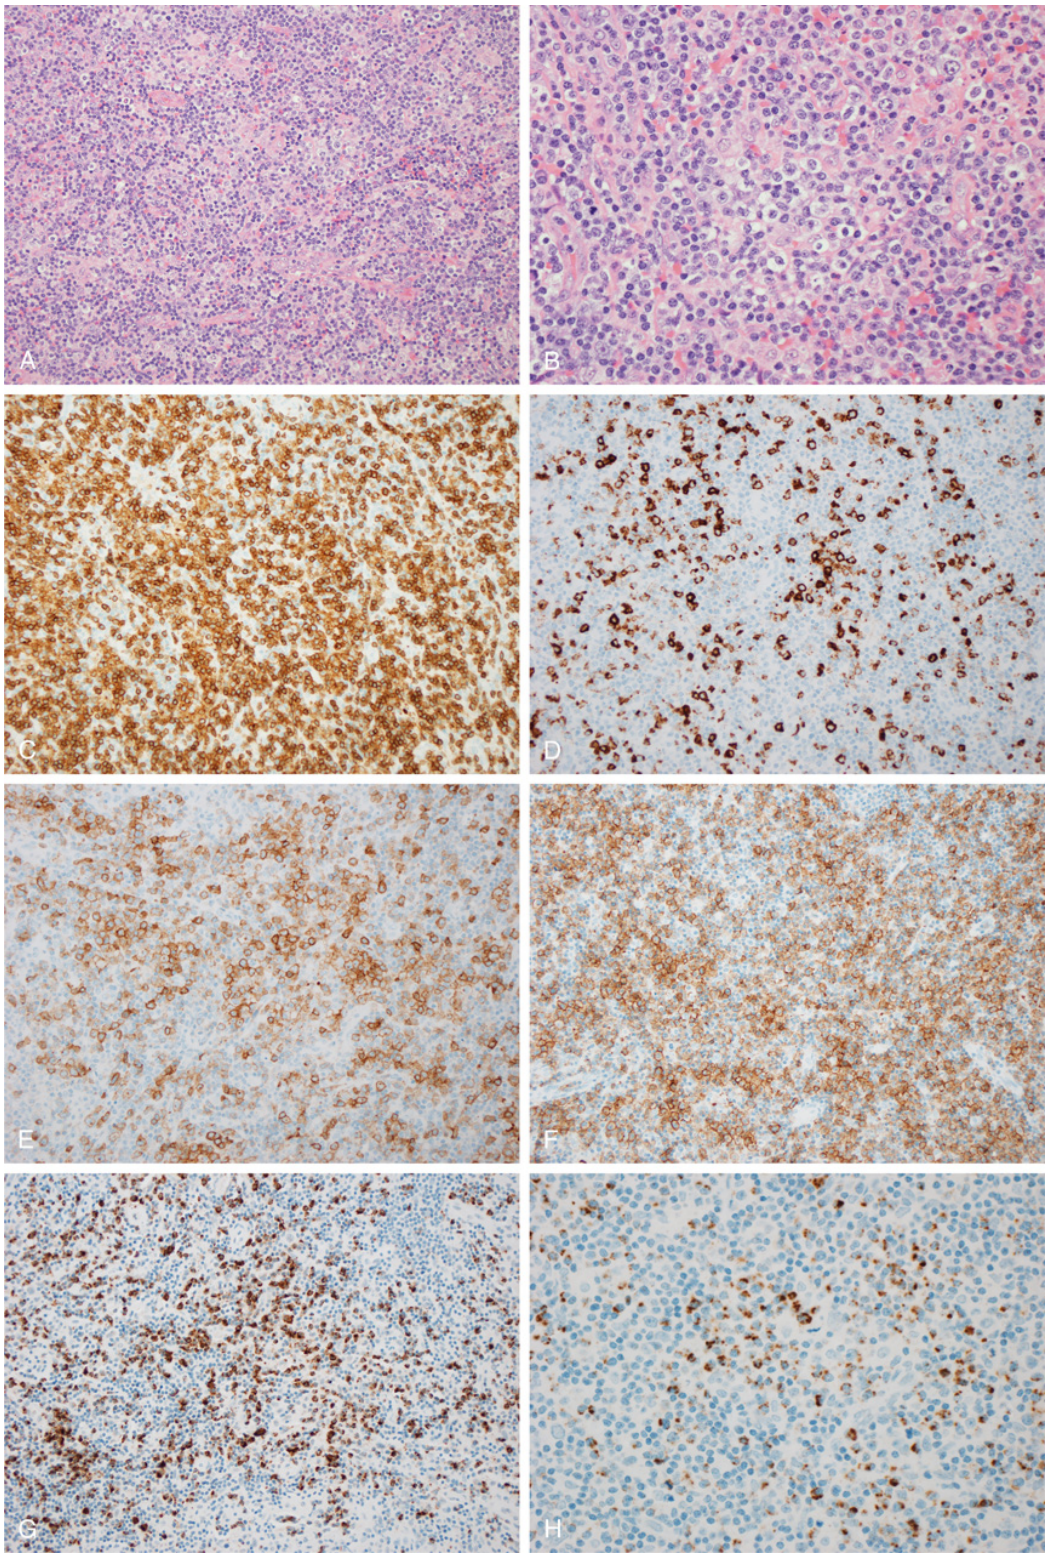

FIGURE 3-2 Immunostains in T-follicular helper (TFH)-cell neoplasm.**A and B,** Low-

power and medium-power images depicting angioimmunoblastic T-cell lymphoma with a polymorphic population of small-sized to medium-sized lymphoid cells. **C,** These lymphoma cells are positive for CD3 and express TFH markers, including **D,** CD10 (abnormal and bright); **E,** programmed death receptor-1 (PD-1); **F,** ICOS; and **G,** CXCL13. Although not shown, there is focal expression of BCL6, which also supports TFH designation. Most nodal TFH lymphomas harbor mutations related to the DNA methylation pathway *(DNMT3A, TET2)* in addition to *RHOA* and, frequently, *IDH2*. **H,** The cells are immunopositive for antibody specific to mutant *IDH2* R172K.

The primary CISH assay used by hematopathologists is for the detection of kappa and lambda immunoglobulin light chains as an assessment of B-cell clonality. Indications for its use are limited to situations in which IHC is not feasible, such as when there is high background in the IHC stain owing to the presence of high levels of interstitial immunoglobulins from serum or when there is high expression of immunoglobulin light chain proteins, such as in some plasma cell dyscrasias or B-cell neoplasms showing plasmacytic differentiation. The applicability of CISH for kappa and lambda detection extends to bone marrow sections. ISH in some settings is preferable to kappa or lambda IHC because the problem of background staining from serum immunoglobulins is eliminated. However, sensitivity with current probes is not necessarily increased.

Use of optimized antigen-retrieval techniques can reduce the high background staining seen in light chain IHC and can permit identification of light chain restriction in up to 80% of B-cell lymphomas.[76]

CISH is also widely used for the detection of infectious agents, particularly viruses, within cells or tissues. One of the most common clinical CISH tests is the detection of Epstein-Barr virus (EBV) in infected cells. In this test, the targets are EBV-encoded RNAs (EBERs), which are short nuclear transcripts that are present early in latent infection and in high copy number (approximately 10 copies/cell). Because of these characteristics and their minimal homology to cellular RNA, EBERs are an excellent target for the detection of EBV-infected cells by ISH on formalin-fixed, paraffin-embedded tissue sections and are preferable to the commonly used IHC target, latent membrane protein (LMP). From an interpretive perspective, pathologists must always make sure that intact RNA is detectable in the tissue of interest using the polyuridine probe against the poly A tail of mRNA ("RNA control").

APPROACH TO USING IMMUNOHISTOCHEMISTRY

There is wide variation in the use of IHC in the context of hematopoietic neoplasms. In general, for leukemic processes where the majority of phenotyping is performed via flow cytometry, additional immunostains performed on the core biopsy should only reflect markers not performed by flow cytometric analysis (NPM1, P53, etc.). In the context of lymphomas, beyond flow cytometry, c-Myc, Bcl-2, Ki-67, cyclin D1, and CD30 are useful in the context of B-

cell lymphomas. However, additional immunostains may be required in the case of nodal T-cell lymphomas, especially with small cell cytomorphology, as flow cytometry may not pick abnormal T-cell populations that could easily be missed. Multiple iterative rounds of immunostains based on diagnostic possibilities in sync with the clinical picture is the most ideal approach toward using immunostains. Familiarity with patterns of staining with specific markers (**Fig. 3-3**) and awareness of the pitfalls (**Fig. 3-4**) are both critical for effective use of IHC in diagnostic hematopathology. **Table 3-3** lists top-level, high-yield immunostain panels (of up to eight markers per scenario) targeting differential diagnostic possibilities in three different scenarios (elderly pancytopenia, blastic processes, and recurrent reactive adenopathy) commonly encountered by most practicing hematopathologists.

Pearls and Pitfalls

- Always use coated or charged slides and bake the slides for 1 or preferably 2 hours at 60° C to enhance tissue adhesion.
- Cut paraffin tissue sections may lose their antigenicity over time. Unstained slides expire after 3 months.
- Once the primary antibody is applied, do not allow the section to dry, or non-specific staining will occur.
- Inconsistent results are most frequently caused by poor control over preanalytic parameters, especially the antigen-retrieval step.

- Antigen-retrieval conditions vary depending on the target antigen. Nuclear antigens often benefit from high pH retrieval, though membrane antigens are better with low pH (pH 6) protocols.
- Overdigestion or excess HIER may result in non-specific staining or unacceptable morphology.
- Positive and negative controls should be run with all test cases, but, for some lymphoid specimens, the tissue itself may serve as an internal control owing to the presence of normal hematolymphoid elements.
- Positive control tissues should express low levels of the target antigen so that immunoreactivity can be appropriately assessed to ensure optimal sensitivity.
- Controls should be handled in the same preanalytic manner as patient samples in terms of fixation and processing.
- Avoid interpreting interstitial staining as membranous. This frequently happens with IgG, kappa, and lambda immunostains (see **Table 3-4** for additional technical and interpretive points on some antibodies).
- The absence of staining may be real, whereas diffuse staining of all tissue elements is likely to be an artifact.

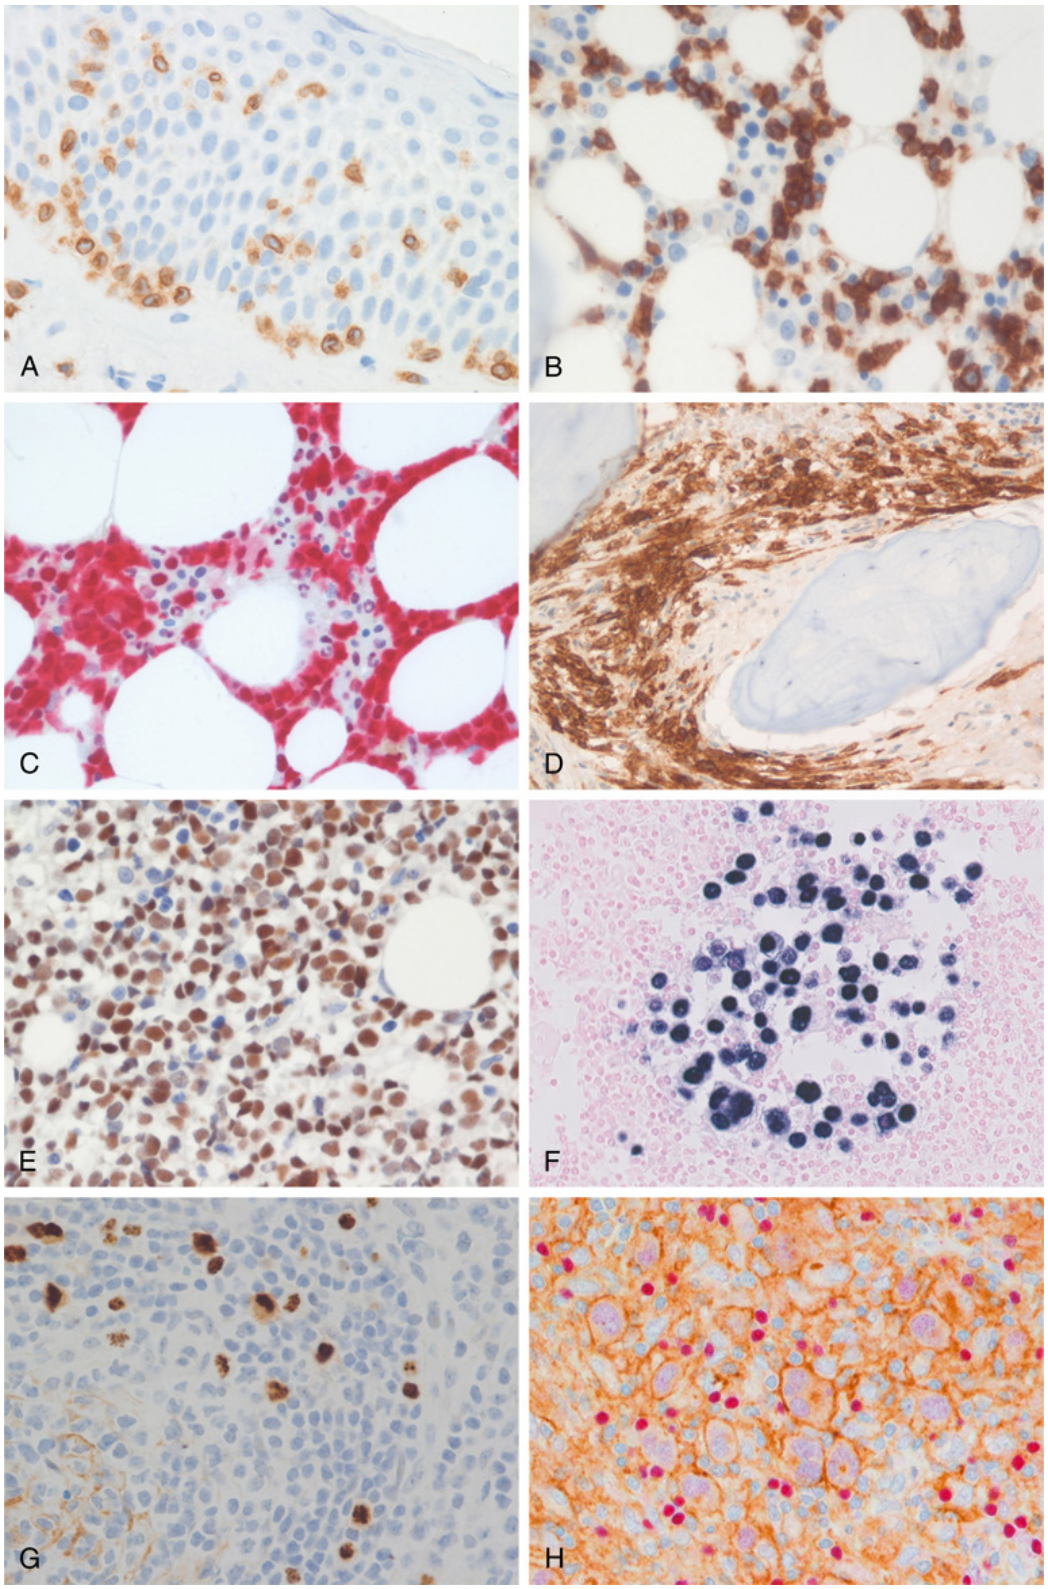

FIGURE 3-3 Staining patterns useful in immunochemistry diagnosis.**A,** CD3

immunohistochemistry decorating abnormal CD3-positive T cells in a “string of pearls” pattern in a skin biopsy with mycosis fungoides. Oftentimes, these abnormal cells are scarce and visible only on immunohistochemistry; hence, a high degree of clinical suspicion is necessary. **B,** Sinusoidal CD8-positive T-cell infiltrate in a patient with T-cell large granular lymphocytic leukemia. These infiltrates are often not visible on the hematoxylin and eosin slide, so CD3 and CD8 immunostains are useful in patients with pancytopenia. **C,** Mutant NPM1-specific immunohistochemistry in a patient with *NPM1* exon 12 mutation showing abnormal cytoplasmic staining of blastic cells. Scattered cells with wild-type isolated nuclear staining are seen in the center of the biopsy. **D,** CD117-positive paratrabecular clusters of spindly mast cells in systemic mastocytosis. CD25 is additionally useful to corroborate neoplastic phenotype in mast cells. **E,** Strong p53 expression in a patient with hypodiploid precursor B-cell acute lymphoblastic leukemia with Li-Fraumeni syndrome. Strong expression usually correlates with underlying missense mutations. **F,** Epstein-Barr virus in situ hybridization (EBER) expression in neoplastic germinal center B cells in a patient with germinotropic lymphoproliferative

disorder. **G,** Scattered single HHV8-positive plasmablasts within the mantle zones of a secondary lymphoid follicle with regression in a patient with HIV-related HHV8-positive multicentric Castleman disease. The cells additionally expressed IgM with monotypic lambda light chain. **H,** Double immunostain for programmed death receptor-ligand 1 (PD-L1) *(brown)*/PAX5 *(red)* in a patient with classic Hodgkin lymphoma. The Hodgkin cells express weak PAX5 with membranous expression of PD-L1 while the surrounding normal small B cells express strong PAX5 without membranous staining for PD-L1.

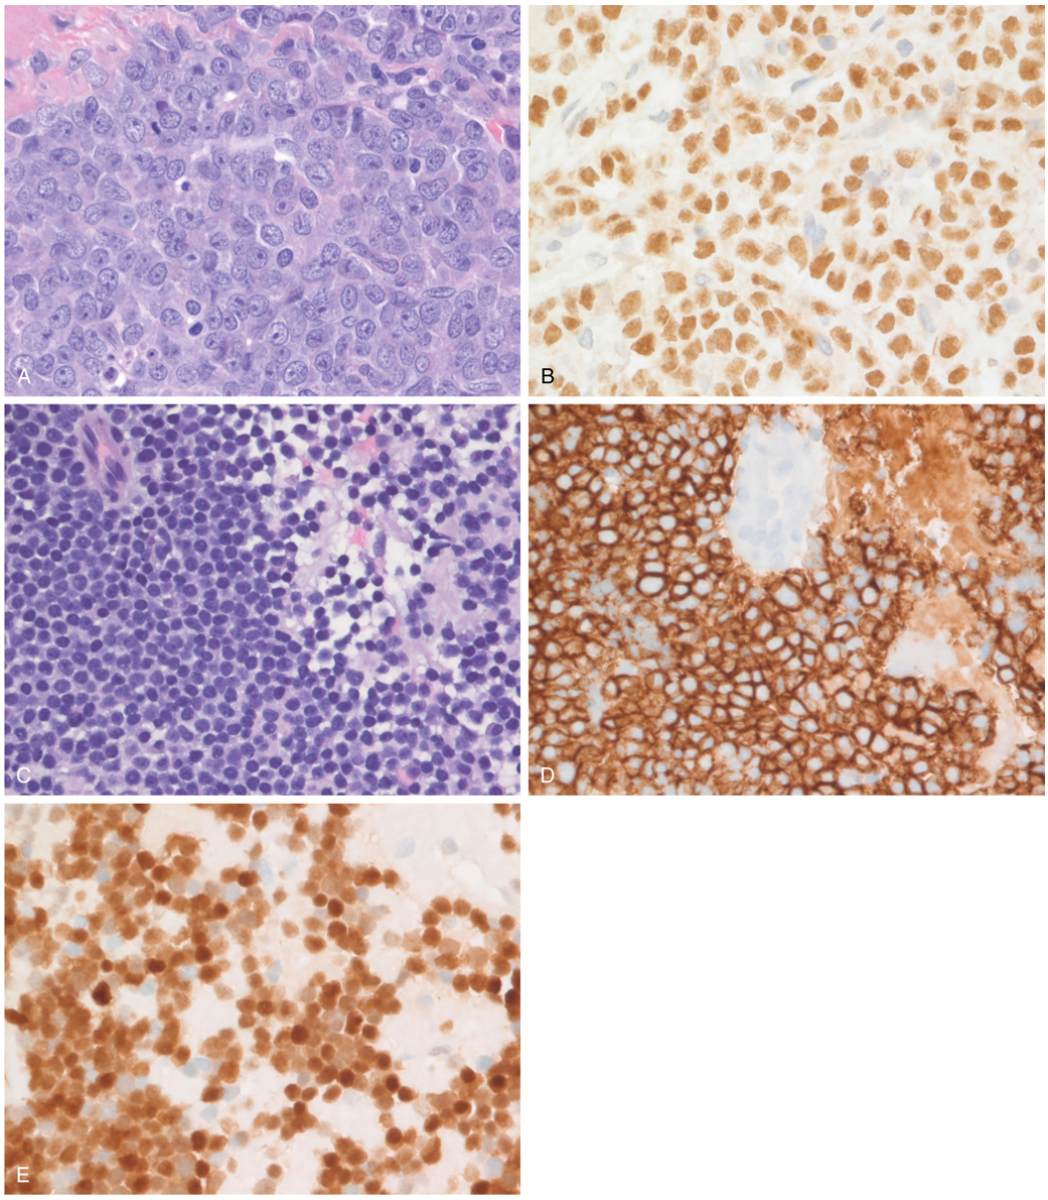

FIGURE 3-4 Pitfalls in immunohistochemistry.**A,** Medium-sized to large-sized monomorphic infiltrate of blastic cells in extramedullary soft tissue mass. **B,** The cells in this case express uniform PAX5, giving the impression of B lymphoblastic leukemia. However, there was underlying *RUNX1-RUNX1T1* fusion with expression of myeloid

markers, confirming the diagnosis of acute myeloid leukemia (AML) with t(8;21). Rarely, these tumors may also express weak CD19; one must be careful not to make a diagnosis of mixed phenotype acute leukemia, B/myeloid. **C-E,** Second case with extramedullary involvement by sheets of medium-sized lymphoid cells **(C)**. The cells are strongly positive for CD20 (not shown) based on strong staining for cyclin D1 **(E)**. This was initially thought to be mantle cell lymphoma, but additional CD138 expression **(D)** was strongly positive with expression of CD56, warranting reclassification as myeloma expressing cyclin D1. Often, myeloma expressing cyclin D1 is known to express CD20 in addition to PAX5 with frequent lymphocyte-like cytomorphology, posing diagnostic confusion.

Table 3-3

Common Clinical and Morphologic Scenarios, Respective Top Differentials, and Pertinent First Round of Immunostains

Presenting Features	Differential	Key Top-Level Stains
Elderly pancytopenia (BM)	MDS	CD34, P53
	HCL/SMZL/THRBCL	CD20
	T-negative LGL leukemia	CD3
	HLH	CD30 (ALCL), EBER
Adenopathy (reactive)	EBV reactivation	EBER
	CMV infection	CMV
	IgG4-related adenopathy	IgG4
Blastoid infiltrate	AML	CD33, CD34, NPM1
	ALL (B-cell and T-cell)	CD3, PAX5, TdT
	BPDCN	CD123

Presenting Features	Differential	Key Top-Level Stains
	Plasmablastic lymphoma	MUM1, CD138
	Blastoid lymphoma (MCL, Burkitt)	CD20, Cyclin D1, MYC (>80%)

ALCL, Anaplastic large cell lymphoma; *ALL,* acute lymphoblastic leukemia/lymphoma; *BPDCN,* blastic plasmacytoid dendritic cell neoplasm; *EBV,* Epstein-Barr virus; *HCL,* hairy cell leukemia; *HLH,* hemophagocytic lymphohistiocytosis; *LGL,* large granular lymphocytic; *MCL,* mantle cell lymphoma; *MDS,* myelodysplastic syndrome; *SMZL,* splenic marginal zone lymphoma; *THRBCL,* T-cell/histiocyte-rich large B-cell lymphoma.

Table 3-4

Specific Technical and Interpretive Pearls With Respect to Common Antibodies and Antibody Combinations in Hematopathology

Antibody	Pearls/Pitfalls to Remember
CD20	About the only B-cell marker that works well, even on necrotic tissues.
OCT2	Useful for nodular lymphocyte predominant B-cell lymphoma and plasmablastic processes that lose B-cell antigens
CD3	Often aberrantly positive in HHV8-positive B-cell lymphomas
CD45	Not a great marker for hematopoietic neoplasms such as plasmablastic lymphoma and ALCL; often can be negative in these
Cyclin D1	Useful for MCL, cyclin D1-positive myeloma, HCL, and LCH
CD34	Separate protocols may be needed for bone marrow to stain blasts
CD5	Look for biphasic dim staining in CLL and bright staining in T cells
MUM1	Great stain to identify rare classic Hodgkin

Antibody	Pearls/Pitfalls to Remember
	cells after therapy/relapse
IgG4/EBER/CMV	Useful trio for seemingly reactive large nodes in the right setting
EBER ISH	Do not order on very necrotic tissues, as RNA is degraded. IHC for EBV-LMP1 or EBNA2 is useful in this setting.
HHV8	Always check HIV history and order before dismissing as a reactive node

ALCL, Anaplastic large cell lymphoma; *CLL,* chronic lymphocytic leukemia; *EBNA2,* Epstein-Barr virus nuclear antigen 2; *EBV-LMP1,* Epstein-Barr virus latent membrane protein 1; *HCL,* hairy cell leukemia; *IHC,* immunohistochemistry; *LCH,* Langerhans cell histiocytosis; *MCL,* mantle cell lymphoma.

Multiparametric flow cytometry (FCM) is invaluable in the diagnosis and classification of hematolymphoid neoplasms, determining prognosis, and monitoring response to therapy. FCM is especially suited for immunophenotypic analysis of blood, fluids (e.g., cerebrospinal fluid [CSF], pleural fluid), and aspirations of bone marrow and lymphoid tissue. FCM is also ideal in small samples; its multiparametric nature allows the concurrent staining of cells with multiple antibodies complexed to different fluorochromes, thus maximizing data obtained from few cells. FCM can characterize surface, cytoplasmic, or nuclear antigen expression. Furthermore,

FCM can provide highly accurate quantitation of cellular antigens/molecules. With increasing use of antigen-directed targeted therapies such as rituximab, ofatumumab (anti-CD20), epratuzumab, inotuzumab (anti-CD22), gemtuzumab (anti-CD33), and blinatumomab (CD19-directed CD3 T-cell engager) and cellular therapies, including T cells genetically engineered to express chimeric antigen receptors (CAR T cells), the use of FCM is likely to increase. FCM identifies therapeutic targets on the surface of malignant cells, thus informing the potential utility of antibody-targeted therapy in a given patient. Once a diagnosis is established, FCM provides high sensitivity in the detection of minimal/measurable disease (MRD). FCM can detect MRD with a sensitivity of 1 in 10^4 to 10^6, allowing for a precise assessment of disease progression and/or the effect of prior therapy and providing valuable prognostic information.

GENERAL PRINCIPLES

In a flow cytometer, cells rapidly pass single file through a series of finely focused lasers. The cell momentarily breaks the laser beam as it passes, scattering light at a low angle (also called *forward scatter*). This forward scatter/low-angle scatter (FSC) is proportional to the cell volume/size. Laser light is simultaneously scattered at a high/wide-angle (*side scatter* [SSC]) by intracellular and nuclear components. This SSC is proportional to the complexity of a cell, which is determined by the type and amount of cytoplasmic granularity, cytoplasmic membrane irregularities (e.g., villous or “hairy-appearing” projections), and nuclear characteristics. Light scatter characteristics are also useful in restricting analysis to single

cells (e.g., excluding doublets [two adherent cells]). These physical scatter properties accurately identify cell types and are the basis for many commercial hematology analyzers that provide automated differential cell counts.[1]

In addition to FSC and SSC properties, cells are further characterized by staining with multiple fluorescent markers, such as antibodies conjugated to fluorochromes or DNA-binding dyes. An antigen on the cell surface binds to a fluorochrome-conjugated antibody, which emits light at a particular wavelength that is measured by detectors. When used in combination with DNA-binding dyes, the DNA content can also be determined, yielding cell cycle data. Multiple fluorochromes (sometimes referred to as *colors*), each with uniquely identifiable spectral emissions, are simultaneously measured with multiple detectors. Most clinical laboratories use six-color to eight-color FCM, with some using 10 or more colors.[2] Four is generally considered the minimally acceptable number of colors to ensure reliable discrimination of neoplastic cell populations in a broad range of sample types.[3,4]

Traditionally, FCM was used to determine the presence or absence of lineage-specific or lineage-associated antigens; however, immunophenotypic interpretation has evolved from a simplistic "positive" or "negative" approach for a given antigen to an assessment of the degree and pattern of antigen expression. This approach is highly reliable in discriminating cell types and identifies characteristic immunophenotypic features and patterns unique to certain hematolymphoid neoplasms. The antigen expression of many hematolymphoid neoplasms overlap with their normal counterparts, making diagnosis a challenge. The ability of multiparametric FCM to

highlight subtle differences in the patterns of antigen expression (aberrant antigen expression or changes in intensity, for instance) makes it extremely powerful in the diagnosis of neoplasia.

TECHNICAL CONSIDERATIONS

General

Appropriate samples for FCM include blood, bone marrow, lymph node samples, extranodal tissue biopsies, fine-needle aspirates (FNA), and body fluids (e.g., pleural, peritoneal, CSF). International consensus guidelines on medical indications for FCM are available and based on patient history and presenting symptoms.[5]

Timely processing of samples is necessary to maximize cell yield, maintain cell viability and integrity, and prevent loss of abnormal cells of interest (see Stetler-Stevenson et al.[4] for recommendations). Blood and bone marrow specimens must be collected in a tube containing an appropriate anticoagulant, such as sodium heparin or ethylenediaminetetraacetic acid (EDTA). Lysis is the preferred approach for removing excess erythrocytes (see Stetler-Stevenson et al.[4] for recommendations). In patients with an inaspirable marrow or “dry tap” (i.e., a fibrotic marrow or a marrow packed with neoplastic cells), submission of core biopsy material for FCM is appropriate. These cores are disaggregated to release cells into fluid suspension for FCM.[4]

If possible, portions of tissue for FCM should represent an area that is also being submitted for histology to minimize discordance as a result of sampling. Intact portions of solid tissue (such as biopsies of bone marrow, lymph nodes, or other tissue masses) must be made into cell suspensions for FCM. Mechanical tissue disaggregation is a

fairly simple and rapid procedure that leaves cells relatively unaltered. It is achieved by slicing, mincing, and teasing apart the tissue with commercial devices or manual tools.[4] Enzymatic dissociation methods are also described for processing fibrotic tissue; however, they can alter antigen expression and decrease viability.

Antibody-staining protocols differ according to application and specimen type. Successful panel design requires an in-depth understanding of antigen-expression patterns in both normal and neoplastic cells. Antibody panels assess lineage and maturation patterns of normal cellular components and characterization and classification of neoplastic cells. The emission spectra of fluorochromes vary, and antibody-fluorochrome conjugates should be used to maximize detection. For example, antibodies conjugated to bright fluorochromes may improve detection and visualization of dimly expressed antigens, and strongly expressed antigens, such as CD3 on T cells, may be adequately visualized on-scale with fluorochromes of only moderate brightness. Multiple antibodies are required for lineage assignment; many are not cell lineage–specific, and neoplastic cells may lack one or more antigens of a particular lineage. Overall, the number of reagents in a panel should be sufficient to allow the recognition of all abnormal and normal cells in the sample; conversely, limiting the number of antibodies may compromise diagnostic accuracy.[3] In general, higher sensitivity and specificity of detection and characterization is achieved with a larger antibody panel. By international consensus, the number of reagents needed to adequately evaluate a specimen for potential hematologic

neoplasms is dependent on the presenting symptoms.[3,6] In addition, markers of potential prognostic utility should be included.

Viability

Regarding viability, no set cutoff exists that dictates automatic specimen rejection for FCM testing. General guidelines suggest rejecting replaceable specimens (such as peripheral blood, which may be redrawn from the patient) if the viability is less than 75%. A variety of viability dyes and instrumentation are commercially available to determine viability.

An important consideration, though, is that many samples submitted for FCM testing are considered irreplaceable specimens. These are specimens either obtained by an invasive procedure with significant trauma to the patient or obtained from a site that is difficult, if not impossible, from which to recollect. In addition, some peripheral blood specimens obtained at certain timepoints in treatment are unique in that the timing is critical for information regarding clinical management and are irreplaceable. In such cases, every effort should be made to obtain diagnostic information, and the results from FCM testing, even on specimens of decreased viability, may still prove valuable.

To maximize the information obtained from low-viability specimens by FCM, all cells are acquired from the sample and exported into the list mode data file. Any removal of non-specific debris events is performed post-acquisition only to avoid missing potentially useful data. Gating for single cells (doublet discrimination) may be performed by examining the forward scatter-height (FSC-H) (and/or forward scatter-width [FSC-W]) versus the

forward scatter-area (FSC-A) parameters, as doublets exhibit disproportionately large FSC-W and FSC-A relative to FSC-H compared with single cells.

Viability gating based on scatter properties is helpful, as nonviable cells show decreased FSC resulting from loss of integrity of the cell membrane. Examination of CD45 versus FSC and CD45 versus SSC may help account for (and potentially remove by gating) small red blood cells, platelets, and debris from relevant cell populations. It is important to be aware that the nonviable cells may bind antibodies non-specifically, causing artifacts that may interfere with accurate immunophenotyping. Decreased sample viability is also commonly observed in solid-tissue samples and aggressive lymphomas (such as Burkitt lymphoma), where the metabolic rate and cell kinetics are quite high. Nevertheless, a low-viability sample composed of many neoplastic cells can still yield meaningful results. In irreplaceable specimens with decreased viability, any abnormal populations should still be reported, though care should be taken to avoid misinterpretation of non-specific antibody staining of nonviable tissue. In poorly viable specimens in which no abnormal population is identified, it is prudent to include a comment noting suboptimal specimen viability. The results from such a sample should not be viewed as a true negative,[4] as subsequent testing may be informative.

Small Specimens

Diagnosis of hematolymphoid malignancies, and in particular lymphoma, is frequently based on evaluation of small biopsies, FNA, and body fluids (e.g., CSF, vitreous humor, effusions). Small samples can provide sufficient cells for FCM, even when cell numbers are too

low to count using conventional methods. FCM can be more sensitive than morphology, especially when neoplastic cells are admixed with normal counterparts or associated with a brisk inflammatory response, as in extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT)[7] or gastric lymphoma in endoscopic biopsies.[8]

FCM increases the sensitivity of detection of hematolymphoid neoplasia in specimens of limited cellularity such as bronchoalveolar lavage specimens[9] and FNA.[10-12] The immunophenotypic information obtained from FCM assists in both detection and diagnostic subclassification of lymphoma.[10,11,13-15]

Involvement of the CSF by hematopoietic malignancies may be difficult to document by morphology alone. FCM improves the detection sensitivity of non-Hodgkin lymphoma in CSF[16-19] and is vital in the diagnostic evaluation of high-grade lymphomas. In a study assessing FCM in evaluating CSF in patients at risk for central nervous system (CNS) involvement in aggressive B-cell lymphoma, FCM was significantly more sensitive than cytology alone in disease detection and prognostication. Large cell lymphoma is susceptible to increased selective cell loss with red blood cell lysis procedures; therefore, processing CSF without red blood lysis will improve sensitivity of detection in such instances. FCM is also useful in identifying CNS leukemia and increases the detection rate over cytology alone.[19,20] Thus, FCM is crucial in the evaluation of CSF for hematolymphoid malignancies.[18] Studies report a rapid decline in CSF cell numbers within the first 30 minutes of sampling, and immediate stabilization with serum-containing media or

commercially available stabilizers is vital to preserve the specimen until it reaches the FCM laboratory.[19,21]

MATURE B-CELL NEOPLASMS

FCM detection of malignant B-cell populations requires extensive knowledge of normal B-cell antigen expression and light scatter characteristics. Markers of B-cell neoplasia include light chain restriction, abnormally large B cells (as demonstrated by an increase in forward light scatter properties), abnormal levels of antigen expression, absence of normal antigens, and presence of antigens not normally present on mature B cells.

Evaluation of Light Chain Expression

B-cell neoplasms are typically characterized by monotypic light chain expression. It should be noted, however, that monotypic B-cell populations may be seen in patients with no evidence of lymphoma.[22-24] In some cases, this finding may represent early, preclinical detection of a B-cell malignancy[25] or, in rare instances, may be seen in reactive settings.[22]

A monotypic B-cell population is characterized by the expression of a single immunoglobulin (Ig) light chain by a B-cell population,[26] resulting in positive staining with only one light chain reagent (e.g., kappa-positive/lambda-negative population, or vice versa) (**Fig. 4-1**, middle row, kappa-vs.-lambda dot plot showing an example of lambda light chain restriction). In normal/benign lymphoid tissue, individual B cells express a single light chain Ig, and the ratio of kappa-expressing to lambda-expressing B cells is approximately 60% to 40%.[27] Lack of surface Ig among mature B cells or a deviation

from this normal ratio (for example, a predominance of lambda-expressing B cells) should prompt a diligent search for an underlying monotypic B-cell population that may be discriminated by CD19, CD20, CD22, or other antigens.

FCM is advantageous because it can identify monotypic B cells, even in B-cell lymphopenia, by facilitating rapid analysis of large numbers of acquired B cells; it can also detect neoplastic B cells in a background of polyclonal B cells[26,27] by detecting aberrant antigens on the neoplastic cells. Antibody panels can be designed to exploit the expression of disease-characterizing antigens, such as CD5 in mantle cell lymphoma or CD10 in follicular lymphoma.[28] By examining B-cell subsets with differential CD19, CD20, or CD22 expression and/or aberrant antigen expression, a monotypic B-cell population may be discovered.[26,29] **Figure 4-1** shows an example peripheral blood sample involved by chronic lymphocytic leukemia (CLL). Normal B cells with appropriate intensity of CD19, CD20, and CD22 are present *(blue)* and demonstrate a polyclonal pattern of surface light chain Ig. CLL *(orange)* is identified by the aberrant expression of CD5 on the CD19-positive B cells, along with the expression of dim CD20 and dim CD22, dim compared with the intensity of CD20 and CD22 on normal B cells. These features allow the CLL cells to be captured by gating; subsequently, they are shown to be monotypic B cells expressing lambda surface light chain, which is also slightly dimmer in intensity compared with the level of lambda expression of polyclonal B cells within the sample.

Absence of surface Ig may also be a feature of both indolent and aggressive mature B-cell neoplasms,[30,31] but caution is imperative when interpreting the significance of such a population. In bone

marrow aspirates, normal plasma cells and most normal immature B cells (hematogones; benign precursor B cells) also lack surface Ig. In lymph node and lymphoid tissues, reactive germinal-center B cells (GCBs) with dim surface Ig may be mistaken for neoplasm. For this reason, it is important to understand the normal patterns associated with lymph node and lymphoid tissue.

The FCM patterns demonstrated in normal lymph node and lymphoid tissue are consistent and reproducible and reflect the cellular compartments of normal lymph node architecture. CD19 is an excellent marker of B cells; however, the use of CD20 for B-cell characterization in FCM evaluation of lymph node and lymphoid tissues (**Fig. 4-2**) adds the advantage of clearly distinguishing the different morphologically recognized cellular components of the lymph node. Using CD20 expression, lymphocyte populations can be divided into T cells from the paracortical region (T: CD20 negative), mantle zone B cells (MB: moderately CD20 positive) and GCBs (bright CD20 positive) (**Fig. 4-2**, photomicrographs and upper row of dot plots). GCBs are distinguished by higher levels of CD20, higher levels of CD38, CD10 expression, and a slight increase in FSC (larger cell size/volume) compared to MB (**Fig. 4-2**, top and middle rows of dot plots). GCBs also express IgG heavy chain, in contrast to MB, which predominantly express IgD heavy chain, IgM heavy chain, and to a much lesser extent, IgA heavy chain (**Fig. 4-2**, bottom row of dot plots). In GCBs, kappa and lambda surface Ig expression is typically dim, especially compared with the polyclonal pattern of kappa and lambda surface Ig in MB; this dim light chain expression is better appreciated compared with Ig-negative T cells within the sample (**Fig. 4-2**, middle row of dot plots).[32] In follicular

hyperplasia, increased GCBs with dim surface Ig may be so prominent as to be mistaken for a B-cell neoplasm, such as follicular lymphoma or CD10-expressing large cell lymphoma; however, knowledge of the normal patterns and intensity of antigen expression of GCBs, including absence of intracellular BCL-2, can prevent misdiagnosis.[33-35]

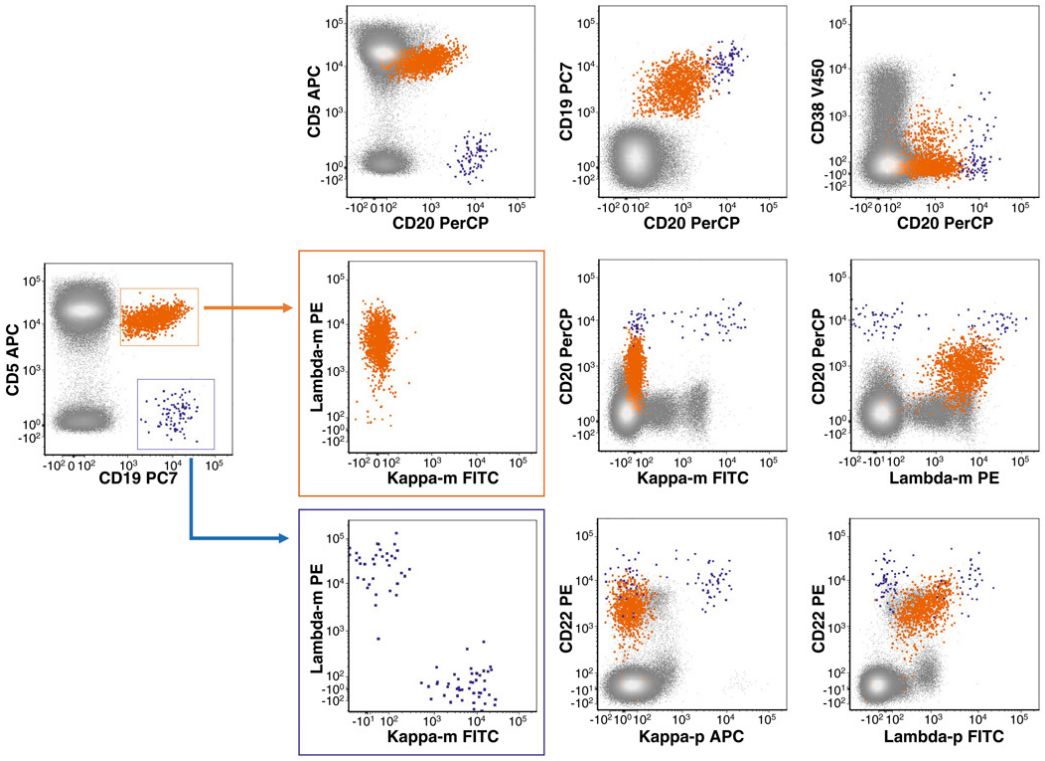

FIGURE 4-1. Flow cytometry detection of chronic lymphocytic leukemia (CLL) in peripheral blood.A significant population of B cells with aberrant CD5 expression *(orange)* corresponding to CLL are detected, along with fewer normal (CD5-negative) B cells *(blue)*; CD5-positive CD19-negative T cells are also present *(gray, far left dot plot)*. The CLL cells *(orange)* demonstrate dim CD20 *(top row, middle row)* and dim CD22 *(bottom row)* compared with normal B cells *(blue)*. The CLL cells are monotypic and demonstrate lambda light chain restriction *(orange, middle row, kappa-vs.-lambda dot plot)*; the normal B cells demonstrate an appropriate polyclonal pattern of both kappa

and lambda light chain expression *(blue, bottom row, kappa-vs.-lambda dot plot)*. The differing intensities of CD20, CD22, kappa surface Ig, and lambda surface Ig can be simultaneously appreciated in both the CLL cells *(orange)* and normal B cells *(blue) (middle row, bottom row)*.

Technical Considerations in Demonstration of Light Chain Restriction

Technical factors, such as antibody choice and cytophilic antibody artifact, can affect a laboratory's ability to assess surface light chain.[26] Cytophilic antibodies may be passively absorbed by Fc receptors present on natural killer (NK) cells, activated T cells, monocytes, granulocytes, and some B cells, resulting in apparent surface light chain expression. Washing a specimen with phosphate-buffered saline (PBS) before staining, either at room temperature or 37° C, is sufficient to eliminate this artifact in most cases.[26] Neoplastic B cells may express light chain epitopes not readily detected by some antibodies. Incorporation of two sets of light chain reagents, including both monoclonal and polyclonal antibodies, may improve the sensitivity of monotypic B-cell detection.[26,36]

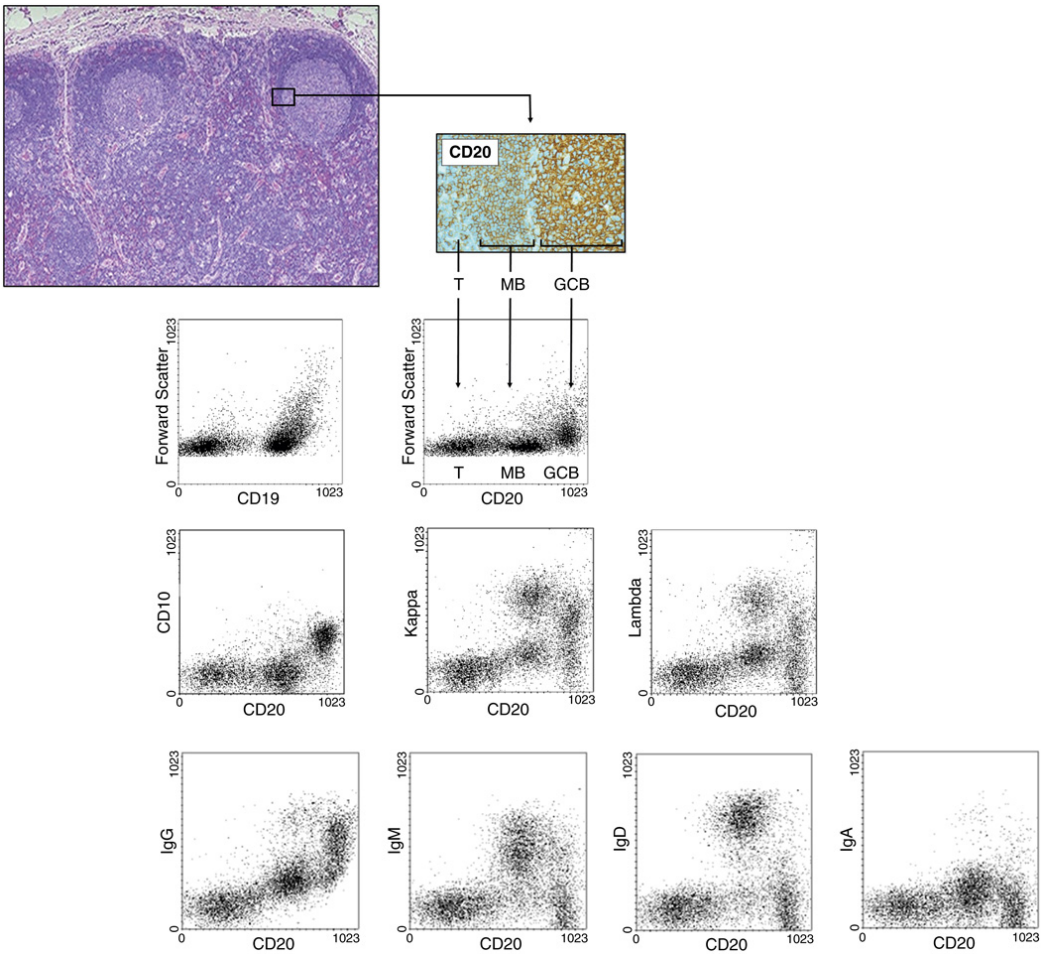

FIGURE 4-2. Flow cytometry evaluation of normal lymph node.H&E (hematoxylin and eosin) stained section of normal lymph node architecture with focus on portion of lymph node follicle *(top row, left photomicrograph, low power)*; CD20 immunohistochemistry shows CD20-negative T cells (T), CD20-positive B cells of the mantle zone (MB) and bright CD20-positive germinal-center B cells (GCBs) *(top row, right photomicrograph, high power)*. These normal cellular compartments are also clearly identified by flow cytometry (FCM) evaluation of

CD20 and forward light scatter *(upper middle row, right dot plot)*, with GCBs showing brighter CD20 expression than MB and increased forward light scatter properties, which reflect the larger size of GCBs. CD20 is superior to CD19 *(upper middle row, left dot plot)* for discrimination of T, MB and GCB lymphoid compartments. GCBs are also distinguished by expression of CD10 *(middle row, left dot plot)* and dim surface light chain immunoglobulin (Ig) compared with the intensity of kappa and lambda staining of polyclonal MB *(middle row, center, and right dot plots)*. GCBs also express IgG heavy chain *(bottom row, left dot plot)* in contrast to MB, which predominantly express IgD and IgM heavy chain and, to a much lesser extent, IgA heavy chain *(bottom row, center, right, and far right dot plots)*. (Data courtesy of Dr. Raul C. Braylan.)

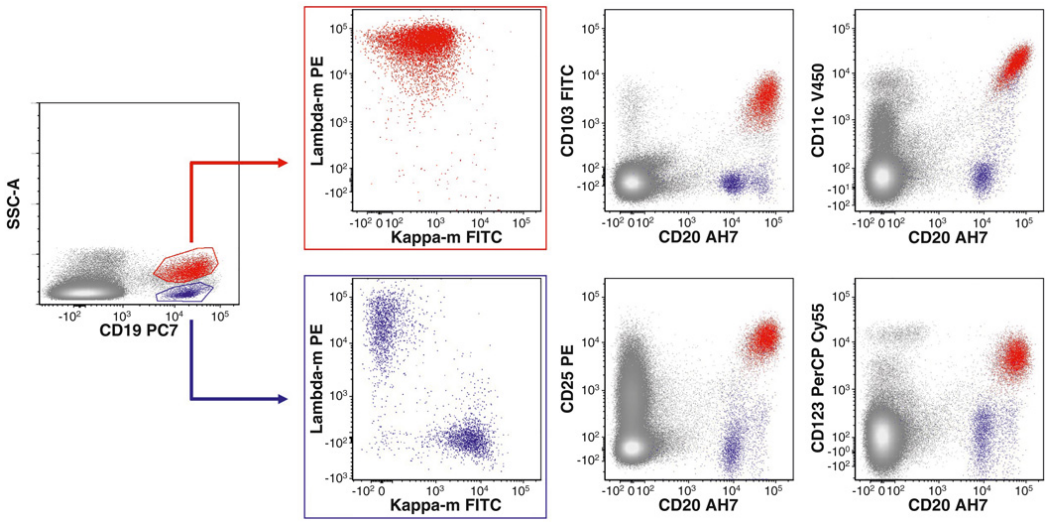

FIGURE 4-3. Flow cytometry evaluation of hairy cell leukemia (HCL).Detection of HCL is usually performed by gating on bright CD20-positive B cells with CD103, bright CD11c, bright CD25, and bright CD123 expression, with subsequent demonstration of monotypic light chain expression. However, this unique case illustrates an example of HCL *(red)* with distinctively increased side scatter-area (SSC-A) that is fully distinguished from normal B cells of low SSC-A *(blue)* within the sample *(far left dot plot)*. The HCL cells *(red)* show restricted expression of bright lambda surface light chain *(top row, kappa-vs.-lambda dot plot)*, in contrast to the polyclonal pattern of surface light chain expression of normal B cells *(blue, bottom row, kappa-vs.-lambda dot plot)*. In addition to the expression of CD103, bright CD11c *(top row, center, and right dot plots)*, bright CD25, and

bright CD123 *(bottom row, center, and right dot plots)*, the HCL cells *(red)* also show brighter expression of CD20 compared with the intensity of CD20 on normal B cells *(blue)*.

Additional Immunophenotypic Characteristics of Mature B-Cell Neoplasms

Abnormalities in B-cell antigen expression can be used to identify malignant B cells.[37] Mature normal B cells express CD19, CD20, and CD22, and except for plasma cells, failure to express one of these antigens is abnormal. An important caveat is a history of monoclonal antibody therapy (e.g., rituximab, ofatumumab), as the therapeutic antibody may mask detection of the targeted antigen. For example, CD20 expression cannot be detected on B cells (normal and malignant) post-treatment with rituximab, and this may persist for 6 months or longer after cessation of rituximab therapy.[38]

The detection of aberrant antigens (not normally expressed on B cells) is a notable feature of malignant B cells. Aberrant expression of T-cell markers (such as CD2, CD4, CD7, and CD8) may be observed in B-cell non-Hodgkin lymphoma.[39-41] Abnormal intensity of antigen expression (e.g., abnormally dim or bright expression) is also diagnostically important and aids in subclassification. CLL is characterized by dim CD20 expression, dim CD22 expression, and CD5 expression (**Fig. 4-1**). Hairy cell leukemia is characterized by expression of CD103, bright CD20, bright CD22, bright CD11c (**Fig. 4-3**, top row), bright CD25, and bright CD123 (**Fig. 4-3**, bottom row).[42] Follicular lymphoma frequently exhibits dim expression of CD19, along with expression of CD10.[43]

In addition, light scatter characteristics may aid in detecting neoplastic B-cell populations. Abnormally high FSC is observed in large cell lymphoma (**Fig. 4-4**, top row, upper left dot plot showing CD19 vs. FSC), reflecting an increase in the neoplastic cell's size/volume. Abnormally increased SSC is a notable feature of hairy cell leukemia (**Fig. 4-3**, left dot plot showing CD19 vs. SSC); it is comparable to the SSC exhibited by monocytes and reflects the membrane irregularities that are characteristic of this disease. Increased FSC is also a helpful feature of primary effusion lymphoma (PEL), which lacks expression of CD19, CD20, CD22, cytoplasmic CD79a, and other B-cell antigens. Morphologically, the size of a PEL cell may be tremendously larger than that of a small lymphocyte (**Fig. 4-3**, upper and lower right micrographs). PEL may only express CD45 (often dim), along with only a few of the following antigens: CD38, CD138, VS38c, HLA-DR, and CD30.[13,44] The increased FSC is a helpful identifying feature; PEL cells may be so large as to compress near the visible edge or "hit the ceiling" of the dot plot, depending on how the data is visually scaled (**Fig. 4-5**, top row, FSC vs. CD45 dot plot).

Another area where the FSC parameter is helpful is in the FCM evaluation of B-cell lymphoma, especially lymphoplasmacytic lymphoma, in the bone marrow. Bone marrow contains many precursor B cells with normal, variable expression patterns of CD10, CD20, and CD45. In addition, plasma cells in bone marrow express a normal and heterogeneous pattern of CD19 and CD45. Both precursor B cells with appropriately progressive maturation and normal plasma cells can obscure identification of B-cell lymphoma and especially of lymphoplasmacytic lymphoma, which contains both

monotypic mature B-cell and plasmacytic-cell components.[45,46] Analysis strategies that examine the FSC of B cells along with CD19, CD20, CD45, and CD38 can often help delineate the normal from abnormal B cells more clearly. Precursor B cells are small cells with distinctly low FSC, whereas plasma cells have slightly higher FSC and distinctly bright CD38. Accounting first for the normal B-cell and plasma-cell compartments subsequently facilitates the identification of B-cell lymphoma in the marrow.[47]

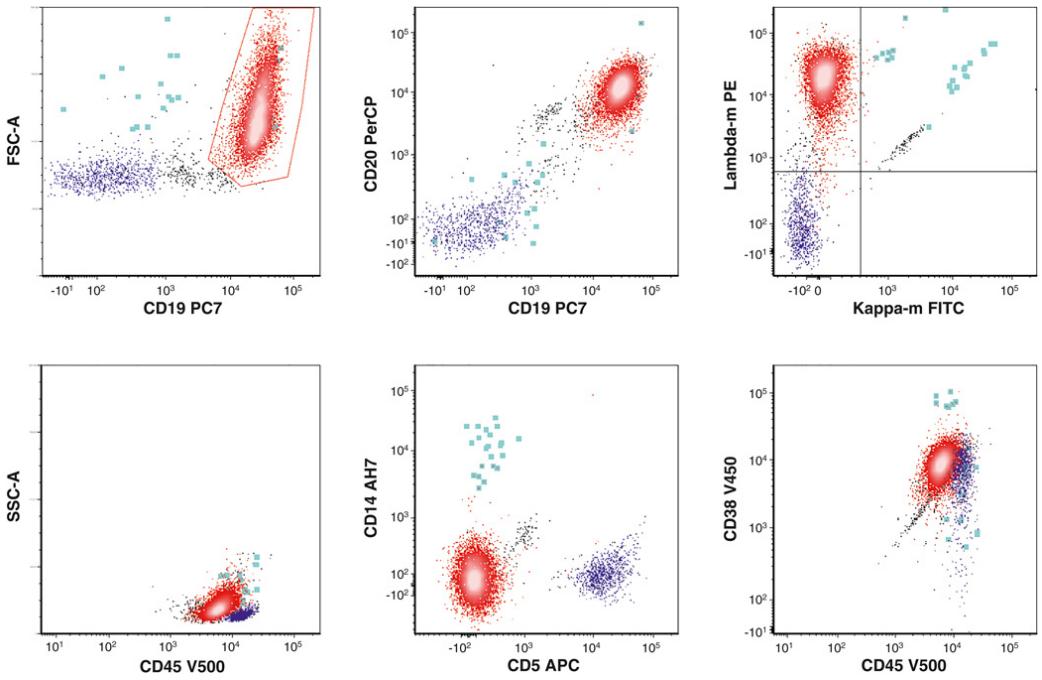

FIGURE 4-4. Flow cytometry evaluation of cerebrospinal fluid involved by diffuse large B-cell lymphoma.The specimen was processed without red blood cell lysis, and CD45-negative small red blood cells were initially gated out of the analysis post-acquisition. Next, a population of CD19-positive B cells is identified *(red)* with abnormally increased forward scatter-area (FSC-A), consistent with B cells of increased size/volume *(top row, left dot plot)*. The FSC-A of the B cells is much larger than that of CD5-positive T cells *(blue)* and equivalent to the FSC-A of CD14-positive monocytes *(aqua)* that are also present in the sample *(bottom row, center dot plot)*. The abnormal B-cell population expresses CD20 *(top row, center dot plot)*, CD45 at a slightly dimmer intensity than T cells *(blue)* and

monocytes *(aqua, bottom row, left and right dot plots)*, and demonstrates monotypic expression of lambda surface light chain *(top row, right dot plot)*.

In FCM, an increase in FSC reflects an increase in cellular volume. Thus, cells with increased amounts of cytoplasm, such as normal plasma cells of bone marrow, may exhibit slightly higher FSC and appear "large" as a result of the increased volume of cytoplasm; however, plasma cells are not considered "large" cells in the traditional histopathologic context, which is based on evaluation of nuclear size on hematoxylin and eosin (H&E)-stained slides. When interpreting FCM data, this distinction is important to bear in mind.

Emerging Role of Flow Cytometry in the Diagnosis of Hodgkin Lymphoma

So far, we have discussed the utility of FCM exclusively in non-Hodgkin B-cell lymphoma and lymphoproliferative disorders. Historically, FCM evaluation was considered suboptimal for evaluation of classic Hodgkin lymphoma (cHL) because of the apparent lack of sensitivity of FCM to detect Hodgkin and Reed-Sternberg (HRS) cells within a heavily infiltrated background of inflammatory cells. This may have been caused by the rarity of HRS cells, the difficulty in aspirating HRS cells from within the fibrotic bands of the nodular sclerosis-subtype of this disease, and/or their fragility/susceptibility to being lost during FCM cell processing.

FCM evaluation for assessment of Hodgkin lymphoma has become increasingly sophisticated. The ability to use a greater numbers of markers, modern instrumentation (6 to 9 colors or more), specific

methods for tissue processing and disaggregation, increased number of acquired cells for analysis, and a specifically tailored gating strategy have improved detection of HRS cells.[48,49] Modern methods of cHL detection boast a diagnostic sensitivity of 89% and specificity approaching 100%, even though HRS cells typically contain less than 1% of the total specimen cellularity.[50]

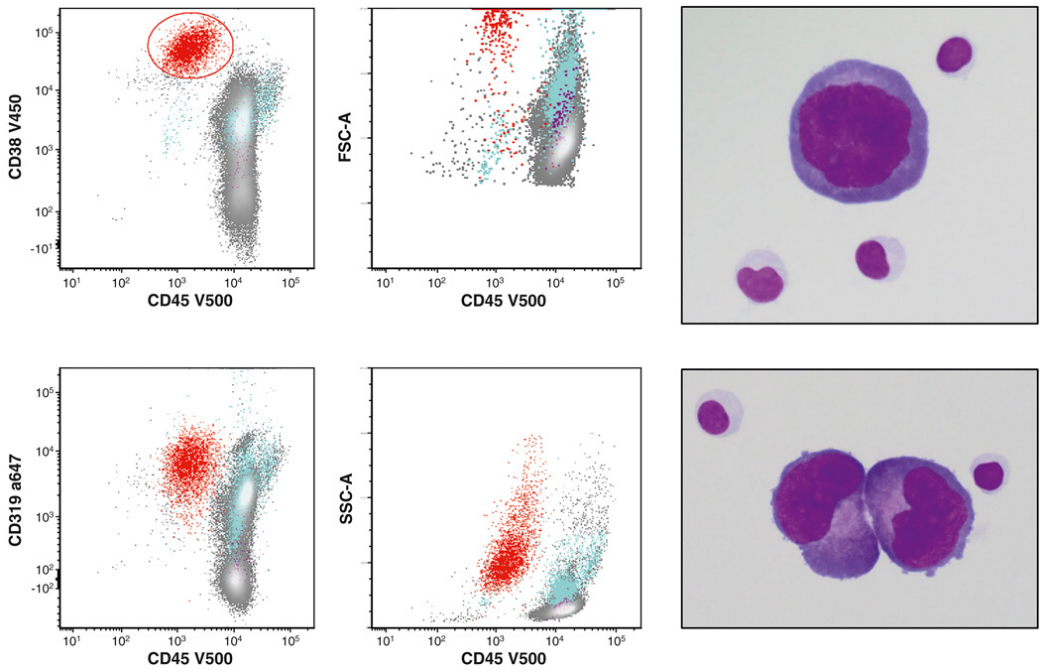

FIGURE 4-5. Flow cytometry evaluation of primary effusion lymphoma (PEL).A population of PEL cells is identified by expression of CD38, dim CD45 *(top row, left dot plot)* and CD319 *(bottom row, left dot plot)*, with atypical side scatter-area (SSC-A; *bottom row, center dot plot*) and markedly increased forward scatter-area (FSC-A; *top row, center dot plot*). Cytologic evaluation identifies malignant PEL cells that are significantly larger than small lymphocytes *(top row, right photomicrograph; bottom row, right photomicrograph)*.

In cHL, HRS cells show distinctively increased side scatter (compared with small lymphocytes within the sample) and expression of CD15, CD30, bright CD40, CD71, and CD95, along with dim/negative expression of CD20.[50,51] Furthermore, FCM reveals T-

cell rosettes (T cells forming a ring around HRS cells), a common histopathologic feature of this disease.[52,53] HRS cells express CD54 and CD58, mediating T-cell binding to the HRS cell surface; FCM identifies HRS T-cell rosettes by their co-expression of both bright CD45 and bright CD5 in a reproducible, slightly diagonal-appearing pattern.[48,51] Certain features of the reactive background cellular infiltrate are also associated with cHL. The CD4-positive T cells in cHL are associated with characteristically bright CD7 and bright CD45 expression[54,55] and contain increased immunosuppressive T-regulatory cells.[56,57] Pioneering work continues to explore the role of FCM, not only in diagnosis of cHL, but in nodular lymphocyte predominant B-cell lymphoma (NLPBL) (synonym and related term: nodular lymphocyte predominant Hodgkin lymphoma [NLPHL], World Health Organization [WHO] Classification)[58] and other related entities.[59,60]

PLASMA CELL NEOPLASMS

Plasma cell neoplasms (PCNs) are a group of disorders with a spectrum of clinical presentations from the asymptomatic monoclonal gammopathy of uncertain significance (MGUS) and smoldering multiple myeloma (SMM) to the symptomatic multiple myeloma (MM) (synonym and related term: plasma cell myeloma [PCM], WHO classification). Although diagnosis is based on serum M (monoclonal) spike, extent of plasma cell involvement of the bone marrow, and presence of end organ damage, FCM characterization and quantification of neoplastic plasma cells have been used in the diagnosis, prognostication, and monitoring of PCN.[46,61-63] In patients with reactive bone marrow plasmacytosis, FCM can

distinguish normal from neoplastic plasma cells. FCM is vital in the diagnosis of unusual cases of myeloma, such as IgM myeloma (differentiating these cases from other IgM secretory diseases) and rare cases of nonsecretory myeloma.[64] FCM is also useful in differentiating myeloma from lymphoplasmacytic lymphoma (LPL) and other non-Hodgkin lymphomas, as the monotypic CD38-positive cells in lymphoma typically are CD19-positive and CD45-positive and lack expression of CD56, an immunophenotypic profile that is uncommon in myeloma.[46,61] Plasma cells are fragile and may deteriorate rapidly and/or be susceptible to loss during processing for FCM.[65] In addition, plasma cell infiltrates in MM may be focal and/or show a patchy distribution in the bone marrow; as such, immunohistochemistry is better suited to visualize and quantitate plasma cells on the bone marrow core biopsy. Nevertheless, FCM detection of plasma cells demonstrates increased sensitivity over immunohistochemistry in MGUS and SMM and is consistent and reproducible, regardless of the choice of anticoagulant, biopsy site, or pull sequence in unilateral and bilateral bone marrow sampling.[66] FCM determination of the proportion of plasma cells that are phenotypically aberrant allows risk stratification of progression of MGUS and SMM to overt MM and is prognostically valuable.[67-73] FCM studies also help predict response to autologous stem cell transplantation.[73-75] In addition, FCM can detect circulating abnormal plasma cells in the peripheral blood, which affects progression-free survival (PFS) and overall survival (OS).[72,76-78] FCM MRD detection post-therapy in MM has been demonstrated to be a robust independent predictor of PFS and OS in prospective studies.[79-84] An FCM-negative MRD study in MM is one of the most

relevant prognostic factors for patients undergoing autologous stem cell transplantation and for patients treated with novel agents.[81-84] This led the FDA to adopt the viewpoint that FCM detection of myeloma MRD is a mature technology with proven prognostic value in predicting PFS and OS and is therefore an acceptable surrogate endpoint in clinical trials.[85,86]

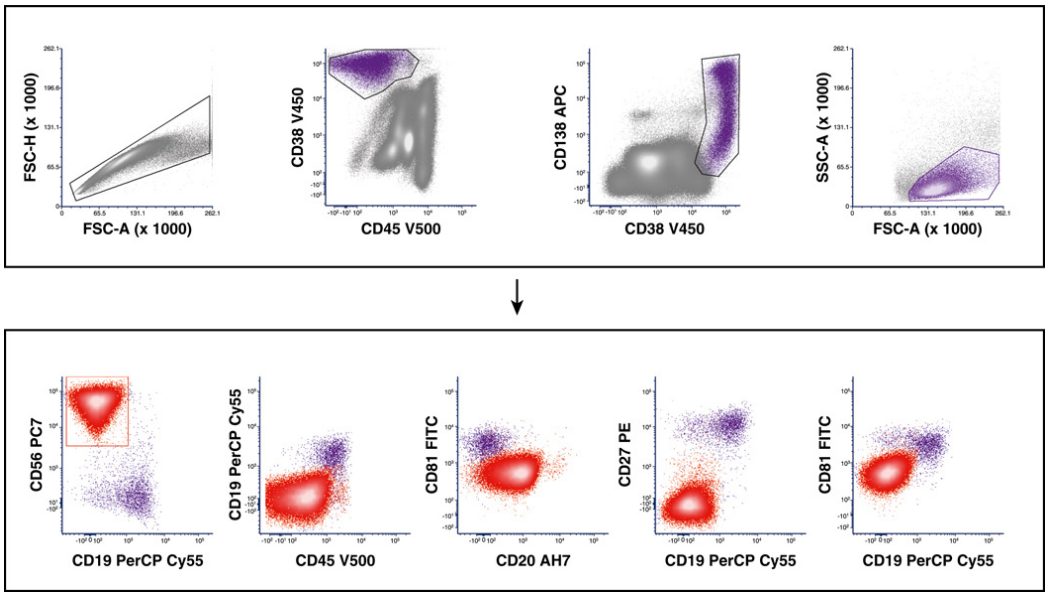

FIGURE 4-6. Flow cytometry evaluation of plasma cells.Both normal and neoplastic plasma cells *(purple)* are captured for analysis using a combination of gates to include single cells *(top row, far left dot plot)* that demonstrate bright CD38 expression, moderate-to-low CD45 expression, and variable CD138 expression *(top row, center left and center right dot plots)* that fall within a generous forward and side scatter gate appropriate for plasma cells *(top row, right dot plot)*. The neoplastic plasma cells are distinguished from normal plasma cells by differential surface expression of CD19, CD45, CD56, CD20, CD27, and CD81. The neoplastic plasma cells *(red)* that aberrantly express CD56 *(bottom row, far left dot plot)* show aberrant CD20 expression, abnormally dim CD81 expression, and lack of CD19, CD45, and CD27.

The remaining plasma cells are normal plasma cells *(purple, bottom row)* with appropriate expression of CD19, CD45, CD81, and CD27 and are appropriately negative for CD20 and CD56.

When designing panels, antibody cocktails must contain CD19, CD38, CD45, and CD138 to adequately identify plasma cells and CD27, CD56, CD81, and CD117 to accurately distinguish between normal and neoplastic plasma cells in the sample.[62,87-90] Intracellular light chain evaluation is appropriate at diagnosis but may be optional post-therapy, as abnormal plasma cells can be identified by surface antigen expression alone; examination of surface CD19, CD38, CD45, CD56, CD138, CD27, CD81, and CD117 is important for identification of subpopulations of clonal plasma cells.[62,67,89,91-94]

Consensus guidelines for PCM MRD detection by FCM highlight special considerations for specimen processing (red cell lysis and cell concentration prior to staining), demonstration of specimen quality (viability and presence of normal marrow elements), the number of cells acquired (2 million minimum, up to 5 million optimal), gating strategies (based on CD38, CD45, CD138, and light scatter), and the definition of malignant plasma cells based primarily on abnormal surface antigen expression.[65,95,96] Plasma cell analysis and gating must be performed with caution to ensure inclusion of plasma cells with aberrant antigen expression (**Fig. 4-6**). Light scatter characteristics are used to select single cells (also referred to as doublet discrimination) and exclude debris while taking care not to exclude hyperdiploid or tetraploid plasma cells, which have abnormally high FSC and SSC.[96] Gating subsequently captures cells

with positive expression of CD138 and bright CD38 (**Fig. 4-6**, top row). Special attention should be focused on examination of plasma cells that may express dimmer-than-normal CD38 and CD45. Once an analysis gating strategy is delineated, neoplastic plasma cells are defined based on their variation from normal plasma cells (**Fig. 4-6**, bottom row). Neoplastic plasma cells are characterized by expression of CD38 (frequently dimmer than in normal plasma cells), CD138, monotypic cytoplasmic Ig, diminished CD27 and/or CD81 expression, absence of CD19 and CD45, and aberrant expression of antigens, including (but not limited to) CD56, CD20, CD28, and CD117.

Normal plasma cells exhibit a highly conserved surface antigen immunophenotype.[87-90,97] Minor subsets of normal plasma cells can immunophenotypically overlap with aberrant plasma cells in expression of single markers; however, this issue is overcome when a larger number of markers are considered for analysis. Normal plasma cells show heterogeneous, moderate-intensity expression of CD45 and CD19 and bright expression of CD27 and CD81 (although rare normal plasma cells with dim-to-negative CD27 and CD81 expression maybe observed with very high acquisition numbers). They are negative for CD20 and CD117. CD56 and CD28 expression can be observed in a small subset (between 5% and 20%) of normal plasma cells with higher frequency in post-treatment bone marrow samples, but they will demonstrate a polyclonal pattern of intracellular light chain Ig.

Daratumumab, a therapeutic anti-CD38 monoclonal antibody used for treatment of PCM, obscures detection of plasma cells by causing them to appear dim or negative for CD38 expression when

FCM is performed. This hinders traditional methods of plasma cell detection, especially if CD138 expression (which can be labile) is decreased in plasma cells. Strategies to improve FCM detection of plasma cells in this particular context have explored the use of alternative markers. These include detection of CD319,[98,99] intracellular IRF4, intracellular CD38,[100] multi-epitope CD38,[101] and intracellular VS38c, which detects cytoskeleton-associated protein 4 (CKAP4).[102,103] These approaches have been met with success and are promising alternatives to the use of traditional anti-CD38 antibody.

The increasingly widespread availability of clinical flow cytometers with 8-color and 10-color capabilities (or more) has allowed for validated panels for PCM MRD testing to include all appropriate antibodies in as little as one or two antibody cocktails. In addition, acquisition of up to 10 million events has improved MRD detection sensitivity.[101,104-107] This type of high sensitivity FCM for myeloma MRD detection shows performance comparable to that of next-generation sequencing (NGS) for the detection of IgH gene rearrangements; although FCM requires the use of a fresh sample (whereas NGS can be performed on DNA from archived, formalin-fixed samples), it offers quick test turn-around, and clonal plasma cells are detectable without the need for comparison to a diagnostic and/or previously characterized disease clone.[108] Efforts continue to further explore and standardize FCM detection of PCM MRD, which will ultimately improve the quality of the testing and its utility in patient care.

MATURE T-CELL NEOPLASMS

FCM immunophenotyping is useful in the evaluation of mature T-cell neoplasms, including initial diagnosis, subclassification, staging, prognostication, monitoring, and identification of therapeutic targets (e.g., for immunotherapy). In general, detection of T-cell neoplasia by FCM is often more challenging than detection of B-cell neoplasia. Typically, T cells are examined for abnormal cell clusters compared with normal T cells by light scatter and/or antigen expression. A variety of phenotypic abnormalities, including a restricted or abnormal CD4/CD8 pattern, abnormal (absent, diminished or increased) expression of pan–T-cell antigens, the presence of aberrant antigens, and expansion of normally rare T-cell populations, may be indicators of T-cell neoplasia.[109,110]

Initial examination of CD4 and CD8 can be informative. Normal reactive lymphoid populations contain a mixture of CD4-positive and CD8-positive cells, with a predominance of CD4-positive cells. The average CD4-to-CD8 ratio is around 1.5 in normal blood, slightly above 1 in the bone marrow, and approximately 3.5 in lymph nodes.[111-113] Mature clonal T-cell populations are restricted to either CD4 or CD8 expression (**Fig. 4-7**, top row, center right and far right dot plots), co-expression of both CD4 and CD8, or lack of CD4 and CD8 (less frequently observed). Caveats include viral infections, which are often characterized by a dramatic increase in CD8-positive T cells, usually in association with other indications of T-cell activation such as increased CD2 expression, decreased CD7 expression, and expression of activation markers.[114] Also, a history of HIV infection may diminish or obliterate the number of CD4-positive T cells.[111]

A significant population of T cells lacking both CD4 and CD8 is abnormal and may be compatible with T-cell lymphoma; however, other non-neoplastic conditions should be excluded first. The majority (70%) of TCRγδ T cells are CD4-negative CD8-negative, and 30% are CD4-negative CD8-positive; rarely (1%), they are CD4-positive CD8-negative.[115] TCRγδ T cells normally constitute only a minor subset (<10%) in peripheral blood but are more abundant in certain tissue (e.g., 25% to 60% in the gut) and may be expanded in various reactive conditions. A reactive increase in CD4-negative CD8-negative TCRγδ T cells should not be interpreted as a T-cell lymphoproliferative disorder.[116] CD4-negative CD8-negative T cells are also present in some immunodeficiency states and are a hallmark of autoimmune lymphoproliferative syndrome (ALPS).[117]

Co-expression of CD4 and CD8 is less common in mature T-cell neoplasms. Although it can occur, often in T-prolymphocytic leukemia, occasionally in proliferations of T-cell large granular lymphocytes, and rarely in adult T-cell leukemia/lymphoma, this finding necessitates excluding T lymphoblastic leukemia/lymphoma (T-ALL) or normal cortical thymocytes, especially if the specimen is from the mediastinum. FCM can distinguish a neoplastic T-cell process from normal cortical thymocytes in thymoma or thymic hyperplasia if normal T-cell maturation subsets are examined, as evidenced by pattern and intensity of CD2, CD3, CD4, CD5, CD7, CD8, CD10, CD34, and CD45.[118,119] In addition, increased CD4-positive CD8-positive T cells (>10% of T cells) are commonly found in lymph node specimens involved by NLPBL and progressive transformation of germinal centers.[120,121] The presence of this CD4-positive CD8-positive population should not be misinterpreted as a

T-cell or composite neoplasm. Finally, apparent double positives can be a technical artifact in staining of unwashed blood and should be interpreted with care.[122]

Because mature T-cell neoplasms frequently exhibit abnormal (absent, diminished, or increased) expression of at least one T-cell antigen (i.e., CD2, CD3, CD5, or CD7), analysis of pan–T-cell antigens is an essential component of the analysis.[109,123] It is important to include multiple T-cell antigens (CD2, CD3, CD5, and CD7) in a diagnostic panel to ensure sensitivity in detection. When interpreting data, one must first recognize the intrinsic heterogeneous patterns in normal T cells. Normally, a small percent of peripheral blood CD3-positive T cells are CD7-negative, and a subset of TCRγδ cells does not express CD5. However, large numbers of CD7-negative CD4-positive CD5-negative T cells (e.g., non–gamma delta T cells) are abnormal. CD2-negative T cells are rare, and absence of surface CD3 is distinctly abnormal. The intensity of the T-cell markers is not uniform among subsets. Notably, TCRγδ T cells express a brighter CD3 than TCRαβ T cells. Among the TCRαβ T cells, CD4-positive T cells express a higher level of CD3 and CD5 than do CD8-positive T cells. The normal CD7-negative T cells typically express slightly higher levels of CD2 and CD5.[124] CD2 expression is often upregulated in reactive T cells.[125]

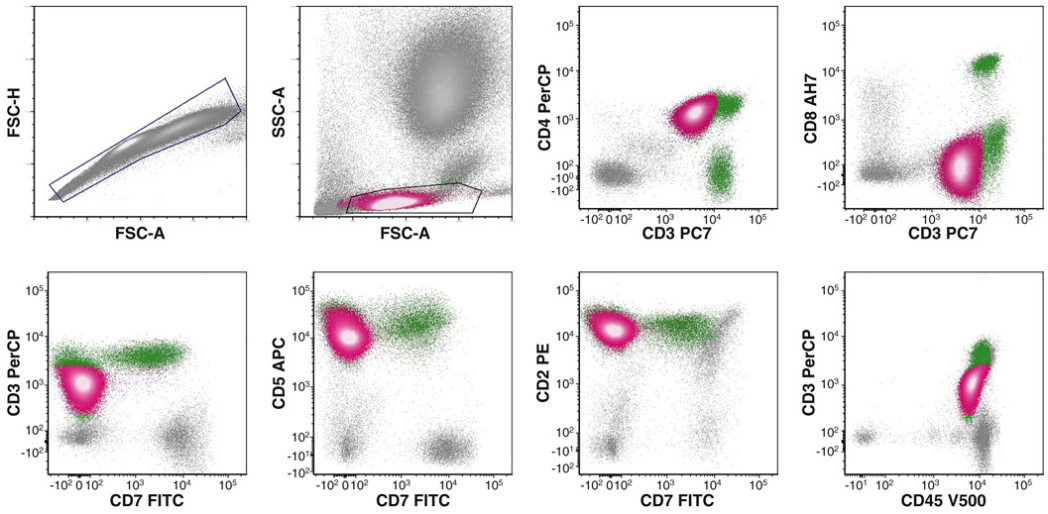

FIGURE 4-7. Flow-cytometric detection of abnormal T-cell populations.Lymphoid cells are identified by gating for single cells and subsequently on cells with appropriate forward scatter (FSC) and side scatter (SSC) characteristics *(top row, middle left and far left dot plots)*. The majority of the abnormal cells are CD4-positive and CD8-negative T cells *(violet)*, and a small population of normal CD4-positive and CD8-positive T cells are present *(green, top row, middle right and far right dot plots)*. The CD4-restricted T cells *(violet)* demonstrate abnormally dim CD3 expression *(top row, middle right and far right dot plots; bottom row, far right and far left dot plots)* compared with the residual normal T cells within the sample *(green)*; the abnormal T cells are CD5-positive, CD2-positive, and CD7-negative *(bottom row, middle right and middle left dot plots)*.

As opposed to the expected normal heterogenous patterns, neoplastic T cells may be detected as a homogeneous population with an abnormal level of antigen expression (e.g., abnormal CD2, CD3, CD5, CD7, or CD45).[109,123] For example, CD3 may be expressed at a higher or lower level than normal as measured by staining with anti-CD3. Dim CD3 expression is characteristic of Sézary cells and adult T-cell leukemia/lymphoma.[126,127] Diminished or absent CD3 is also a typical feature of follicular helper T-cell lymphoma, angioimmunoblastic type (also known as angioimmunoblastic T-cell lymphoma, WHO classification 4th edition, and nodal T-follicular helper cell lymphoma, angioimmunoblastic type, WHO classification 5th edition).[128,129] T-cell large granular lymphocytic leukemias typically have abnormally dim levels of CD5 expression. Abnormal levels of CD2 and CD7 expression may also be observed in T-cell lymphoproliferative processes.

A subgroup of clonal T-cell processes is characterized by increased numbers of T-cell subpopulations normally present in low numbers. In T-cell large granular lymphocytic leukemia, CD8-positive T cells co-expressing CD57, CD56, or CD16 are increased. Dim CD5 expression and absence of normal T-cell antigens, such as CD7 and CD2, assist in the diagnosis. CD20, considered a B-cell antigen, is expressed by a small subgroup of normal T cells. However, detection of a significant population of CD20-positive T cells is highly abnormal.

In addition, T-cell lymphoma may occasionally show aberrant expression of non–T-cell lineage antigens. Aberrant expression of myeloid markers such as CD13 and/or CD33 may be seen in ALK-positive anaplastic large cell lymphoma.[130] Rare peripheral T-cell

lymphomas may show aberrant B-cell markers, including CD19.[131] Those cases are generally rare, but the aberrant phenotype may become a diagnostic pitfall.

In all T-cell neoplasms, correlation with patient history and morphology is essential. When the vast majority of cells are neoplastic by morphology, a corresponding aberrant immunophenotype can be easily interpreted. Caution should be exercised when interpreting single immunophenotypic abnormalities, as these can be found in benign T-cell populations that are highly activated or when subsets are present in numbers increased above normal (e.g., increased gamma delta T cells, loss of CD7 on T cells in Epstein-Barr virus [EBV] infection). Neoplastic T cells usually have multiple abnormalities in antigen expression and light scatter properties, which, because of the multiparametric nature of FCM, can be detected in the same cell, differentiating these cells from normal cells.

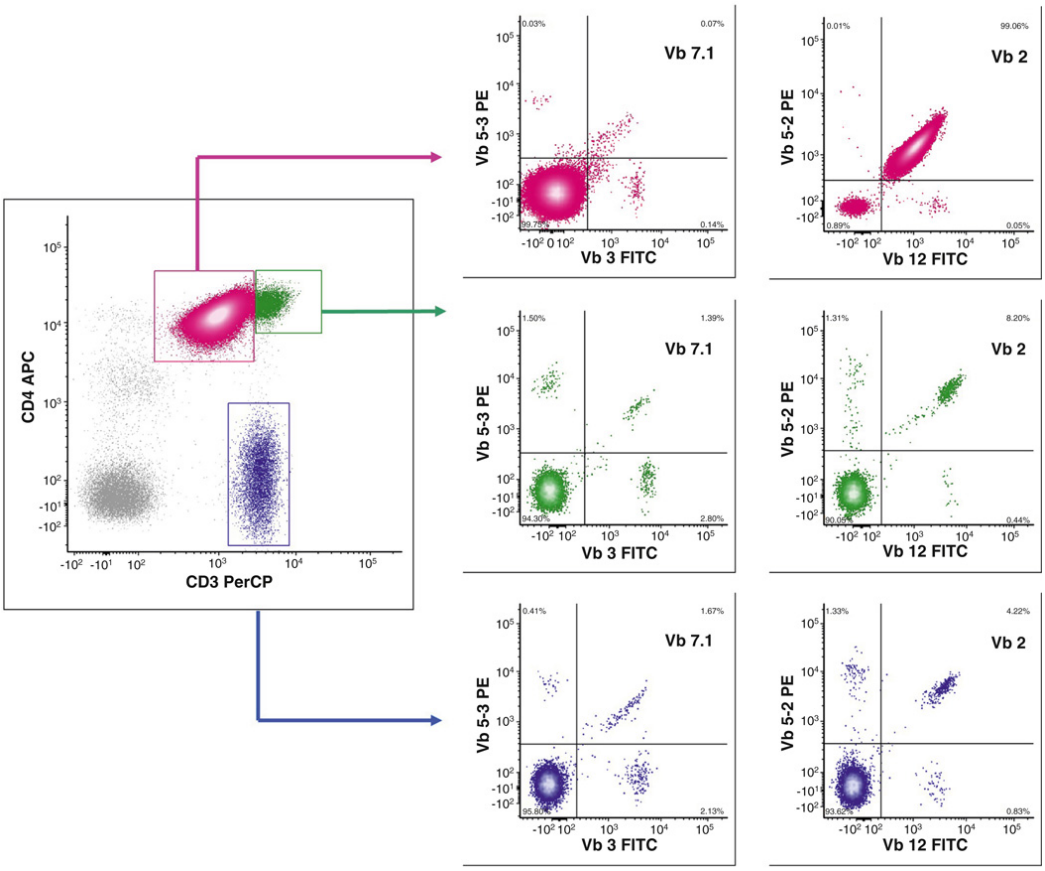

FIGURE 4-8. T-cell receptor Vβ repertoire flow cytometry analysis to identify a clonal T-cell population.Three populations of T cells are discriminated by expression patterns of CD3 and CD4 *(far left dot plot)*. The majority of the T cells are abnormal and express dim CD3 and CD4 *(violet)*. Normal T cells with appropriate intensity of CD3 that are either CD4-positive *(green)* or CD4-negative *(blue)* are also present. The abnormal T cells *(violet)* demonstrate uniform expression of a single Vβ family, consistent with a clonal T-cell population *(top row)*. Normal T cells expressing CD4 *(green)* demonstrate

nonrestricted/non-clonal Vβ family usage *(middle row)*. Similarly, normal T cells that are CD4-negative, likely corresponding to normal CD8-positive T cells *(blue)*, also demonstrate nonrestricted/non-clonal Vβ family usage *(bottom row)* and serve as an internal control.

In addition, as in clonality analysis in B-cell neoplasms, T-cell clonality can be directly assessed by FCM analysis of the β-chain variants of the T-cell receptor (TCR Vβ).[132,133] Commercial antibodies are available against approximately 70% of the human class-specific sequences among the TCR Vβ segments. Normal T cells have a relatively stable distribution of the Vβ repertoire, which is well defined,[134] but a clonal T cell population has the same variable, diversity, and joining segments and hence a restricted Vβ expression pattern. An abnormal expansion of a Vβ-expressing population is consistent with a clonal T-cell population. A panel of antibodies can be combined with anti-Vβ antibodies to detect abnormal T-cell populations and determine the clonality of the immunophenotypically defined abnormal T cells (**Fig. 4-8**). This TCR Vβ repertoire analysis can be used to establish an initial diagnosis of T-cell neoplasia and to monitor MRD.[132,133,135-137]

Alternatively, T-cell clonality can be examined by analyzing the expression pattern of the TCR β-chain constant region 1 (TRBC1),[138-140] which is less laborious and costly than Vβ repertoire analysis. The TCR β-chain constant region is encoded by two mutually exclusive T-cell receptor β-chain constant region genes: TRBC1 and TRBC2. The utilization of TRBC1 or TRBC2 during TCR gene rearrangement is a random process, and thus normal T cells express

a mixture of TRBC1 and TRBC2, whereas a clonal T-cell population exhibits restricted expression of either TRBC1 or TRBC2. Monoclonal antibody is currently available to detect TRBC1 by FCM. In combination with a panel of antibodies, analysis of the TRBC1 expression pattern allows clonality assessment on immunophenotypically defined abnormal T cells. **Figure 4-9** shows an example of peripheral blood that contains two clonal T-cell populations with a monotypic TRBC1 expression pattern (the red population is TRBC1 positive; the green is TRBC1 negative); the normal T cells in the background demonstrate a polytypic pattern.

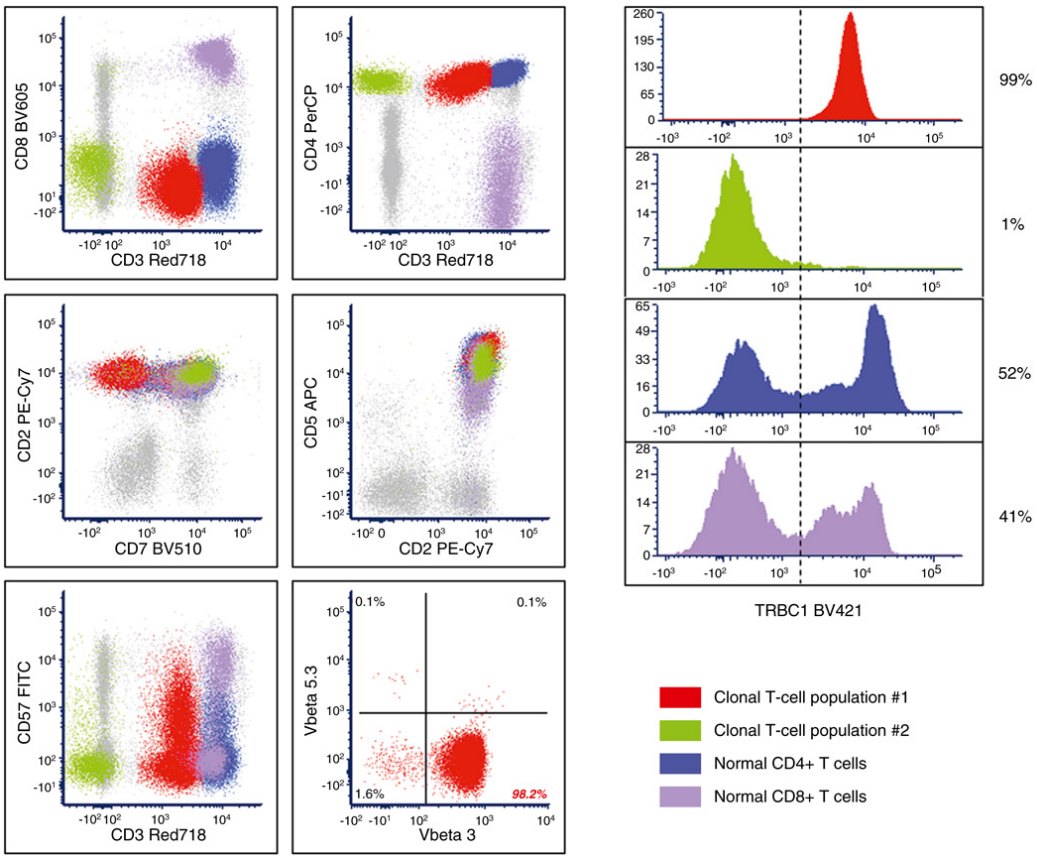

FIGURE 4-9. Flow cytometric evaluation of T-cell receptor β-chain constant region 1 (TRBC1) expression for assessment of T-cell clonality.Two abnormal T-cell populations with an aberrant phenotype are identified in this peripheral blood specimen. One population *(red)* demonstrates abnormally dim CD3 and partial CD57, lacks CD7, and expresses CD2, CD4, CD5, and a monotypic TRBC1 pattern (99% positive). Concurrent Vβ repertoire shows restricted expression of Vβ-3, supporting a clonal T-cell population. An additional abnormal T-cell population *(green)* lacks surface CD3, expresses CD2, CD4, CD5 and CD7, and is negative for

TRBC1 expression. The normal CD4-positive *(blue)* and CD8-positive *(purple)* T cells show a polytypic TRBC1 expression pattern.

NATURAL KILLER CELL NEOPLASMS

Normal NK cells are characterized by the expression of CD16 and/or CD56, and they also express a subset of T-cell antigens, including CD2 and CD7. Unlike T cells, NK cells only express subunits of the CD3 complex, including the epsilon and zeta chains (CD3ε and CD3ζ); they lack the gamma and delta chains (CD3γ and CD3δ) and are unable to form CD3 heterodimers.[141,142] Thus, NK cells are usually CD3 negative by FCM immunophenotyping assays using anti-CD3 antibodies that recognize assembled CD3 heterodimers and are often CD3-positive by immunohistochemical assays that typically use anti-CD3ε antibodies. This difference in the pattern of CD3 expression is useful in distinguishing NK-cell neoplasms from T-cell neoplasms.[143]

NK cells express neither TCRαβ nor TCRγδ and have the TCR genes in the germline configurations. They are usually negative for CD4 and CD5 and often show partial and dim expression of CD8. Normal NK cells usually exhibit a heterogeneous pattern of CD16, CD56, and CD57. The bright CD56-positive and dim CD16-negative NK cells are found primarily in the second lymphoid tissue and are abundant cytokine producers with limited cytotoxic activity. Dim CD56-positive and bright CD16-positive NK cells are the major circulating subset and act primarily as cytotoxic effector cells.[144,145]

Although no specific immunophenotypic markers exist that accurately distinguish reactive from neoplastic NK cells, changes in the pattern of surface antigen expression may be helpful to identify abnormal NK cells.[146] CD16 may appear unusually homogeneous, and CD56 may be abnormally bright or uniformly dim, as has been observed in chronic lymphoproliferative disorders of NK (CLPD-NK) cells (synonym and related term: NK-large granular lymphocytic leukemia, WHO classification).[147] Diminished expression of CD2 or CD7, aberrant expression of CD5, and a homogeneous pattern of CD8 expression may also be helpful features. In addition, the number and proportion of NK cells and the NK-cell FSC properties (presence of large cells) also help the diagnosis, especially in extranodal NK/T-cell lymphoma, which has a marked inflammatory background.

Both extranodal NK/T-cell lymphoma and aggressive NK-cell leukemia often exhibit a bright CD56-positive, dim to negative CD16 phenotype, reflecting the possible origin from this NK-cell subtype.[148] CLPD-NK cells have been shown to consist of two major entities: one subtype is characterized by signal transducer and activator of transcription (STAT) pathway activation, including STAT3/5B variants, and exhibit a bright CD16-positive immunophenotype; the other subtype demonstrates loss of function, *TET2* mutation, and a dim CD16 phenotype.

Confirming clonality in NK cells in the clinical laboratory setting is often challenging. Unlike T-cell neoplasms, a true NK-cell neoplasm will exhibit germline configuration of the T-cell receptor gene. Human NK cells express multiple receptors that recognize specific ligands on target cells, such as the major histocompatibility complex

(MHC) class I molecules, and deliver inhibitory or activating signals to finetune the cells' cytotoxic activity. FCM analysis of NK-cell receptors, including the killer-cell Ig-like receptors (KIRs) and the C-type lectin receptors, such as CD94/NKG2 heterodimers and CD161, have been applied to evaluate NK-cell neoplasms.[149,150] Individual NK cells express different sets of KIR molecules, and the combinational diversity of KIRs leads to a broad range of NK-cell specificity.[151] Thus, analysis of the repertoire of KIRs (e.g., CD158a, CD158b, and CD158e) in a normal NK-cell population yields an unrestricted distribution of KIR expression, but a clonally expanded NK-cell population may demonstrate a restricted or skewed pattern.[152] It should be noted that the KIR expression patterns are mainly determined epigenetically through DNA methylation and can be stably maintained over multiple cell generations,[153] allowing the use of KIR repertoire analysis to investigate NK-cell clonality.

In contrast to KIRs, the C-type lectin receptors CD94/NKG2 and CD161 are not clonally expressed. Nonetheless, these NK-cell receptors may still be useful in evaluating NK-cell neoplasms. Bright expression of CD94 and NKG2A has been shown to distinguish CLPD-NK from a reactive NK-cell population.[154] Diminished CD161 expression is also frequent in CLPD-NK.[146,152,154] However, these findings are not specific and have also been described in viral processes and EBV-driven lymphoproliferations,[155-157] so clinicopathologic correlation should be used and care should be exercised in their interpretation. Currently, these modalities are limited in availability and are not routinely used in clinical FCM laboratories.

FLOW CYTOMETRY IN DIAGNOSIS AND CLASSIFICATION OF ACUTE LEUKEMIA

The approach to diagnosis of acute leukemia by FCM often begins with evaluation of a CD45-versus-SSC plot. Most abnormal progenitor or blast populations have decreased CD45 and intermediate SSC and can be recognized as an expanded population in a CD45-versus-SSC–defined "blast gate"[158] (**Fig. 4-10A** and B). As the CD45-versus-SSC–defined blast gate also contains cells that are not blasts (these include basophils, plasmacytoid dendritic cells, plasma cells, hypogranular neutrophils, and immature monocytes), any suspected blast population should be evaluated by a panel that will (1) allow definition of a population as a blast with specific markers and (2) allow lineage assignment. Some populations of blast equivalents fall outside the typical CD45-versus-SSC–defined blast gate (**Fig. 4-10C** and D); therefore, the evaluation for leukemic blasts should not be limited to this region. As true myeloid leukemias can aberrantly express lymphoid markers, and vice versa, the use of a comprehensive panel is vital for accurate lineage assignment.[3,13,159-161] The WHO and International Consensus Classification (ICC) diagnostic classification systems incorporate specific genetic alterations and characteristic translocations that carry prognostic and sometimes therapeutic implications into the classification of leukemia.[13,162,163] Associations between specific genetic and immunophenotypic features in acute leukemia have been described, and FCM may provide the first clue to the presence of a specific underlying genetic alteration. In addition, FCM MRD detection carries important prognostic implications and may guide further therapeutic options.

Acute Myeloid Leukemia

FCM immunophenotyping plays an important role in the WHO classification of acute myeloid leukemias. FCM is highly sensitive and specific in differentiating acute myeloid leukemia (AML) from acute lymphoblastic leukemia (ALL) and in identifying granulocytic, monocytic, erythroid, and megakaryocytic differentiation. In general, blasts in AML express a combination of antigens associated with an immature phenotype (which may include CD34 and/or CD117)[13,159,161] in conjunction with myeloid antigens (which may include CD13, CD33, CD15, and myeloperoxidase). Aberrant expression of lymphoid markers (such as CD2, CD5, CD7, CD19, or CD56) may be seen in some cases as well.[13,159,161] A typical example of AML is illustrated in **Figure 4-10E** to **H**. The patterns of antigen expression that characterize neoplastic blasts generally differ from that seen on normal regenerating myeloid blasts; for this reason, an understanding of normal antigen expression patterns is critical in differentiating leukemic blast populations from marrow regeneration. This is particularly important in the setting of MRD detection post-therapy.

In addition to the standard myeloid blast seen in most subtypes of AML, blast equivalents may include abnormal promyelocytes (seen in acute promyelocytic leukemia) or immature monocytic cells (monoblasts or promonocytes that are seen in AML with monocytic differentiation). These blast equivalents are more differentiated than typical myeloid blasts and may not fall in the standard CD45-versus-SSC–defined blast gate (**Fig. 4-10C** and D). For instance, compared with typical myeloid blasts, abnormal promyelocytes generally have

increased SSC, and immature monocytic cells may have higher CD45.

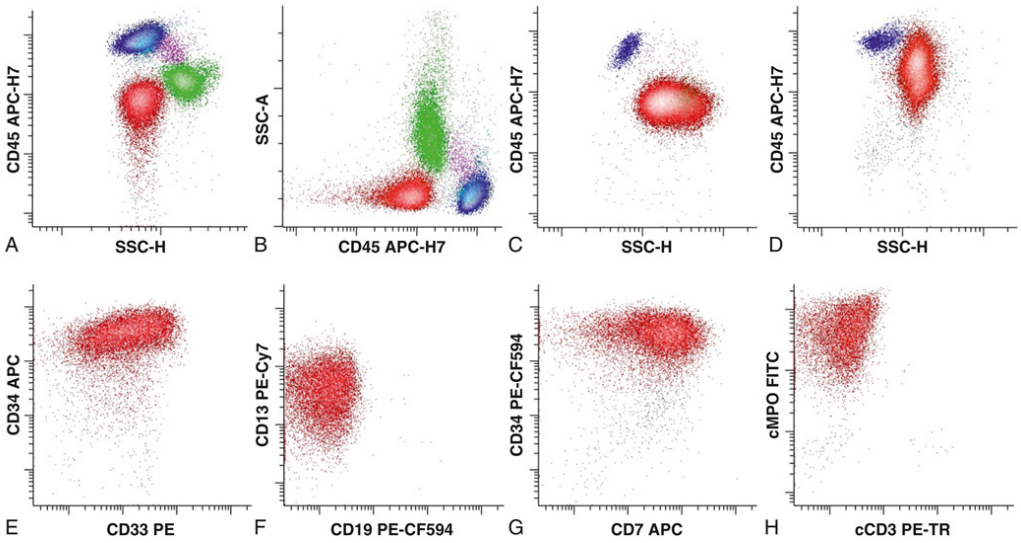

FIGURE 4-10. Acute leukemia.A CD45-versus-SSC plot from a bone marrow specimen involved by acute myeloid leukemia (AML) is shown in panels **A** and **B**. All viable cells are displayed. **A** shows CD45 on the *y*-axis and side scatter (SSC) height (log scale) on the *x*-axis. Panel **B** shows SSC area on the *y*-axis (linear scale) and CD45 on the *x*-axis. Blasts in both histograms *(red)* are identified as a population with decreased CD45 and intermediate SSC. Mature lymphoid cells *(blue)*, monocytes *(pink)*, and granulocytes *(green)* are shown. **C** and **D**, All viable cells are displayed. Blast equivalents are shown *(red)*. **C**, As the blast equivalent in acute promyelocytic leukemia has higher SSC than a typical myeloid blast, the neoplastic promyelocytes may overlay the area of normal granulocytic cells on a CD45-versus-SSC plot. **D**, The blast equivalent in monocytic leukemias may express increased

CD45 compared with a typical myeloid blast and may overlap with the typical position of monocytes on a CD45-versus-SSC plot. Panels **E-H** show blasts from the case depicted in panels **A** and **B**. These are myeloid blasts expressing CD34 and with CD13, variable CD33, and cytoplasmic MPO. The blasts are negative for CD19 and cytoplasmic CD3 but aberrantly express CD7, an antigen typically expressed on T-cell and NK-cell populations. Aberrant expression of a marker of a different lineage is an abnormality that may be seen in leukemic blasts.

In the current WHO and ICC classifications, a few notable subtypes of AML are described with "recurrent genetic abnormalities," or characteristic genetic features. These include several AML subtypes with balanced translocations that respond well to therapy, have a high rate of complete remission, and carry a favorable prognosis. Because some of these AML subtypes exhibit a characteristic immunophenotype as well, FCM often provides the first clue that a case of AML may fall into a favorable subgroup and can prompt appropriate molecular and cytogenetic studies/correlation.

The immunophenotype of AML with t(8;21)(q22;q22.1) (AML with *RUNX1*::*RUNX1T1* fusion in the WHO 5th edition) translocation is usually CD34-positive, with expression of CD13 and CD33. Frequently, the B-lymphoid marker CD19 is co-expressed on a subset of the blasts.[164,165] CD56 may also be co-expressed, though less

frequently than CD19, and may portend a poor prognosis, perhaps due in part to an association with *KIT* mutations.[166-168]

Among the acute myeloid leukemias with characteristic genetic abnormalities, the diagnosis of acute promyelocytic leukemia (APL, AML with *PML*::*RARA* fusion in the WHO 5th edition) carries with it specific clinical, prognostic, and therapeutic implications, setting it apart from other AML subtypes. APL carries an increased risk of disseminated intravascular coagulation, and the microgranular variant is known to present with a high white blood cell count and rapid doubling time. Despite this, APL is sensitive to treatment with agents including all-trans retinoic acid and arsenic trioxide and, if identified and treated in a timely fashion, carries a favorable prognosis. The leukemic promyelocytes exhibit a characteristic immunophenotype: (1) CD33 expression is usually bright and homogeneous; (2) CD13 is expressed in a heterogeneous fashion; (3) HLA-DR and CD34 are usually absent or may be dimly expressed on a minor subset; and (4) in contrast to normal promyelocytes, which show strong CD15 expression, CD15 is negative or only dimly expressed on abnormal promyelocytes. In the microgranular variant of APL, the leukemic promyelocytes frequently co-express CD2 and may express CD34 at some level.[169,170]

Blast equivalents in AML with monocytic differentiation may exhibit brighter CD45 expression and may overlap with the location of normal monocytes on the CD45-versus-SSC plot. In monocytic differentiation, cells initially express HLA-DR, CD33, and CD64, and with maturation to mature monocytic cells, acquire high levels of CD14 and CD300e. Acute monoblastic and monocytic leukemia can express such monocytic antigens to varying degrees. Other

characteristic antigens may be expressed, such as CD4, CD11b, CD11c, CD35, CD36, and lysozyme. Monocytic and myeloid cells share expression of many common antigens (e.g., CD13 and CD33); however, the normal maturation patterns are distinct and exhibit subtle differences in the timing and intensity of expression.[171,172] Expression of antigens typically associated with a different lineage may be seen in monocytic leukemia. For instance, aberrant expression of CD56 may be seen in AML with monocytic differentiation.[168] It is important to note, however, that CD56 may also be expressed in reactive monocytic populations and is not sufficient in isolation to denote neoplasia.[173] CD2 co-expression may be observed in AML with inv(16)(p13.1q22) (AML with *CBFB*::*MYH11* fusion in the WHO 5th edition), a subtype of AML with an expanded abnormal eosinophil component that often shows myelomonocytic maturation and carries a favorable prognosis.[159,174]

In addition to cytogenetic abnormalities, AML can be associated with gene mutations that carry prognostic significance. For instance, *FLT3* internal tandem duplications confer a poor prognosis, whereas *NPM1* mutations in the absence of *FLT3* mutations are associated with a favorable prognosis.[13] Detection of such abnormalities can be particularly helpful for prognostication in normal-karyotype AML. FCM may provide a clue to gene mutations in some cases. For example, in AML, blasts with cuplike nuclear indentations by morphology in conjunction with myeloperoxidase expression and decreased or absent CD34 and HLA-DR expression have been associated with *FLT3* and *NPM1* mutations.[175-177]

True pure erythroid leukemia is a rare entity. Immunophenotypically, it can be highlighted by bright expression of

CD71 and glycophorin A. Erythroid blasts in pure erythroid leukemia with less evidence of maturation may lack glycophorin A. CD36 is also expressed in erythroid progenitors and may be observed in erythroid leukemia.[13,159] Interpretation, however, should be made with care, as both CD36 and CD71 are not lineage-specific. In addition, as glycophorin A is positive on mature red blood cells, lysis of red blood cells before staining is critical to avoid a false-negative result.

Blasts of acute megakaryoblastic leukemia characteristically express CD36 and can exhibit high FSC as a result of the larger size and volume of the cell relative to typical myeloblasts. Expression of CD36, the platelet glycoproteins, CD41, CD61, and CD42 (to a lesser extent) are also noted. Myeloid antigens CD13 and CD33 may be expressed. Because this entity is uncommon among AML cases (<5%), it is important to fully exclude the consideration of an undifferentiated acute leukemia, another subtype of AML, a plasmacytoid dendritic-cell neoplasm, or lymphoblastic leukemia in the immunophenotypic workup.[13] Careful examination of lymphoid markers, terminal deoxynucleotidyl transferase (TdT), and myeloperoxidase may be helpful. Also, care should be taken in the interpretation of CD41, CD42, and CD61, as platelets adhering to the surface of blasts or monocytes may lead to a false-positive result with these reagents.[13,159]

A recognized group of AML in children that may occasionally be associated with megakaryocytic differentiation is AML with an RAM immunophenotype (RAM are the initials of the first patient in whom this immunophenotype was described).[168,178] This subset of AML is characterized by expression of bright CD56 with dim-to-absent CD45

and CD38 without HLA-DR. AML with an RAM immunophenotype is sometimes associated with a *CBFA2T3–GLIS2* fusion, and studies suggest this subtype has a poorer overall prognosis.

Finally, when considering an AML diagnosis, one entity that may be included in the differential diagnosis is a blastic plasmacytoid dendritic-cell neoplasm (BPDCN). These are neoplasms of plasmacytoid dendritic cells (PDCs) that typically involve the skin, blood, and marrow. Both normal and neoplastic PDCs usually occupy the standard CD45-versus-SSC–defined "blast region" and express high levels of CD123 with HLA-DR and CD4. Unlike normal mature PDCs, neoplastic PDCs associated with BPDCN usually express strong CD56. A thorough immunophenotypic profile is needed to identify and definitively distinguish this entity from other CD56-positive hematopoietic neoplasms, including some AMLs and neoplasms of NK/T-cell origin.

B Lymphoblastic Leukemia/Lymphoma

The blasts of B lymphoblastic leukemia/lymphoma (B-ALL) typically express B-cell markers (CD19, CD22, cCD79a), with markers denoting immaturity (CD10, TdT, CD34, dim CD45). Surface Ig is almost always negative (though rare exceptions are described), and CD20 is often negative but may be expressed, often at a low level. Normal bone marrow contains B-cell precursors (hematogones) that can be increased in children and in the setting of bone marrow regeneration.[179] Hematogones demonstrate coordinated expression of many of the same markers listed earlier in very conserved patterns associated with normal B-cell maturation,[179,180] whereas B-ALL typically expresses patterns of antigen expression that deviate from

that seen on normal hematogones (**Fig. 4-11**).[181] An understanding of normal hematogone antigen expression is critical for distinguishing a leukemic blast from a regenerating hematogone and is particularly important in the setting of MRD detection.

Similar to AML, there are some immunophenotypic correlates with genotype. For instance, in B-ALL with a t(1;19)(q23;p13.3) translocation fusing the *TCF3* and *PBX* genes, there is often a relatively mature immunophenotype (increased CD45, decreased CD34, and expression of cytoplasmic mu chain) and co-expression of CD9.[13] An association also exists between B-ALL lacking expression of CD10 and CD24 and aberrant expression of CD15 and 11q23 translocations involving the *KMT2A* gene, a poor prognostic feature.[13] Conversely, intense co-expression of CD10 with dim-to-absent expression of both CD9 and CD20 is characteristic of the prognostically favorable t(12;21)(p21;q22) *ETV6*::*RUNX* translocation.[13,182,183] Identification of these immunophenotypic features provides the first clue that cytogenetic studies may yield prognostically important information and prompt appropriate clinicopathologic correlation.

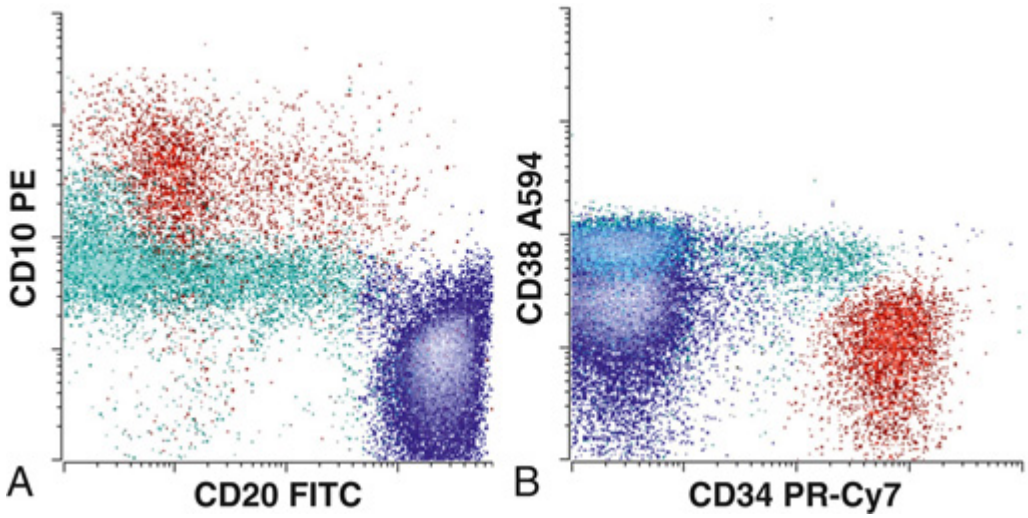

FIGURE 4-11. Residual disease in acute leukemia.The histograms depicted in panels **A** and **B** show all CD19-positive B cells from a bone marrow specimen of a patient with a history of B lymphoblastic leukemia/lymphoma. Normal mature B cells *(dark blue)*, normal hematogones *(aqua)*, and abnormal blasts *(red)* are shown. Normal hematogones have a predictable and conserved pattern of expression of antigens including CD10, CD20, CD34, and CD38; abnormal blasts are easily identified, as they express abnormally high CD10 and CD34 and lack CD38. This pattern is not seen with normal hematogone maturation and allows separation of the abnormal blasts from the normal mature and maturing B cells. Additional examples of minimal residual disease (MRD) in acute leukemia are seen in Chapter 56 (Evaluation of Bone Marrow After Therapy).

T Lymphoblastic Leukemia/Lymphoma

In T-ALL, blasts typically express T-cell markers in conjunction with markers of immaturity.[13,159,160] The most commonly expressed T-lineage markers are cytoplasmic CD3 and CD7, though variable expression of CD2, CD5, and occasionally surface CD3 may be seen. CD4 and CD8 may be double positive, double negative, or singly expressed. TdT is typically expressed and indicates immaturity. Occasionally, CD34 expression can be seen as well. CD1a and CD10 may be expressed in some cases, and aberrant myeloid antigen expression, most commonly CD13 and/or CD33, has been observed.

Normal T-cell precursors are not present in significant numbers in the bone marrow; however, T-cell precursors are abundant in thymic tissue. Thymic T cells (as may be seen in a normal thymus, thymic hyperplasia, or thymoma) show a spectrum of maturation with highly conserved patterns of antigen expression. In contrast to normal thymic tissue, in which a spectrum of maturation is seen, T-ALL shows both aberrant antigen expression and relatively homogeneous antigen expression, allowing distinction of T-ALL and thymic tissue in most cases.[118,119]

One subtype of T-ALL that can be distinguished by FCM is the early T-cell precursor (ETP) subtype. ETP T-ALL has been associated with poorer response to induction therapy and poor prognosis in some, though not all, studies and has a distinctive immunophenotype with lack of CD8, lack of CD1a, and expression of myeloid and/or stem-cell antigens (CD13, CD33, CD34, CD117, and/or HLA-DR).[184,185] Although initial studies describing this entity indicated CD5 is characteristically dim or absent, more recent

studies suggest a lesser significance to the pattern of CD5 expression.[186,187]

Acute Leukemia of Ambiguous Lineage

Occasionally, an acute leukemia may defy classification as AML or ALL. One may consider such cases as undifferentiated acute leukemia or mixed phenotype acute leukemia (MPAL). Before a diagnosis of undifferentiated acute leukemia or MPAL is rendered, an extensive FCM panel is required and should include the lineage-specific markers cytoplasmic CD3 and MPO, monocytic markers, and several B-cell markers.[13,162,163] A designation of MPAL may be considered when two distinct blast populations of different lineages are present or if a single blast population is present expressing antigens of more than one lineage (often myeloid or monocytic and lymphoid). In the later situation in which a single blast population is present, criteria for assigning lineage are well defined in the WHO 5th edition. To assign B-cell lineage, strong expression of CD19 with one additional strongly expressed B-cell antigen (CD10, CD22, or CD79a) or weak expression of CD19 with two additional strongly expressed B-cell antigens is required. Assignment of myeloid lineage requires expression of myeloperoxidase (with intensity of expression in part exceeding 50% of that expressed by a mature neutrophil) or expression of two or more monocytic antigens (non-specific esterase, CD11c, CD14, CD64, or lysozyme). Finally, T-lineage assignment requires strong expression of CD3 (surface or cytoplasmic). For lymphoid antigens, strong expression is defined as expression exceeding in part at least 50% of that of mature B or T lymphoid cells. Though the WHO 5th edition provides guidelines for intensity

of antigen expression, a percentage threshold for positivity has not been specified. When undifferentiated acute leukemia is a consideration, evaluation of antigens to definitively exclude megakaryocytic, erythroid, and PDC differentiation is recommended as well.

Measurable Residual Disease Testing in Acute Leukemia After Therapy

MRD testing is emerging as a powerful prognostic factor in ALL and AML in both pediatric and adult populations.[188-192] In general, MRD detection by FCM relies on the principle that normal populations have very conserved and predictable patterns of antigen expression that accompany normal maturation. In neoplastic cells, these normal patterns are altered secondary to underlying mutations, leading to immunophenotypes not seen in normal healthy tissue. FCM allows for recognition of abnormal cells in the setting of normal background tissue, such as resting or regenerating marrow, on the basis of these immunophenotypic abnormalities. The two primary approaches to identifying MRD are the difference from normal (DfN) approach and the leukemia associated immunophenotype (LAIP) approach. In the DfN approach, normal maturation patterns are established using a standardized antibody panel, and leukemic cells are defined by their differences from normal patterns. In the LAIP approach, immunophenotypic abnormalities associated with leukemic cells are established at the time of diagnosis, and subsequent time points are evaluated for these abnormal populations. Most effective strategies incorporate elements of both approaches, and a combined approach is recommended by

the European LeukemiaNet (ELN).[193] MRD testing allows for identification of abnormal blast populations at very low levels (often less than 1 cell in 10,000 can be detected).[194-196] This topic will also be discussed in **Chapter 57**: Evaluation of the Bone Marrow After Therapy.

Modern therapeutic regimens for acute leukemia often incorporate antigen-directed targeted therapies. Overlap may exist between targeted antigens and antigens used for gating or assessing populations by FCM in the post-therapy setting. Awareness of therapies used and the potential effect they may have on the immunophenotypic characteristics of normal and leukemic cells is critical for accurate interpretation of FCM data in the post-therapy setting.[197]

CHRONIC MYELOID NEOPLASMS

The use of FCM in evaluating chronic myeloid stem neoplasms (MSNs), such as myelodysplastic syndromes/neoplasms and myeloproliferative neoplasms, has grown significantly. Advances in this area have paralleled the increase in our understanding of normal patterns of antigen expression on myeloid progenitors and maturing myeloid forms and the routine use of multiparametric FCM in clinical laboratories. As has been noted, very conserved and synchronized patterns of antigen expression accompany normal maturation, and such patterns are disrupted in MSNs. Identifying aberrant antigen expression by FCM can aid in the diagnosis of MSN and, in some cases, FCM may provide additional prognostic data. Similar to MRD testing, it is worth emphasizing that experience and knowledge of how normal antigenic patterns can shift in various

reactive states (for instance, growth factor administration or with bone marrow regeneration after a toxic marrow insult) is critical for accurate interpretation of FCM data.[171]

Myelodysplastic Syndromes/Neoplasms

Although bone marrow morphology with concurrent cytogenetic study remains the gold standard for the diagnosis of myelodysplastic syndromes/neoplasms (MDS), a significant number of patients have blood and bone marrow findings that make diagnosis and classification difficult.

Studies have demonstrated that FCM is useful in distinguishing MDS and non-MDS cytopenias,[198] with some studies suggesting the presence of abnormalities by FCM in patients with cytopenias correlates with morphologic dysplasia, genetic data, and risk of progression. For this reason, FCM is increasingly being used in diagnostic evaluation of potential MDS cases in an attempt to increase sensitivity and specificity of diagnosis.[199-201] This is reflected in the inclusion of FCM in the minimal diagnostic criteria for MDS developed at a 2006 international working conference.[202] Moreover, the 2016 *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues* recognized the utility of FCM in the evaluation of MDS.[13] Specific recommendations have not yet been provided in the WHO 5th edition or ICC classification systems. The ELN provides suggested standardized strategies for incorporation of FCM data into the diagnostic workup of MDS.[203,204]

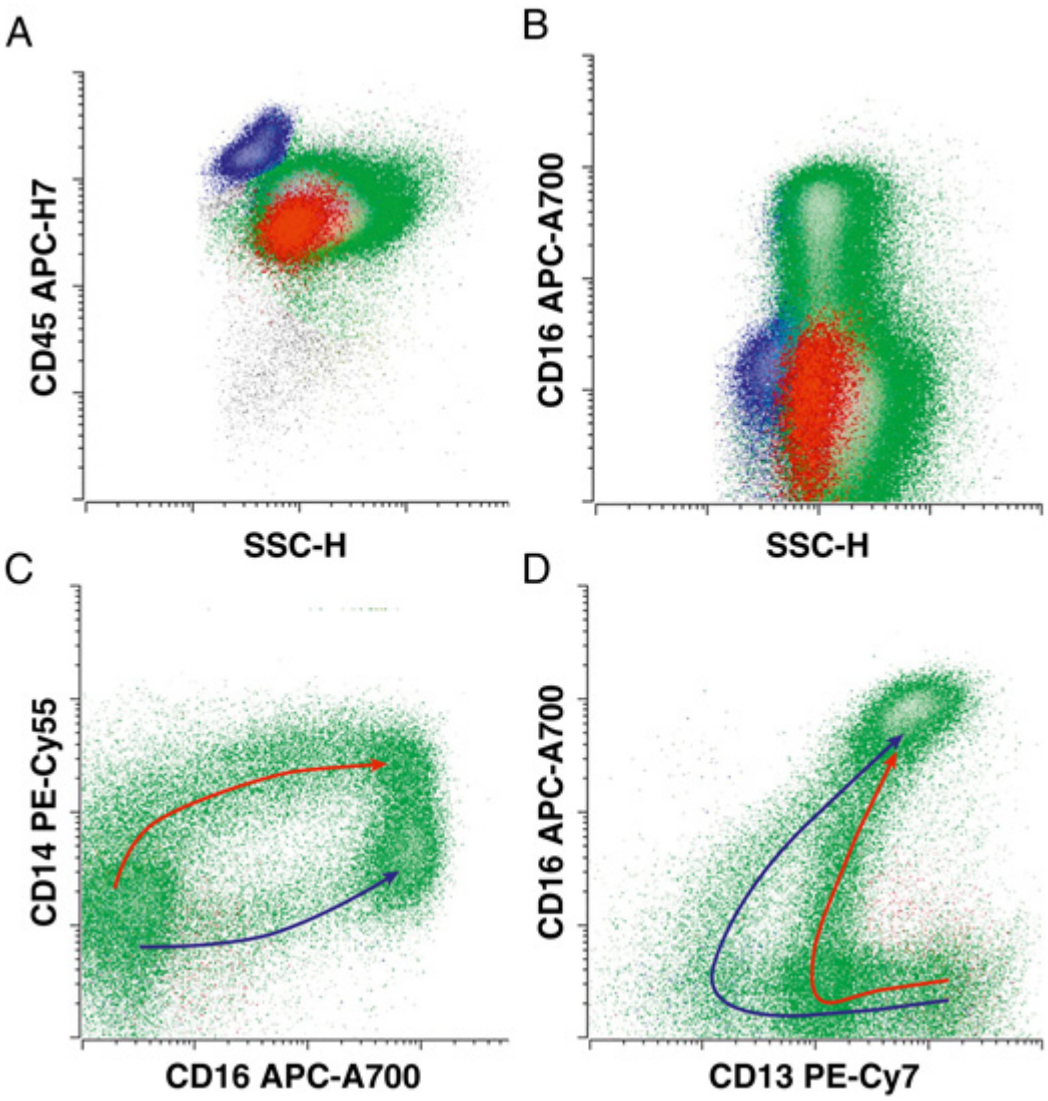

FIGURE 4-12. Flow cytometry in myelodysplastic syndrome (MDS).**A** and **B,** Decreased side scatter (SSC) on neutrophils. Dot plots show all viable cells from a bone marrow specimen involved by MDS. Lymphoid cells *(blue)* and maturing granulocytic cells *(green)* are shown. Myeloid blasts *(red)* are highlighted for emphasis. The maturing granulocytic population has variable SSC in this case, with the SSC of a major subset of granulocytic cells overlapping

with the position of blasts and monocytic cells on the CD45-versus-SSC plot. The mature neutrophils (myeloid forms with the highest levels of CD16) have very low SSC (similar to that of the myeloid blasts). This finding is analogous to the neutrophil cytoplasmic hypogranulation seen in some cases of MDS. **C** and **D,** Abnormal patterns of antigen expression on maturing granulocytic forms. Dot plots show all maturing granulocytic cells from a bone marrow specimen involved by MDS. Normal granulocytic cells show conserved and variable expression of CD13, CD14, and CD16 markers, with maturation from the promyelocyte stage to the mature neutrophil. In this specimen, two separate lines of maturation can be appreciated. The *blue arrows* follow normal patterns of antigen expression with maturation, but in this case, a second, aberrant clone is present with increased expression of CD13 and CD14 *(red arrows)*.

Normal hematopoiesis is characterized by conserved changes in the appearance of cells that are predictable and orderly and accompany different stages of maturation. In MDS, normal hematopoiesis is rendered ineffective, leading to dysplastic changes that alter normal morphology. Similarly, this ineffective hematopoiesis leads to alterations in the normally highly conserved patterns of antigen expression accompanying normal maturation. Such changes in antigen expression can be detected by FCM and may

be seen in a variety of lineages ranging from myeloid blasts to maturing granulocytic, monocytic, and erythroid cells.

No single MDS-specific immunophenotype exists; rather, it is a difference from normal that characterizes MDS. In addition, identifying MDS by FCM is best approached by considering several populations (e.g., myeloid progenitors, maturing myeloid forms, monocytic forms, erythroid forms). The types of abnormality seen on myeloid blast typically fall into one of four categories: (1) abnormal intensity of antigen expression; (2) dyssynchronous expression of mature and immature antigens; (3) homogeneous expression of an antigen normally expressed at varying levels during maturation; and (4) expression of an antigen of a different lineage (e.g., expression of CD5, CD7, or CD56 on myeloid blasts). Maturing granulocytic forms may show decreased SSC (**Fig. 4-12A** and B), paralleling the decreased cytoplasmic granularity seen in dysplastic neutrophils by morphology. In addition, maturing myeloid or monocytic forms may show aberrant patterns of antigen expression (e.g., an aberrant pattern of CD11b or CD13 vs. CD16 (**Fig. 4-12C** and D) or an increase or decrease in the intensity of a normally expressed antigen. Detection of the multiple characteristic immunophenotypic abnormalities that have been described in MDS depends on incorporation of large numbers of antibodies in a multiparameter panel. Antigens that are useful in detecting MDS on myeloid progenitors, maturing myeloid populations, and monocytic populations include, but are not limited to, CD5, CD7, CD10, CD11b, CD13, CD14, CD16, CD33, CD34, CD38, CD56, CD117, and HLA-DR.[171,198-201,205-209] Occasional associations between genotype and immunophenotype have also been described in MDS.[210]

Evaluation of erythroid precursors can be challenging, in part because specimen preparation often involves red cell lysis; however, several abnormalities have been described by FCM in association with erythroid maturation and include aberrancies in expression of CD36, CD71, and CD117.[206,211,212]

Myeloproliferative Neoplasms

Many patients with chronic-phase chronic myeloid leukemia (CML) are easily monitored for residual disease by molecular methods, typically fluorescence in situ hybridization (FISH), to detect the t(9;22) translocation. Virtually little-to-no role exists for FCM in a patient with chronic-phase CML with stable white blood cell counts. However, FCM can provide accurate blast characterization and an approximate enumeration of blasts and basophils for patients with increasing white blood cell counts who may be undergoing disease progression or entering blast phase.

The role of FCM is limited in uncomplicated polycythemia vera or essential thrombocythemia. In fact, neither isolated thrombocytosis nor polycythemia is considered an indication for FCM per the 2006 Bethesda International Consensus Recommendations for FCM or the American Society of Clinical Pathology Choosing Wisely recommendations for peripheral blood FCM.[5,213]

In cases of myelofibrosis, either primary or secondary to a preceding myeloproliferative neoplasm, abnormalities are often seen by FCM and are typically similar to those described regarding MDS.[172,200] There appears to be some relationship between the presence of cytogenetic abnormalities and FCM abnormalities in

non-CML myeloproliferative neoplasms[172]; however, further study is needed to clarify the role of FCM in these diseases.

Acknowledgements

The authors wish to acknowledge Dr. Raul C. Braylan, Dr. Jonni Moore, Dr. Maryalice Stetler-Stevenson, and Dr. Brent Wood for their mentoring of colleagues and influential work in applying FCM to the diagnosis of hematolymphoid disorders.

Chapter 5: Molecular Pathology of Hematologic Neoplasms

Eric Duncavage, Gabriel C. Caponetti, and Adam Bagg

OUTLINE

INTRODUCTION

BIOLOGICAL AND TECHNOLOGIC ISSUES

- **Nucleic Acid Isolation and Tumor Enrichment**
- **Antigen Receptor Gene Rearrangements**
- **Major Molecular Methodologies**

LYMPHOID NEOPLASMS

- **Mature Lymphoid Neoplasms**
- **Precursor Lymphoid Neoplasms**

MYELOID NEOPLASMS

- **Acute Myeloid Leukemias**

Myeloproliferative Neoplasms

Myeloid and Lymphoid Neoplasms Associated With Eosinophilia and Tyrosine Kinase Gene Fusions

Mast Cell Neoplasms

Myelodysplastic Syndromes/Myeloproliferative Neoplasms

Histiocytic and Dendritic Cell Neoplasms

Myelodysplastic Syndromes

Hematologic Neoplasms With Germline Predisposition

POTENTIAL PITFALLS OF MOLECULAR TESTING

Antigen Receptor Gene Rearrangements

Translocations and Mutations in Normal Individuals

SUMMARY AND CONCLUSIONS

INTRODUCTION

The understanding of the biological basis of hematopoietic diseases in general and neoplasia in particular has been significantly

enhanced by the application of genetic and especially molecular techniques to the study of these diseases. The use of Southern blotting hybridization analysis, although now obsolete, initiated the integration of molecular biological techniques into hematopathology and substantially contributed to understanding the clonality status of lymphoproliferative disorders. The availability of molecular probes to the antigen receptor loci facilitated identification and molecular cloning of partner genes involved in chromosomal translocations underlying the pathogenesis of several lymphoid neoplasms. The advent of the polymerase chain reaction (PCR) had a dramatic effect on the ability to interrogate primary tissue samples for molecular aberrations, including refinement of the understanding of clonality in lymphoproliferative disorders and detection of translocations. The versatility of PCR resulted in adaptations including rapid amplification of cDNA from both 5′ and 3′ ends for the identification of genes involved in chimeric fusions driving hematopoietic neoplasia. The implementation of PCR-cycle sequencing profoundly enhanced the ability to identify somatic point mutations in a variety of neoplasms and tracking of clonal genetic aberrations after therapy and in tumor progression. The advent of next-generation (also referred to as massively parallel or high throughput) sequencing (NGS) has offered the most detailed view of genetic aberrations in hematologic neoplasms, with an acute myeloid leukemia (AML) genome being the first cancer genome to be sequenced.[1] This development led to the refinement of our understanding of the genetic basis of most hematologic neoplasms and facilitated diagnoses and recognition of prognostically relevant subgroups. Today the identification of recurrent genomic findings is required for

the accurate classification of many myeloid neoplasms and has an increasing role in the assessment of a number of lymphoid neoplasms.[2-5] Sequencing-based diagnostics have been rapidly adopted by most laboratories, with applications extending into risk-stratification, therapy selection, and tracking disease after therapy. A summary of the major genomic methods and their features is presented in **Table 5-1**.

BIOLOGICAL AND TECHNOLOGIC ISSUES

Nucleic Acid Isolation and Tumor Enrichment

The successful implementation of molecular techniques depends on the reliable and robust extraction of nucleic acids. The protocols implemented depend on the specimen type and quantity and on the quality and amount of nucleic acid required for the assay. PCR now permits the analysis of a wide variety of specimens, including fresh whole blood, bone marrow aspirates, plasma, serum, fine-needle aspirates, tissue biopsies, cultured cells, cerebrospinal fluid, dried aspirates, and fixed paraffin-embedded tissues. Microdissected cells or ethanol-fixed cells scraped from cytologic slide preparations may have DNA or RNA extracted that is readily interrogated by molecular techniques. For most clinical applications, filtration column-based DNA/RNA extraction methods are preferred over simpler ethanol precipitation methods which tend to result in lower DNA/RNA purity. In general, DNA or RNA extracted from fresh (nonfixed) samples is preferable to formalin-fixed samples; fixation results in extensive nucleic acid cross-linking and lower (often <200 base pairs [bp]) fragment sizes.[6]

Table 5-1

ARGR, Antigen receptor gene rearrangements; *b,* base; *CG,* cytogenetics; *CMA,* chromosomal microarray; *CNA,* copy number alterations; *D,* diagnosis; *FISH,* fluorescence in situ hybridization; *kb,* kilobase; *M,* monitoring; *Mb,* megabase; *MRD,* measurable residual disease; *NGS,* next-generation sequencing; *PCR,* polymerase chain reaction; *R,* relapse; *RT-PCR,* reverse transcription *PCR*; *SNV,* single nucleotide variants; *SV,* structural variants; *TAT,* turnaround time (actual TAT availability and cost may vary significantly by region and laboratory); *WGS,* whole genome sequencing; *WTS,* whole transcriptome sequencing.

Antigen Receptor Gene Rearrangements

B cells and T cells exhibit the unique characteristic of undergoing somatic DNA rearrangements of their antigen receptor gene loci to produce functional immunoglobulin (IG) and T-cell receptor (TR) molecules, respectively. The rearrangements provide a critical mechanism for generation of a significant component of the diversity of the IG and TR genes involved in the specificity of the immune response.[7]

Immunoglobulin Gene Rearrangement

The IG genes encode IGs that are produced exclusively by B cells. IG molecules are heterodimeric proteins consisting of two identical heavy chains linked with two identical light chains, kappa (κ) and

lambda (λ). The IG genes are located on different chromosomal loci: the IG heavy (IGH) chain gene is located on 14q32, the IG kappa on 2p12, and the IG lambda on 22q11.

In the germline configuration, the antigen receptor loci are composed of noncontiguous segments of DNA grouped into variable (V), diversity (D), joining (J), and constant (C) regions. All three IG genes contain V, J, and C regions, but only IGH genes contain D regions (**Fig. 5-1A**). The IGH region contains approximately 45 functional V region segments and approximately 23 DH and 6 JH segments. The human IG constant region contains 11 C region segments that define nine functional IG classes and subclasses (IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE). Early in B-cell development in the bone marrow, genetic recombination events occurring at the DNA level result in the initial joining of a single D segment with a J segment, followed by rearrangement of the partially rearranged D-J region to a V segment (**Fig. 5-1B**). These events are mediated by the recombination activating gene (RAG1/RAG2) complex. The fused V-D-J region is transcribed and joined to the Cμ (IgM) constant region segment at the RNA level. Successful rearrangement of one of the IGH loci is followed by light chain gene rearrangement, which entails direct joining of the V to J region segments because the light chain genes lack D segments. IGK rearrangement typically precedes IGL rearrangement. Further combinatorial diversity is generated by addition of nongermline palindromic (P) nucleotides through nonhomologous end joining and incorporation of nontemplated (N) nucleotides by the enzymatic activity of DNA terminal deoxynucleotidyl transferase (TdT).

The IGH genes are subjected to somatic hypermutation (SHM), which occurs when naïve B cells migrate to germinal centers of peripheral lymphoid tissues such as lymph nodes and is generally followed by class-switch recombination (CSR), where the IGH V-D-J segment is fused to a G, A, or E constant region segment, leading to expression of the gamma (γ), alpha (α), or epsilon (ε) heavy chains, respectively, in the B cells, although there is also evidence that CSR can occur prior to SHM.[8] Both of these processes are mediated by activation-induced cytidine deaminase.[7] SHM refines the specificity of the antibodies, with the highest level occurring in the third complementarity-determining region (CDR3). Thus primers for IGH gene rearrangements by PCR are designed to anneal to the framework regions where the hypermutation rate is lowest.

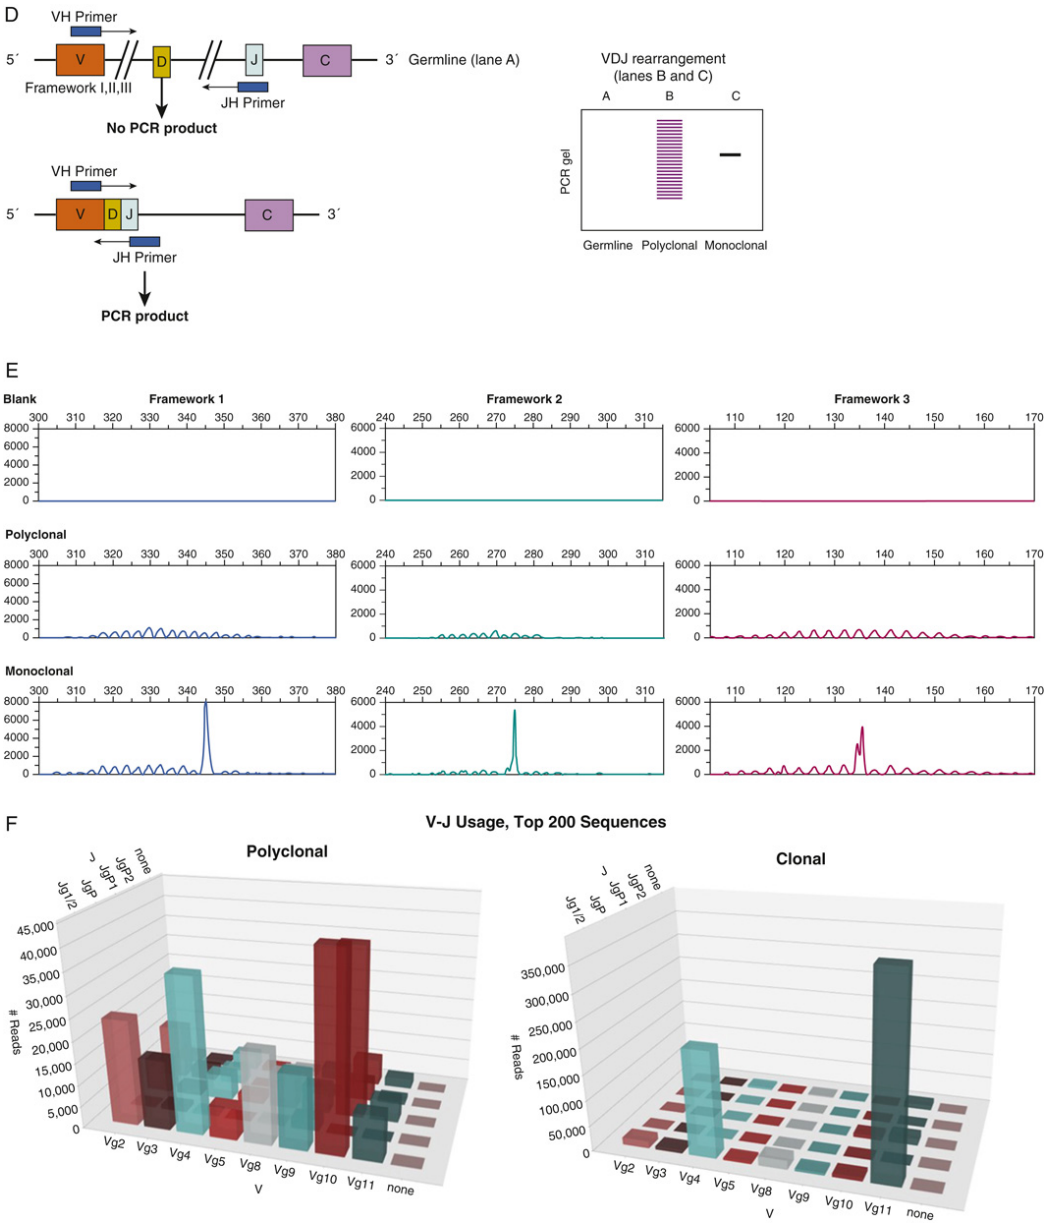

FIGURE 5-1 Structure of antigen receptor gene rearrangements and detection of clonal populations by polymerase chain reaction and next-generation sequencing (NGS).**A,** Schematic representation of germline configurations of immunoglobulin heavy chain and kappa (κ) and lambda (λ) light chain loci. *Top panel,* Immunoglobulin heavy (IGH) chain locus

contains variable (V) region genes, diversity (D) region, joining (J) region, and constant (C) region segments. *Middle panel,* IG light chain kappa locus contains V, J, and C regions but no D regions. *Bottom panel,* IG lambda light chain locus contains V, J, and multiple C loci and no D regions. **B,** Genetic recombination events occur at the DNA level, resulting in rearrangement of the D segment with a J segment, followed by rearrangement of the partially rearranged D-J region to a V segment. In loci containing V, D, J, and C regions, the process begins with a D-J (partial) rearrangement, followed by a V-D-J or V-J (complete) recombination. This process is mediated by the RAG1/2 recombinases and results in deletion of all intervening segments and juxtaposition of V-D-J or V-J segments that are otherwise distantly (several kilobases) located from one another in the genome. **C,** Schematic representation of germline configurations of the T-cell receptor (TR) TRA/D, TRG, and TRD genes. Note the absence of D region segments in the TRG genes.**D,** Schematic representation of antigen receptor gene rearrangement detection by the polymerase chain reaction (PCR) and gel electrophoresis. Illustrated example is representative of PCR for clonality analysis of IGH gene showing V, D, J, and C regions

separated by several kilobases. Consensus primers complementary to the V segment framework regions are used to recognize the majority of V regions. Similarly, primers recognizing the J region genes are used in the PCR amplification. No amplification occurs in the germline configuration from nonlymphoid cells because the V and J region genes are located several kilobases apart (lane A). A similar pattern would be observed in a no-template (H_2O only) control. In reactive conditions, each B cell has a unique (V-D-J or V-J) rearrangement and thus when resolved by gel electrophoresis yields a polyclonal ladder pattern reflective of the different recombination event (lane B). By contrast, clonal B-cell populations yield a single or two prominent bands on gel electrophoresis (lane C). **E,** Capillary electropherogram depicting IGH PCR clonality assay. *Top panel,* Template-free control. *Middle panel,* Polyclonal control showing multiple peaks distributed over a broad size range. *Bottom panel,* Single dominant peak in all three framework panels. **F,** TR clonality testing by NGS. This is similar to PCR-based testing, except that detection of PCR products is performed by sequencing instead of amplicon sizing by gel or capillary electrophoresis (CE). In this example, the plot on the left shows results

from a reactive lymph node. Similar to electrophoretic detection, a number of peaks are seen representing various combinations of V (x-axis) and J (z-axis) regions. The height of the plot (y-axis) represents the number of reads (abundance). The plot on the right shows a T-cell lymphoma. Note that essentially all observed sequences are accounted for by two bars indicating a clonal cell population with two rearranged TRG loci. Image F courtesy of Bijal Parikh, MD PhD.

T-Cell Receptor Gene Rearrangement

The TCR is a heterodimeric protein comprising either an alpha (α) and beta (β) chain or a gamma (γ) and delta (δ) chain. A mature T cell expresses only either an αβ or a γδ TCR heterodimer. The TCR alpha (TRA) and delta (TRD) genes are located on chromosome 14q11.2. Indeed, the entire TRD gene is located within the TRA locus. The TRB encodes the TCRβ protein and is located at chromosome 7p34, and the TRG gene encodes TCRγ and is located at 7p14.

Precursor T cells migrate from the bone marrow to the thymus to undergo maturation into competent peripheral (postthymic) T cells. The hierarchy of the TCR gene rearrangements occurring during T-cell development is such that the TRD genes are the first to undergo rearrangement, followed by the TRG genes. As a result of these rearrangements, a small proportion of T cells express γδ TCRs. The TRB genes are the next to undergo rearrangement.[9] This is detectable in the CD4-positive CD8-positive cortical thymocyte

stage. The TRA genes are the next to rearrange, and this leads to deletion of the TRD locus that is located within the α locus. Successful TRB and TRA rearrangements lead to expression of TCRαβ protein expression. T-cell maturation occurs with further thymic selection and egress of the mature T cells out of the thymus to the periphery.[10] This sequence of rearrangements has practical implications for T-cell clonality assays because although most T-cell lymphomas express TCRαβ, most of these will have undergone rearrangements of the TRG genes. The TCR gene rearrangement process is similar to that which occurs at the IG loci (**Fig. 5-1C**). Notably, however, SHM does not occur in the TCR genes and thus does not contribute to diversity of the T-cell repertoire, and CSR does not occur either.

Determination of Clonality in Lymphoid Proliferations

The expression of IG light chain molecules in mature B cells provides an avenue for convenient immunophenotypic assessment of clonality status in mature B-cell populations. Thus whereas clonality may be readily determined in mature B cells by immunophenotypic methods, determination of clonality by immunophenotyping of T cells has been technically challenging,[11] although more user-friendly flow cytometric assays have become available.[12] Clonality assays are frequently used in clinical contexts to establish the monoclonal status of suspicious lymphoid proliferations. Notwithstanding their utility in this setting, it is important to recognize that monoclonality is not equivalent to malignancy, and all laboratory results should be interpreted within relevant clinicopathologic contexts. Conversely, the inability to detect clonality does not exclude the presence of

(lymphoid) malignancy, since these assays have a well-documented low rate of false negativity.

PCR (which will be discussed in detail) is the main approach for the detection of clonal lymphoid proliferations. The assay design uses consensus V region and J region primers in PCR amplification followed by electrophoresis. Because each lymphocyte harbors a unique IG or TR gene rearrangement, clonality analysis of polyclonal populations yields multiple products distributed over a size range within the amplicon detection limit of the PCR assay. This was historically visualized as a smear in agarose gels, a ladder pattern on polyacrylamide gels (**Fig. 5-1D**), or a multipeak pattern in capillary gels that are capable of single-base resolution. Protocols for the assessment of clonality evaluating the IGH, IGK, and IGL loci have matured to routine use and standardization in clinical laboratories.[13] Similarly, standardized T-cell clonality assays assessing the TRG, TRB, and TRD have also been successfully implemented.[14]

Capillary electrophoresis (CE), which separates products based on nucleotide number (amplicon size), has emerged as a reliable platform for the analysis of products from clonality PCR assays. Other options have included denaturing gradient gel electrophoresis and heteroduplex analysis on polyacrylamide gels that discriminate PCR products based on denaturation parameters, such as melting temperature, reflecting their nucleotide composition. Polyclonal B- or T-cell populations yield a pseudo-gaussian distribution of peaks when analyzed by CE (**Fig. 5-1E**). Each of the discrete peaks represents many antigen receptors that yield amplicons of identical size.[13,15,16]

Digital sequencing methods (i.e., NGS) have begun to replace CE for detection of clonal PCR products. Rather than relying on fragment size, sequencing-based detection determines the actual clonal sequence of the rearranged IG or TR locus and can be useful in resolving oligoclonal patterns caused by similarly sized PCR products that may represent different rearranged sequences (**Fig. 5-1F**).[17,18]

Interpretation

Monoclonal populations are identified with CE when one or two dominant peaks substantially above that of the next highest background peak are observed. The sensitivity of clonality assays by PCR and CE reliably permits detection of neoplastic populations at a 5% level in the background of polyclonal lymphocytes. Detection of clonal populations by sequencing generally involves counting the number of unique clonal sequences generated to determine whether any one (or two) sequences represents a larger than expected fraction (generally >3%–5%) of total observed sequences. A major advantage of sequencing-based detection is that the exact clonal sequence can be compared with previous cases, allowing for distinction between new primary lymphomas versus recurrences.[18] Sequencing-based detection can also be used for measurable residual disease (MRD) detection by simply querying all reads to determine whether a previously identified clonal sequence is present. These methods can be used from blood, marrow, or cell-free DNA to detect MRD in mature and precursor lymphoid neoplasms.[19,20]

Major Molecular Methodologies

Polymerase Chain Reaction

The PCR is primer-directed amplification of nucleic acid using a thermostable polymerase and thermal cycling to generate exponential copies from a DNA template.[21] In most protocols, the PCR requires template DNA, thermostable DNA polymerase, oligonucleotide primers that are designed to be complementary to target sequence, deoxynucleoside triphosphates (dNTPs) from each base (dATP, dTTP, dGTP, dCTP), and Mg^{2+}. For amplification of RNA, a cDNA synthesis step precedes the PCR amplification. The amplification reaction entails multiple cycles of denaturation, primer annealing, and extension. For conventional PCR, postamplification analysis involves electrophoresis of the products generated from the amplification reaction. Authentication of the product generated is based on visualization of bands or peaks of expected size for the amplicon. An alternative and popular quantitative format is real-time PCR, wherein homogeneous assays are performed with amplification product synthesis and analysis simultaneously occurring in a closed-tube format. A perfectly efficient PCR assay (i.e., doubling of DNA copy number every cycle) in one 30-cycle reaction yields approximately 10^9 (or more accurately 1,073,741,824 = 2^{30}) copies of product. This amplification capacity renders PCR extremely sensitive and well suited for the molecular diagnosis and monitoring of hematopoietic neoplasms that carry characteristic genetic aberrations, such as translocations. Accordingly, PCR is more sensitive than conventional cytogenetics or fluorescence in situ hybridization (FISH) analysis and can detect 1 neoplastic cell in a background of 1000 normal cells when interrogating antigen receptor gene rearrangements or 1 copy of mutant DNA in a background of approximately 10^5 wild-type DNA sequences.

Real-Time Polymerase Chain Reaction

Real-time PCR is used to describe a technique wherein nucleic acid synthesis is monitored during amplification rather than at the end point. The technique incorporates fluorescent reporters into the amplification reaction and is monitored by use of thermal cyclers integrated with devices configured to monitor fluorescence. Fluorescence monitoring during the amplification reaction permits identification and quantification of the PCR product.[22] Because amplification and detection occur simultaneously in the same tube, real-time PCR is advantageous in that the process is rapid and less subject to the risk of contamination arising from liberation of amplicons from opening tubes before electrophoresis. Further, the ability to perform accurate relative and absolute quantification has favored the use of this approach in many applications in the clinical laboratory.

The fluorescent reporters used in real-time PCR assays are broadly classified into two major categories: non-specific nucleic acid binding dye-based and specific probe-based methods. The profile of real-time PCR resembles a logistic regression curve wherein there is an initial lag phase followed by a log-linear or exponential phase and finally a plateau phase. Efficient PCR is associated with doubling of the number of copies of the target, and this is reflected in a flat linear phase. At a critical fractional cycle number known as the cycle threshold (C_T), there is an exponential increase in product abundance reflected as geometric increases in the fluorescence levels above background. Accordingly, the C_T is defined as the number of cycles required for the fluorescent signal to exceed the background signal. C_T levels vary in inverse proportion to the starting quantity of

the target nucleic acid in the sample, that is, the C_T value is lower when the initial quantity of the template DNA is most abundant. Conversely, lower levels of input template will yield higher C_T values.

Three basic fluorescence chemistries are used in real-time monitoring of amplification reactions: double-stranded DNA binding dyes (generally no longer used in the clinical laboratory), fluorescently labeled primers, and target-specific probe-based detection.

Fluorescently Labeled Primers

Oligonucleotide primers labeled with fluorophores at the 5′ end may be used in real-time PCR assays.[23] In the simplest configuration, a primer can be labeled with one fluorophore at the 5′ end, and amplification results in increased synthesis of labeled template accompanied by changes in fluorescence that occur with hybridization. In another design, a primer can be labeled both with a fluorophore on the 5′ of a hairpin and a fluorescence quencher toward the 3′ end. During PCR, the primer undergoes conformational changes that result in separation of the fluorophore from the quencher, leading to an increase in fluorescence during each round of extension in the amplification reaction. Use of different-colored fluorescently labeled primers offers the ability to perform multiplex assays because the different products may be monitored in different fluorescence channels.

Target-Specific Probe Detection

Target-specific probes that are complementary to a sequence within the amplicon may be incorporated into PCR. The use of target-specific probes provides an additional level of specificity for

detection of the authentic product. In general, three specific probe chemistries may be used in target-specific probe-based amplification reactions: hybridization probes, hydrolysis probes, and dual-mechanism probes. The target-specific probe-based mechanisms depend on fluorescence resonance energy transfer (FRET) occurring between donor and acceptor fluorophores, and fluorescence emissions from the reporter probe may be monitored as an index of amplicon synthesis during PCR.

Hybridization Probes

In this design, two oligonucleotide probes are included in the amplification reaction. Both probes are complementary to an internal sequence within the target and hybridize to the template. The 5′ probe has a donor fluorophore on its 3′ end, and the second probe carries the acceptor (reporter) fluorophore on its 5′ end (the interfluorophore distance is optimally ≤1 nucleotide). Excitation of the donor fluorophore with light leads to emission with FRET transfer to the acceptor fluorophore. The transferred energy results in the release of light at a longer wavelength that is then detected. This approach provides high specificity of identification of the target amplicon because fluorescence is a FRET–based event requiring hybridization of the probes to the template. Hence, low background levels are observed, ensuring high signal discrimination from background noise. The hybridization probe-based formats also offer the opportunity for further verification of the identity of the product by probe melting curve analysis. Despite this advantage and the exquisite specificity associated with this design, the requirement for

a total of four oligonucleotides in the amplification reaction results in a higher level of complexity in hybridization probe-based assays.

Hydrolysis Probes

Target-specific probe-based systems may also be designed with fluorescently labeled probes configured with a donor fluorophore conjugated to the 5′ end of the probe and a quencher at the 3′ end. Because of the 5′ → 3′ exonuclease function of Taq polymerase, the probe is hydrolyzed and the donor fluorophore is separated from the influence of the quencher, leading to fluorescence. Because the target-specific probes are hydrolyzed, probe-melting analysis for verification of the identity of the amplicon is not reliably performed with this probe design. However, minor-groove binders functioning as hybrid stabilizing agents can be incorporated with the probe to improve the robustness of this system. Overall, the simplicity (only three oligonucleotides in the reaction for detection of one target) and specificity provided by this design favor its use in routine clinical settings.

Dual-Mechanism Probes

Several probe designs incorporate both hybridization and hydrolysis mechanisms. These include the hairpin probe-based system that incorporates a design wherein the loop portion of the hairpin is complementary to a specific target sequence and the stem sequences are a shorter segment on either end of the probe with base complementarity to one another. The 5′ end of the hairpin is labeled with a donor fluorophore and the 3′ end with a quencher. Hybridization separates the donor from the quencher and results in

fluorescence. This approach is highly specific because fluorescence is based on a hybridization event to the authentic target.

Product Detection and Quantification

Real-time PCR provides an analytically precise and technically robust approach for quantification of nucleic acid species in a sample. The quantitative applications of real-time PCR take advantage of the large dynamic range of more than five orders of magnitude. Quantification by real-time PCR is most often achieved by determination of the C_T. The C_T represents a fractional cycle number obtained by interpolation of the amplification profile of the PCR. The C_T may be calculated by a variety of approaches, including the threshold analysis method, in which a baseline level of fluorescence is selected (typically from the early amplification cycles) and adjusted by arithmetic or proportional adjustment methods to represent a normalized baseline. This approach suffers the drawback of yielding less reliable results if sample fluorescence levels are low, as might occur in samples with low copy numbers of the intended target. An alternative and suitable approach not requiring such normalization is the *second derivative* maximum method. In the second derivative maximum method, calculation of the fractional cycle number takes the shape of the amplification curve into consideration. This is advantageous in that there is no requirement for baseline corrections or normalization of fluorescence values. Regardless of method used, well-optimized amplification reactions double template copy numbers with each cycle, and the C_T is inversely related to the logarithm of the initial template concentration (**Fig. 5-2**). Thus a log-fold increase in copy numbers

between samples is reflected in a 3.3 cycle number decrease in CT ($2^{3.3} = 10 = 1$ log). Quantitative real-time PCR assays are continually used for the quantification of fusion transcripts such as *BCR*::*ABL1* in routine clinical diagnostics.

A more recent modification of real-time PCR is droplet digital PCR (ddPCR).[24] Using this approach, single DNA or cDNA molecules along with primers, fluorescently labeled probes, and PCR reagents are added and emulsified in individual nanoliter-sized droplets through the use of microfluidics. PCR is carried out on a standard thermocycler and the droplets are then read by a fluorescent reader to determine whether they are positive (amplified DNA present) or negative (no amplified DNA present). Each ddPCR reaction typically contains more than 10,000 droplets that are read individually. Unlike qPCR, the amount of template DNA with a mutation is not measured based on the number of PCR cycles (C_T value), but is instead calculated based on the abundance of droplets containing the amplified product with the mutation relative to those without the targeted mutation after a fixed number of PCR cycles. The large number of "digital" observations allows for more accurate quantification of targeted regions in the original template DNA, which can be calculated using a Poisson distribution. ddPCR can also be used to detect low abundance mutations such in *JAK2* p.V617F or *KIT* p.D816V in myeloproliferative or mast cell neoplasms, respectively, with sensitivities of 0.1% or better.[25]

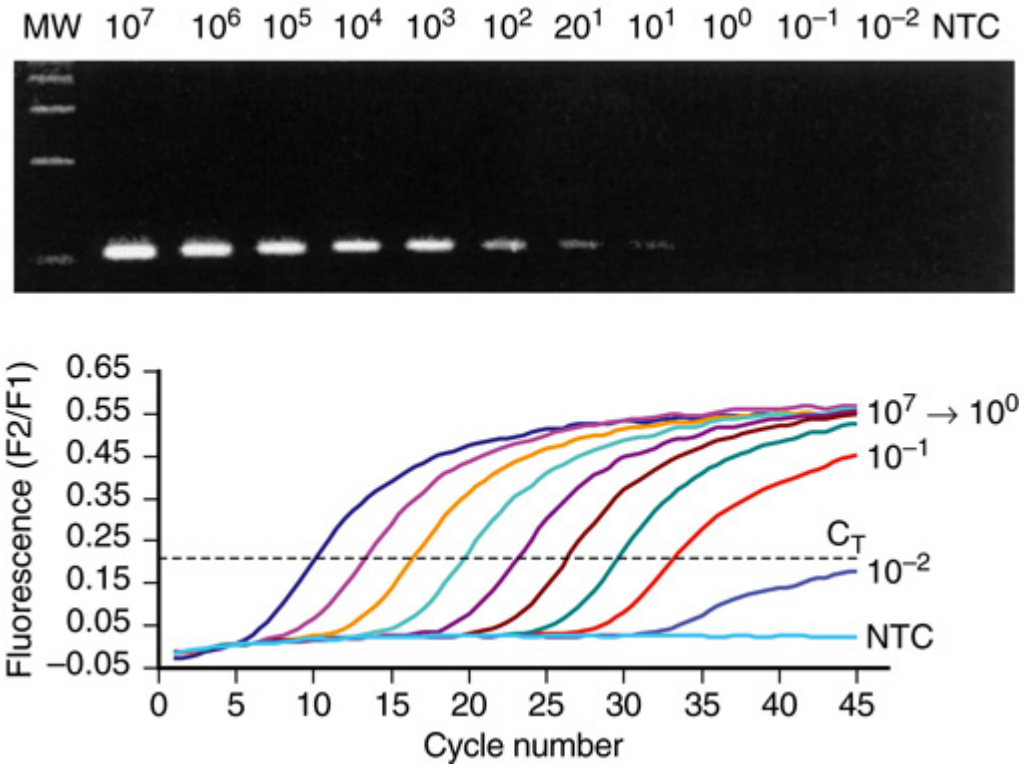

FIGURE 5-2 Quantitative polymerase chain reaction (PCR).*Upper panel,* Conventional quantitative PCR. Serial dilutions of template DNA are amplified over a range of initial template abundance from 10^7 to 10^{-2} copies. Amplification product is visible at 10^1 copies. Such "end-point"–based assays are more susceptible to quantification error because quantification may be performed at the nonlinear points of PCR amplification. *Lower panel,* Quantitative real-time PCR. Serial dilutions as in the upper panel. Crossing thresholds (C_T) increase in magnitude inversely to initial template quantity; although the specimens with 10^7 to 10^0 copies yield similar end-point amounts after 45-plus cycles, those

with greater initial template amounts cross the C_T earlier. For example, the C_T value for the *dark blue line* (reflecting 10^7 copies) is approximately 10, whereas that for the *brown line* (reflecting 10^2 copies) is approximately 25.

Sequencing

Sanger Sequencing

Sanger sequencing is a method of DNA sequencing that uses nonextendable dideoxynucleotide incorporation by a DNA polymerase.[26] The classical dideoxy chain termination method includes a DNA fragment of interest, a DNA primer, a DNA polymerase, and deoxynucleoside triphosphates (dATP, dGTP, dCTP, and dTTP). One of four of the dideoxynucleoside triphosphates (ddATP, ddGTP, ddCTP, or ddTTP) is added to each reaction; the other three nucleotides are the standard unmodified deoxynucleoside triphosphates. PCR cycle sequencing entailing repeated denaturation, annealing, chain extension, and termination steps is used to generate amplicon fragments of different lengths by incorporation of one of the four dideoxynucleotide base analogs (**Fig. 5-3**). The pentose ring in the dideoxynucleotide analogs lacks the 3′ hydroxyl and the 2′ hydroxyl groups. Given that DNA chain extension requires the 3′ hydroxyl group, incorporation of such a base terminates further chain elongation. The fragments generated are fluorescently labeled either by fluorescently labeled primers or by fluorescently labeled dideoxynucleotide terminators. In modern sequencers, the products of cycle sequencing are resolved with

denaturing polyacrylamide gels or, more frequently, CE. Detection is achieved by interrogation of fluorescence signals as the DNA fragments traverse the gel past a detector. When fluorescently labeled primers are used to label the amplified fragments, four tubes are required for separate termination reactions. In assay configurations wherein one color is used, each dideoxy termination reaction mixture is subjected to electrophoresis in a separate lane or capillary. Alternatively, if four fluorophores are used, the termination reactions may be combined in one tube during electrophoresis and resolved with only one capillary. Conventional Sanger sequencing permits routine analysis of DNA fragments of up to 800 to 1000 bases in multiwell plate assays containing 96 or 384 samples in a 2-hour analytical run. Sanger sequencing is capable of reliable detection of mutant alleles constituting 20% of the allele burden in somatic conditions (neoplasms) with heterozygous mutations (**Fig. 5-3**).

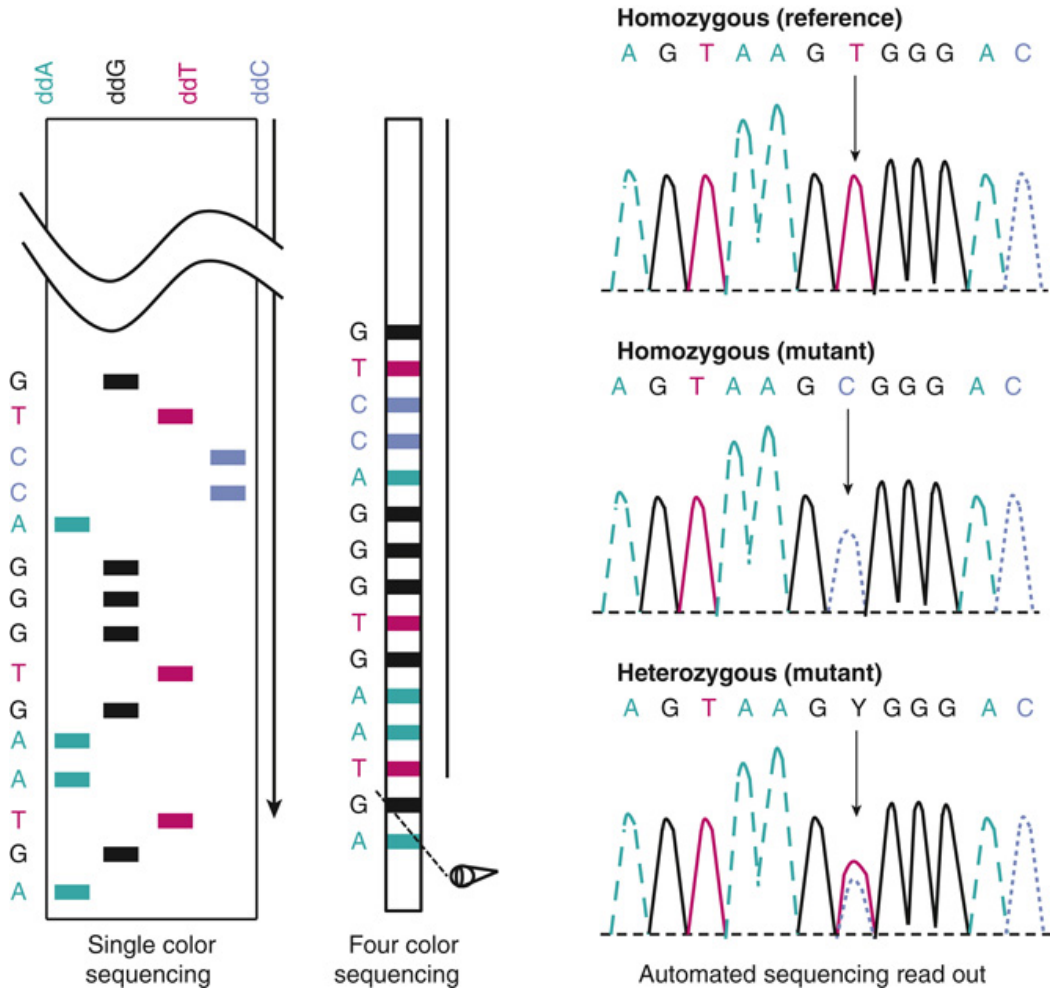

FIGURE 5-3 Sanger sequencing and next-generation sequencing (NGS) workflow.Schematic representation of Sanger sequencing using single-color and four-color sequencing. *Left panel,* Sanger sequencing with all dideoxynucleoside triphosphates labeled with the same single-color fluorophore (single color) and run on four parallel lanes on a sequencing (slab) gel. Chain termination at different lengths results in each lane's yielding polynucleotides of different lengths ending with the dideoxynucleotide containing the same base. The

DNA sequence of the target is read by progressive identification of sequences with increasing lengths until the last base is reached. *Right panel* , Sanger sequencing with all dideoxynucleoside triphosphates labeled with distinct fluorescence tags: dideoxyadenosine (ddA), dideoxyguanosine (ddG), dideoxythymidine (ddT), and dideoxycytidine (ddC) and products run on one lane. Each base is discriminated by color, and sequencing is by progressive length based on migration time through a capillary that is read by a fluorescence detector positioned to detect changes in fluorescence. These changes are reflected as colored peaks identifying each base. *Right panel,* Sequencing electropherogram showing base-specific color peaks representing bases in their respective positions. *Upper right panel,* Reference sequence. *Middle right panel,* Homozygous T-C transition (single-base substitution). *Bottom right panel,* Heterozygous T-C transition showing superimposed peaks representative of both bases.

Next-Generation Sequencing

Next-generation sequencing (NGS) is arguably the most disruptive of technologic advances in molecular biology since the development of PCR and has dramatically transformed the landscape of molecular diagnostics testing. NGS has also been referred to as massively

parallel sequencing or high throughput sequencing. Typical workflow for the role of NGS for the clinical diagnostics laboratory is represented in **Figure 5-4**. In the research setting, NGS is used for de novo genome assembly, DNA resequencing, transcriptome and exome sequencing, and epigenomics studies that continue to reveal novel insights in constitutional genetics and the genetic basis of disease.[27] NGS is not a single technology, but represents multiple sequencing approaches that rely on massive parallelization of the sequencing process to generate massive amounts of sequencing data for comparatively little cost.[27] Historically, most NGS technologies have relied on short-read sequencing approaches, where read lengths are generally shorter (75–400 bp) than those generated by Sanger sequencing. However, newer approaches now facilitate read lengths of >10 kb, allowing for sequencing of low complexity parts of the genome and providing the ability to phase genomes by reconstructing haplotypes.[28] Clinical diagnostic sequencing is currently dominated by two platforms, one made by Illumina Inc. (San Diego, CA) and the other by Thermo Fisher Scientific (Waltham, MA). However, with expiration of key patents in the field, it is expected that new companies and technologies will enter the space, further driving down the cost of sequencing.

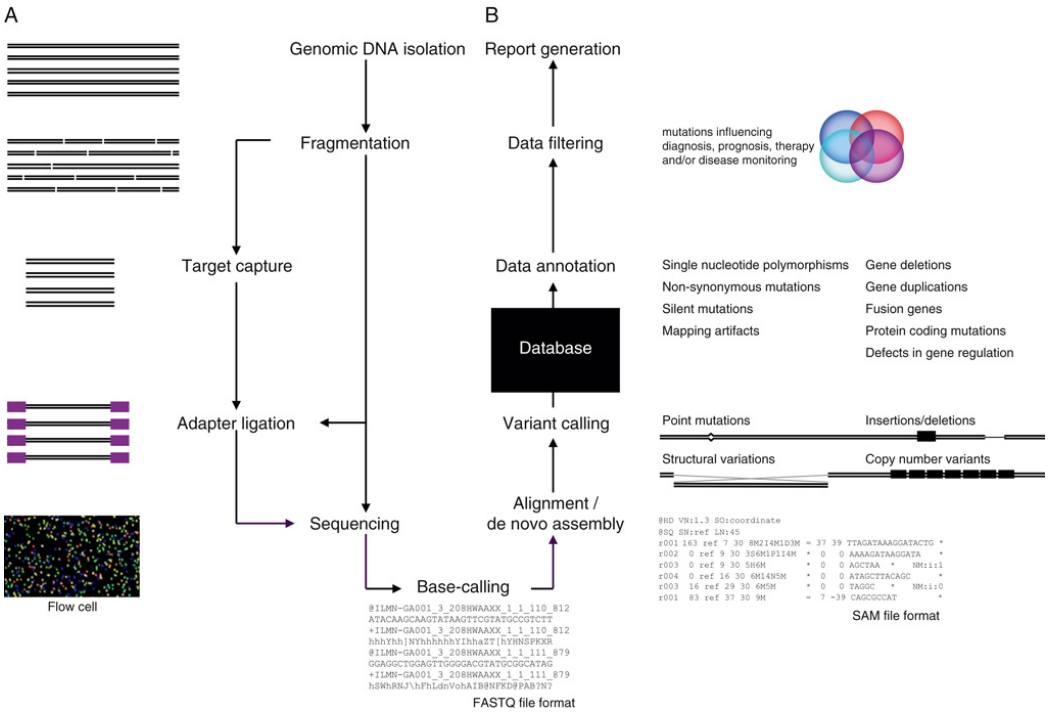

FIGURE 5-4 Next-generation sequencing (NGS) workflow.**A,** Extracted nucleic acid is fragmented by one of several methods (e.g., shearing or ultrasonic fragmentation). This is followed by ligation of adapter sequences (oligonucleotide sequences that permit universal amplification) onto the ends of the DNA fragments. Nucleic acid (DNA or cDNA) templates are generated from the libraries, which are then clonally amplified for subsequent sequencing. When sequencing is complete, the analysis pipeline for NGS data includes a preprocessing step to remove adapter sequences, end trimming and removal of low-quality reads, mapping to the reference genome, or de novo alignment and alignment of compiled sequences.

B, Sequence analysis includes base-calling, detection of single nucleotide variants and insertion/deletion variants, chimeric fusion sequences (RNA sequencing), and juxtaposed genomic sequences from noncontiguous loci resulting from large structural variations such as deletions, insertions, and translocations. Sequence variants are annotated in a first step, and secondary annotation is achieved by conversion of the nucleic acid variants to amino acid sequences. Further annotation may be performed, including prediction of the functional consequences of DNA or encoded amino acid variations (e.g., deleterious). Interrogation of databases to catalog variants and to assess association with specific clinical end points, such as diagnostic, prognostic, and therapeutic implications, may be performed and indicated in an integrated report.

The Illumina series of instruments use a sequencing-by-synthesis approach coupled with reversable fluorescent dye terminators. With this chemistry, DNA libraries are flowed over a glass substrate called a *flow cell* where they bind fixed oligonucleotides complementary to either the 3′ or 5′ end of the library.[29] The affixed DNA is then amplified in situ in a process known as *bridge amplification* to produce clusters of replicated DNA molecules attached to the flow cells. Fluorescently labeled dNTPs (four colors to one color per base in older chemistries, or two colors in newer sequencing by synthesis

chemistries) are added to the flow cell along with DNA polymerases; these dNTPs are modified with a reversible terminator so that only a single fluorescently labeled dNTP can be added to the newly synthesized strand. Once the dNTP is added to the synthesized DNA molecule attached to the flow cell, the flow cell is scanned with a laser to determine the color (identity) of the incorporated base. The reversable block on the incorporated nucleotide is then removed, completing the sequencing cycle, and the process repeated, allowing for reads as long as 300 bp. Illumina sequencing is also capable of paired-end sequencing where the library is sequenced from both the 3′ and 5′ directions, which allows for better read-mapping during analysis.

The Thermo Fisher Ion Torrent sequencing approach is similar in that it also uses a sequencing-by-synthesis approach but uses a unique semiconductor pH-based detection method instead of fluorescently labeled bases. In this approach, DNA template molecules are confined to nano wells on the sequencing chip and deoxyribonucleotide triphosphate bases are added one at a time (as opposed to Illumina chemistry, where all four bases are added during each sequencing cycle). If the added base is incorporated into the synthesized DNA molecule, a proton (H+) and pyrophosphate molecule are released. Release of the proton is measured by detecting a change in pH in the nano well using a complementary metal oxide semiconductor (CMOS) sensor embedded below. The order that bases are added to the flow cells is called the *flow space* and is recorded in the sequencing data file along with the identity of the incorporated base called the *base space*. Advantages of this approach over fluorescently labeled nucleotide include more rapid

data acquisition and less reagent consumption. Disadvantages include difficulty resolving long homopolymer runs (>7 bp) and lower overall throughput compared with dye-labeled methods.

In addition to commonly used Illumina and Thermo Fisher sequencing approaches, several other technologies have entered the clinical market. PacBio HiFi sequencing (Menlo Park, CA) allows for accurate single molecule read lengths of >15 kb and has found utility in phasing genomes and sequencing in difficult-to-resolve, low-complexity areas of the genome.[30] Oxford Nanopore Technologies sequencing (Oxford, UK) uses a α-hemolysin-like protein nanopore to generate real-time sequencing data by passing single DNA molecules through the pore and measuring changes in charge across the pore. Charge profiles are specific for each base and allow for rapid real-time sequencing without the need for chemical detection systems, which allows for much smaller instrument sizes. Nanopore sequencing can generate long reads and directly detect methylated cytosine bases, similar to PacBio. Disadvantages of the Nanopore approach include higher error rates than other methods and lower overall throughput than competing methods.

Multiple other sequencing platforms are beginning to enter the market, including MGI Tech (Shenzhen, China), Ultima Genomics (Newark, CA), Roswell Biotechnologies (San Diego, CA), and Element Biosciences (San Diego, CA). Regardless of platform, all sequencing methods first require library preparation, which can include targeting of specific regions of the genome.

Sequencing Concepts

One of the most important sequencing concepts is coverage or sequencing depth, which refers to the number of reads that span a given position in the genome. To a large extent the sensitivity or limit of detection of an NGS assay is based on the amount of coverage obtained. Sequencing coverage is ultimately determined by the user and is a function of both the sequencing instrument and the number of samples in each run. Coverage can be further divided into total coverage and unique coverage, which reflects the number of nonduplicate reads. Unique coverage is related to the number of DNA molecules present in the library and determines the limit of detection for a particular sample.

Another important sequencing concept is the variant allele frequency (VAF). The VAF is simply a measure of abundance for a particular mutation or variant and is calculated by dividing the number of reads with a particular mutation by the total number of reads that span the position. For inherited or germline variants, VAF are either 50% (heterozygous) or 100% (homozygous); however, for somatic (acquired) variants, mutation VAFs can range from <1% to 100%, the latter when there is a concurrent copy number alteration.

DNA Library Preparation

An important first step in library preparation involves DNA fragmentation by acoustic sonication or enzymatic methods, followed by DNA repair and end polishing. Synthetic DNA adapters are then covalently ligated to each 3′ and 5′ end of the genomic DNA, termed an *insert*, by a DNA ligase enzyme to create a library. These adapters are platform-specific universal sequences that are used for amplification of the library fragments and are required to anneal the

libraries to the flow cell. DNA libraries prepared from genomic DNA can be used directly for whole genome sequencing (WGS) or enriched for exome or targeted sequencing. During the library preparation step, sample-specific indexes (usually 8–10 bp DNA oligonucleotides) can be added to one or both ends of the library. Sample indexes allow for multiple libraries to be sequenced in a single run, optimizing throughput and reducing overall costs. Once sequencing data is generated, reads can be demultiplexed based on the sample index. The use of multiplex sequencing is common in clinical applications. Libraries may also be modified to include unique molecular identifiers (UMIs, also called *molecular barcodes*). UMIs are generally synthesized as random (degenerate) oligonucleotides ranging from 8 to 16 bp, but they may also represent fixed sequences in some implementations. UMIs allow for tracking of individual DNA molecules throughout the amplification and sequencing process and are typically used for high sensitivity sequencing applications where low background error rates are required.

Whole Genome Sequencing

WGS provides a comprehensive annotation of the genome of an individual or sample. WGS provides a detailed map of the structural variations occurring in a genome, including complex and large structural aberrations such as translocations and rearrangements, copy number variations including whole chromosomal additions and losses, loss of heterozygosity, small insertions and deletions, and single nucleotide variations (e.g., point mutations), all within a single assay.[31] While WGS is the simplest NGS method to implement in the

clinical laboratory because of the lack of enrichment steps, until recently WGS was limited to research studies because of the high cost of sequencing and complexity of data analysis. Continued reductions in sequencing costs, coupled with cloud-based and hardware-accelerated informatics platforms, have now made it possible to perform clinical WGS from blood or marrow in as little as 3 days at a cost comparable with conventional multiplatform genomic evaluation.[32] As sequencing costs continue to drop, it is expected that WGS will ultimately replace current cytogenetic testing for hematologic neoplasms.

Transcriptome Sequencing

Transcriptome (RNA) sequencing (RNA-Seq) is a large-scale and comprehensive analytical interrogation of the transcriptome.[32] RNA-Seq entails isolation of RNA, from which a library of cDNA fragments is generated. Adapters are ligated to one or both ends of the cDNA fragments, and each molecule is then sequenced in a massively parallel fashion. Short polynucleotide sequences varying in length from 30 to 400 base pairs are obtained from one end in single-end sequencing or from both ends in paired-end sequencing. RNA-Seq entails conversion of isolated RNA (total or subspecies such as poly[A]$^+$) into a cDNA library to which adapters are attached. The reads obtained from sequencing may be aligned to a reference genome or transcripts or assembled de novo to generate a genome-level transcription map that includes the transcriptional architecture and expression levels of each gene. The flexibility of NGS platforms permits powerful applications, such as massively parallel cDNA sequencing or RNA-Seq, which has led to significant advances in the

characterization and quantification of transcriptomes. Unlike gene expression arrays, RNA-Seq is not limited to detection of known transcripts and thus, RNA-Seq can offer information on small RNAs, such as microRNAs, PIWI-interacting RNAs, and short interfering RNAs with greater dynamic range.[33-35] RNA-Seq also permits characterization of alternative splicing events and gene-fusion identification.[35] RNA-Seq–based gene-fusion identification has been pivotal in the identification of novel gene fusions that are oncogenic drivers in many forms of human cancer, including many hematologic neoplasms.[36-38]

Accordingly, several algorithms have been developed to facilitate the identification of chimeric fusions from RNA-Seq data. These include TopHat-Fusion,[39] ChimeraScan,[40] and deFuse,[41] among others. Although WGS and some targeted sequencing panels can also detect translocations from DNA, this requires sequencing of large intronic regions to identify DNA-level breakpoints, making RNA-Seq more efficient in terms of sequencing usage. Potential disadvantages of RNA-based fusion detection include preanalytic variability in RNA preservation leading to false negative results and the inability to detect translocations that do not result in fusion gene products (e.g. *IGH*::*MYC*).[42] RNA-Seq has also been applied for detection of mutations,[43] but this is subject to variations in the abundance of transcripts. Targeted multiplex panels focusing on multiple recurrently translocated genes that participate as fusion partners in several neoplastic conditions can be configured for diagnosis.

Whole Exome Sequencing

Whole exome sequencing (WES) involves the massively parallel sequencing of protein-coding regions of the genome. This method has dramatically facilitated the investigation of genomic alterations that lead to mutations in coding sequences that are associated with diseases. The human exome contains ~30 million base pairs, thus constituting approximately 1% of the human genome (~3 billion base pairs) and representing approximately 180,000 exons. Both mendelian and somatic genetic abnormalities underlying human diseases are readily identifiable by exome sequencing. WES requires use DNA capture to enrich for protein-coding sequences in genomic DNA. An important consideration is that there is no formal definition of the exome, and exome reagents vary by manufacturer in terms of exactly what regions are included.

The sensitivity of exome sequencing varies depending on the depth of coverage but typically ranges from 2% to 5% VAF given mean coverages of 100× to 500×. Although WES covers all coding regions and is therefore useful for the discovery of coding region mutations, exome sequencing cannot detect structural variants such as translocations, because breakpoints generally occur in intronic regions. Depending on the analysis methods used, exome sequencing may be able to detect copy number alterations (CNAs); however, there may be difficultly in detecting smaller CNAs in regions of the genome in which there are few or widely spaced gene exons.[44]

Targeted Sequencing

Targeted sequencing panels make up the vast majority of clinical NGS tests performed for hematologic neoplasms. Targeted sequencing methods are similar to exome methods in that they

require enrichment of sequencing libraries for specific target genes or regions. The number of targeted genes varies greatly depending on the application but typically ranges from 5 to 1000 genes. Enrichment technologies can be divided in to two main categories: PCR enrichment (amplicon-based), which is generally faster and suited to small (<50 gene) panels; and capture-based enrichment, which is well suited to larger panels (**Fig. 5-5**). The genes or regions targeted by the panel can be chosen by the laboratory or may be part of a vendor-supplied kit. The major advantages of targeted panels over broader sequencing approaches such as WES or WGS is lower cost and higher sensitivity. By focusing sequencing on clinically significant genes, it is possible to obtain high coverages (500×–1000×) for minimal cost.

Sequencing for Measurable Residual Disease

Advances in sequencing methods, especially error-corrected sequencing using UMIs, have allowed for ultrasensitive sequencing to evaluate for measurable (previously termed *minimal*) residual disease in follow-up blood, marrow, or cell-free DNA (cfDNA) specimens. The limit of detection for these methods typically ranges from 0.1% VAF for detection of somatic mutations in AML to $<10^{-6}$ for detection of clonal IG or TCR sequences in B-lymphoblastic leukemia/lymphoma (B-ALL) or T-ALL. In general, mutations are first identified in a diagnostic sample and subsequent posttreatment samples are evaluated to determine the extent to which these mutations have been cleared. Mutation clearance has become an important biomarker for many hematologic neoplasms and can be

used to assess patient relapse risk or response to a specific therapy.[45-47]

Optical Genome Mapping

Optical genome mapping (OGM) is a technique that allows for detection of structural variants in DNA including translocations and CNAs. In this approach DNA is not directly sequenced and is instead digested by multiple restriction enzymes and stained with a fluorescent dye, creating a fragment map of the genome from which structural variants can be inferred. Modern OGM methods use microfluidics to create restriction maps from numerous single DNA molecules, which are then analyzed to create a high-resolution consensus map. Similar to WGS, OGM has been shown to be more sensitive than conventional G-banded cytogenetics to detect structural variants in myeloid neoplasms.[48,49] OGM is currently less expensive than WGS, making it a potentially appealing technology for clinical laboratories. Limitations of OGM include the requirement for ultrahigh molecular weight DNA and the inability to detect gene-level mutations, including single nucleotide variants and insertions/deletions, the latter of which necessitates running OGM in parallel with panel-based NGS testing for complete genomic evaluation.

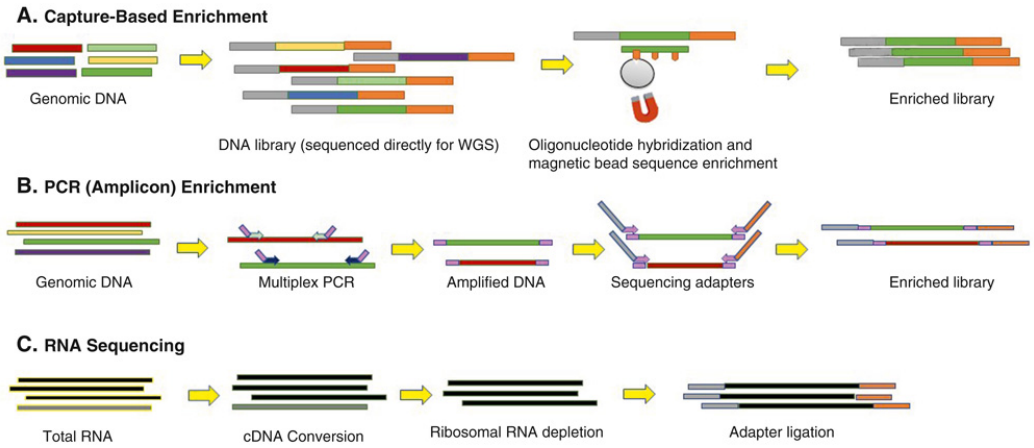

FIGURE 5-5 Capture-based versus amplicon-based enrichment for next-generation sequencing (NGS).**A,** Capture-based enrichment is the most common approach for most clinical sequencing applications. Genomic DNA is generally first fragmented by either mechanical or enzymatic methods. Adapter sequences (specific to the sequencing platform) are then ligated on to the 3′ and 5′ ends of DNA inserts to make a library. This library can be sequenced directly for whole genome sequencing (WGS). The library can also be enriched using oligonucleotide probes to target genes or regions of interest. The probes then bind DNA inserts by sequence-complementary hybridization. Probes are synthesized to contain biotin molecules, allowing for magnetic bead enrichment when coming after the addition of streptavidin-coated magnetic beads. DNA not bound to probes is washed away, leaving a library enriched for specific sequences of interest. **B,**

Amplicon-based sequencing can be implemented in a variety of ways. In the simplest approach, genomic DNA is amplified using primers that target genes or regions of interest, often using multiplex PCR reactions. PCR primers are typically tailed with a short motif that can be recognized by a second set of longer primers with sequencer specific adapters. **C,** RNA sequencing libraries can be prepared multiple ways. In general, total RNA is extracted and converted to cDNA using random hexamer primers. The resulting cDNA is then depleted of ribosomal RNA, and sequencing adapters are added. Similar to DNA, cDNA libraries can be enriched by hybrid capture to focus sequencing to specific regions, permitting for targeted translocation detection or detection of specific transcripts.

Epigenomics

The role of epigenetic changes is increasingly being recognized in the pathogenesis of cancers.[50] The implementation of NGS–based methods may be used for assessing DNA methylations status, mapping of transcription factor occupancy, and evaluation of histone modification. Genome-wide interrogation of DNA methylation can be performed by sequencing libraries before and after treatment with sodium bisulfide. Methylated cytosines will be converted to uracil (thymidine). Post-bisulfide-treated DNA can then be compared with pretreatment data to determine how many cytosine bases have been

replaced by thymidine, indicating the presence of methylation at that position. Less expensive but informative alternative strategies, such as reduced representation bisulfite sequencing and targeted enrichment followed by bisulfite treatment, can also be used.[51,52] Affinity enrichment-based methods with methylcytosine-specific antibodies (MeDIP-Seq) and recombinant methyl binding domains of proteins[53] enable identification of genome regions that are modified by methylation. It is important to note that newer sequencing technologies such as PacBio and Oxford Nanopore instruments can detect methylated cytosines directly and do not require bisulfite sequencing.

Single-Cell Sequencing

Sequencing-based evaluation can now be performed on the single-cell level, allowing for more granular evaluation of genomic events, including dissection of clonal hierarchies. Although not currently used in the clinical setting, single-cell sequencing can identify RNA expression patterns or DNA mutations within individual cells.[54,55] This can be used to define how specific mutations drive changes in gene expression. Single-cell methods have also been adapted to measure protein expression (CITE-Seq) by coupling antibodies to oligonucleotide tags that can be detected by the sequencer in conjunction with DNA or RNA sequencing data.[56]

Bioinformatics and Computational Methods for Next-Generation Sequencing

Bioinformatic analysis remains a challenge and bottleneck in the interpretation of NGS data. Many of the analytical programs still require command line computer languages and can be difficult for

bioinformatics nonexperts to use. Nevertheless, several programs now exist to simplify NGS data analysis by provision of easy-to-use graphical interfaces.

In general, the primary data outputs from each platform typically consist of text files containing sequence reads and the quality scores for each base (typically a FASTQ file). Reads are then aligned to a reference genome in a computationally intensive step using algorithms such as BWA (Burrows-Wheeler Alignment), MAQ (Mapping and Assembly with Quality), Bowtie, and Novoalign to produce a binary BAM or CRAM file.[57-59] The data can be visualized in genome browsers such as IGV (Integrative Genomics Viewer).[60] The next step is to identify sequence variations from reference with specialized algorithms. These algorithms generally use Bayesian rules that compute the probability of a variant's occurring at a specific position while taking into account the known polymorphism rate and sequencing errors. Typically, multiple different variant callers will be used to identify the full spectrum of mutations, including single nucleotide variants, indels, CNAs, and translocations. Variant detection is followed by annotation with gene and transcript identifiers and prediction of the functional consequences of the variants (i.e., nonsynonymous; missense, stop, or frameshift mutations). Once functional annotation is complete, genotypic-phenotypic associations of the individual variants can be determined by querying the published literature or websites that contain information about mutations and disease association (e.g., OMIM for mendelian diseases and COSMIC for cancer). An important consideration in cancer sequencing is separating inherited (germline) variants from somatically acquired variants. This can be

accomplished by comparing cancer data to paired normal tissue or more frequently comparing variant data to population databases such as gnomAD to remove polymorphisms,[61] with testing of uninvolved and blood-uncontaminated tissue (such as cultured skin fibroblasts or hair follicles) being the recommended gold standard.

LYMPHOID NEOPLASMS

Mature Lymphoid Neoplasms

Molecular technologies have a variety of roles in the evaluation of mature and immature lymphoid neoplasms of B-cell, T-cell, and NK-cell lineage, ranging from documenting clonality in morphologically or immunophenotypically equivocal cases to facilitating the diagnosis of specific entities and determining prognosis to defining targets of and responses to therapy.

Mature B-Cell Lymphomas/Leukemias

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Cytogenetic abnormalities in chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) mostly encompass numerical abnormalities that are better detected by FISH than by metaphase cytogenetics and are relevant for risk stratification. Del(13q), del(11q), trisomy 12, del(17p), and del(6q) are the most common.[62-64] When seen in isolation and in <60% of nuclei, del(13q14) portends a favorable prognosis, whereas trisomy 12 predicts an intermediate prognosis; del(11q22-q23) and del(17p13) correlate with aggressive behavior.[63,64] FISH for del(17p13)*(TP53)* is

recommended prior to therapy initiation.[64] A complex karyotype (≥3 chromosomal abnormalities) may be a stronger predictor of poor outcomes than del(17p) or *TP53* mutation in patients treated with ibrutinib-based regimens, while a highly complex karyotype (≥5 chromosomal abnormalities) is an even more robust adverse prognostic factor.[62,63] Patients with unmutated IGHV (≥98% germline sequence homology) have a poorer outcome than those with SHM.[62-64] VH3-21 usage (of stereotype subset 2) correlates with unfavorable prognosis independent of the IGHV mutational status.[63] Cases carrying the R110-mutated lambda V3-21 light chain gene defines a subgroup with specific biological features and an unfavorable prognosis independent of IGHV mutational status.[65]

The most commonly mutated genes in CLL/SLL include *NOTCH1, ATM, SF3B1, TP53, BIRC3, POT1,* and *MYD88* (**Table 5-2**) and, with the exception of *MYD88,* they portend unfavorable prognosis.[63,64,66,67] *TP53* mutations are also associated with resistance to cytotoxic chemotherapy independent of 17p chromosome status, and patients with this mutation (or del17p) are instead treated with BTK or BCL2 inhibitors or immunotherapy.[62-64] BTK, PLCG2, and *CARD11* mutations confer resistance to BTK inhibitors,[68] while *BCL2* mutations and other mechanisms may underlie resistance to venetoclax.[69] Risk-stratifying prognostic scores incorporate several of the earlier mentioned genomic prognostic markers.[62,63] Genetic testing in CLL/SLL is also of value in determining whether diffuse large cell lymphomas arising in this setting are clonally related (true Richter transformation) or de novo, which is of prognostic relevance, noting that even the latter may show mutational profiles reminiscent of those seen in CLL/SLL.[70]

Follicular Lymphoma

Follicular lymphoma (FL) is characterized by the presence of t(14;18)(q32;q21) in ~85% of cases, which juxtaposes *BCL2* next to IGH, leading to BCL2 overexpression and apoptosis inhibition.[71-73] FISH/karyotypic evaluation for *BCL2* translocation is not necessary for diagnosis of FL as long as *BCL2* immunohistochemical positivity is demonstrated in germinal center B cells. FL grade and the presence of a *BCL2* translocation are inversely related.[4,74] *BCL2* rearrangements are not specific for FL.[72,75-77] Some subtypes of FLs either lack the *BCL2* translocation (testicular FL, pediatric-type FL), or display it in only in minor subsets (primary cutaneous follicle center lymphoma, PCFCL).[78,79]

Certain deletions and gains, biallelic *B2M* mutations/deletions, *TP53* or *PIM1* mutations, and other genomic abnormalities may associate with a higher risk of transformation to diffuse large B-cell lymphoma (DLBCL).[80] The rare acquisition of *MYC* rearrangement in FL is currently not sufficient for the diagnosis of high-grade B-cell lymphoma,[81] although these cases might have more adverse outcomes[4] or develop the so-called "lymphoblastic transformation" of FL.[82] *BCL6* translocations (seen in 10%–15% of cases) appear to predict an aggressive course[71,72]; association with high histologic grade FL is controversial.[74]

Genes involved in epigenetic regulation (*KMT2D, EZH2, CREBBP,* and *EP300*) are frequently mutated in FL (**Table 5-2**).[71,72,78,83] Other frequently mutated genes in FL include *BCL2, TNFRSF14, ARID1A, CARD11, STAT6*, *MEF2B,* and *IRF8*.[71,72,78] Although uncommon, *TP53* mutations/deletions and *CREBBP* deletions are associated with decreased overall survival (OS).[78,83,84] Mutational

status of *EZH2, ARID1A, MEF2B, EP300, FOXO1, CREBBP,* and *CARD11* helps predict treatment outcome of front-line immunochemotherapy.[71,72,83] The mutational profile of FL may also help tailor treatment with targeted therapies. Mutations of histone modifiers render the disease amenable for treatment with histone deacetylase inhibitors, and *EZH2*-activating mutations (Y641) predict response to *EZH2* inhibition.[71]

Genomic features may help distinguish less-common types of FL that tend to lack *BCL2* rearrangements from systemic (nodal) FL. PCFCL shows no *BCL6* translocations, and displays del(1p36) in 10%.[72,78] The presence of two or more mutations in *CREBBP, KMT2D, EP300,* and *EZH2* and the presence of a *BCL2* translocation can help distinguish secondary cutaneous involvement by systemic (nodal) FL from PCFCL.[79] In pediatric-type FL, the most common genomic abnormalities include del(1p36) and *TNFRSF14, MAP2K1,* and *IRF8* mutations.[72] *BCL2*-rearrangement-negative, *CD23*-positive follicle center lymphoma, a provisional new entity in the 2022 ICC, presents with localized inguinal involvement, often a predominantly diffuse growth pattern, and harbors frequent *STAT6* mutations.[4,85]

Table 5-2

BCR, B-cell antigen receptor; *JAK/STAT*, Janus kinase/signal transducer and activator of transcription; *NF-κB*, nuclear factor kappa B; *RAS/MAPK*, rat sarcoma virus/mitogen-activated protein kinase.

* Includes deletions.

† Mainly in ocular MALT lymphoma.

‡ Mainly in IGHV4-34-positive hairy cell leukemia and hairy cell leukemia variant.

In situ follicular neoplasia (ISFN) is an incidental early germinal-center lymphoid neoplasia that shares many genomic aberrancies with FL, including the presence of t(14;18)(q32;q21)/*IGH*::*BCL2,* del(1p36), and *EZH2, TNFRSF14,* and *KMT2D* mutations.[72]

Although FL is among the lymphomas with the lowest levels of circulating tumor DNA (ctDNA), evaluation of ctDNA in FL appears to be promising in predicting prognosis, evaluating MRD, and assessing tumor volume.[86]

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is characterized by the presence of t(11;14)(q13;q32)/*IGH*::*CCND1* in >90%.[73,87,88] FISH is far superior to PCR for the detection of *CCND1* translocations.[89] FISH/karyotypic evaluation for *CCND1* translocation is not necessary for diagnosis of MCL as long as CCND1 immunohistochemical positivity is demonstrated. In cases in which cyclin D1 overexpression is observed (typically by immunohistochemistry), but no *IGH*::*CCND1* fusion is detected by

FISH, the possibility of *IGK*::*CCND1* or *IGL*::*CCND1* rearrangements should be suspected[90,91]; a subset of these rearrangements is cryptic, even to FISH.[92] *CCND2* or *CCND3* is translocated predominantly with IG light chain genes or their enhancers in the majority of the rare cases of MCLs without *CCND1* rearrangements.[91,93]

Nodal and leukemic nonnodal MCL are two subtypes of the disease that differ clinically, immunophenotypically, and in their development.[88] Conventional nodal MCL typically shows unmutated IGHV; mutations in *ATM, CDKN2A, TP53, RB1, KMT2D, CCND1,* and *BIRC3* (**Table 5-2**); and a variety of copy number abnormalities (CNAs), while the more indolent leukemic nonnodal variant of MCL exhibits mutated IGHV, a comparatively stable genome, fewer epigenetic modifications, more frequent del(8p21.3), and +8q.[94]

Disease progression in MCL is associated with acquisition of mutations in *ATM, TP53, CDKN2A,* and *CCND1*.[87] *TP53* abnormalities, *MYC* translocations, complex karyotypes [≥3 chromosomal abnormalities in addition to t(11;14)(q13;q32)], a higher number of CNAs, and the degree of DNA methylation is associated with poor outcomes.[87,88,94-96] The prognosis of leukemic nonnodal MCL can be negatively affected because of a high number of DNA methylation changes, mutations in *TP53* and *ATM*, or del(13q14).[88,97] *TP53* mutations confer resistance to both chemotherapy and ibrutinib in MCL.[87,88] Mutations in *CCND1* and in genes involved in chromatin modification, oxidative phosphorylation, or the noncanonical NK-κB pathway have also been implicated in resistance to ibrutinib or disease progression.[87,88]

Currently, real-time quantitative PCR amplification of clonal IGH or *IGH*::*CCND1* rearrangements is the gold standard for MRD

monitoring in MCL; however, ddPCR may be a technically advantageous methodology with better quantification.[98,99] The detection of ctDNA appears to be a promising methodology for the assessment of prognosis and MRD.[87,88,99]

Marginal Zone Lymphoma

Marginal zone lymphoma (MZL) subtypes include extranodal MZL of mucosa-associated lymphoid tissue (MALT lymphoma), nodal MZL (NMZL), splenic MZL (SMZL), primary cutaneous marginal zone lymphoproliferative disorder (PCMZLPD) (which has been reclassified as no longer being termed a lymphoma), and pediatric MZL (PMZL).[73]

The majority of MZLs show SHM of IGVH indicative of transit through the germinal center.[100,101] The presence of the ongoing mutations and the biased usage of certain IGHV segments, seen in all MZL subtypes, suggest that lymphomagenesis in MZL may be antigen-driven.[100,101] MZLs display a variety of recurrent chromosomal translocations, mostly seen in MALT lymphomas (but not in other MZL subtypes),[101] and numerical abnormalities.[101-103]

Extranodal Marginal Zone Lymphoma of Mucosa-Associated Lymphoid Tissue

The translocations associated with MALT lymphomas mainly include t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), and t(3;14)(p14.1;q32); the frequencies with which these occur vary markedly with the primary site of disease and the putative etiology (**Fig. 5-6**).[73]

t(11;18)(q21;q21)/*BIRC3*::*MALT1* is specific for MALT lymphoma[100] and is detected in 40% to 50% of gastric, intestinal,

and pulmonary cases, and less commonly in other organs.[101] Testing for *BIRC3*::*MALT1* at diagnosis may help guide treatment as it is associated with lack of tumor response to alkylating agents and eradication of *H. pylori*.[101] t(14;18)/*IGH*::*MALT1* is detectable in 3% to 20% of MALT lymphomas, typically in the ocular adnexa, lung, liver, salivary glands, and skin.[101,103] t(1;14)(p22;q32)/*IGH*::*BCL10* is observed in <5% of MALT lymphomas from various anatomic sites.[101,103,104] t(3;14)(p14.1;q32)/*IGH*::*FOXP1* is found in ~10% of MALT lymphomas, mainly from the thyroid, ocular adnexa, and skin.[101] Numerical chromosomal abnormalities in MALT lymphoma more frequently include +3 (<85% of cases), +18 (~20%), and various gains and losses.[101]

Mutations in MALT lymphoma mainly affect *TNFAIP3, CREBBP, KMT2C, TET2, SPEN, KMT2D, LRP1B,* and *PRDM1* (**Table 5-2**)[101,105,106] and these vary according to the anatomic locations involved (**Fig. 5-6**).[73,101] *TP53* abnormalities and t(3;14)(p14.1;q32)/*IGH*::*FOXP1* portend high-grade transformation of MALT lymphomas.[101,107] TNFAIP3 inactivation is associated with reduced lymphoma-free survival in ocular adnexal MALT lymphoma.[101]

Nodal Marginal Zone Lymphoma

Trisomy of 3 and 18, gains of 2p15, 3p25, and 3p14, and losses of 1p36, 1p21, 6q23, and 12q21 are the most frequent cytogenetic abnormalities in NMZL.[102] The most common mutations involve *PTPRD, NOTCH2,* and *KLF2* (**Table 5-2**).[100,105] *PTPRD* mutations are almost exclusively seen in NMZL.[100,108]

Splenic Marginal Zone Lymphoma

SMZL commonly displays a variety of cytogenetic abnormalities including a complex karyotype, del(7q31), +18, and gains of 3q.[102,109] The most frequent mutations affect *KLF2, NOTCH2, TP53,* and *TNFAIP3* (**Table 5-2**), the latter three of which predict transformation.[105,108]

Lymphoplasmacytic Lymphoma

The detection of an *MYD88* L265P mutation that is present in >90% of lymphoplasmacytic lymphomas (LPLs) is a useful diagnostic tool in the appropriate context[110,111]; however, it is not completely specific for LPL as it can be identified in other B-cell neoplasms[108] and in non-neoplastic mature and immature B cells.[112] The lack of a *MYD88* L265P is an adverse prognostic factor in LPL.[113,114] *CXCR4* mutations, seen in a subset of cases of LPL (**Table 5-2**), predict more aggressive disease and resistance to ibrutinib.[110,115] The combination of *MYD88* L265P and *CXCR4, KNMT2D, or ARID1A* mutations appears to be diagnostic of LPL.[108]

Hairy Cell Leukemia

Hairy cell leukemia (HCL) harbors the *BRAF* V600E mutation (exon 15) in >95% of cases and lacks recurrent cytogenetic abnormalities.[116] The identification of *BRAF* V600E mutation may predict response to *BRAF* inhibitors. *BRAF* mutations in exon 11 have been identified in some cases without the V600E mutation.[116] A search for *TP53* mutations and/or del(17p) is recommended in cases resistant to therapy with purine analogs.[116] Additional mutations can also be observed in HCL (**Table 5-2**).[116] A high prevalence of *MAP2K1* mutations is observed in IGHV4-34-positive HCL and HCL-variant, whereas they are rare in IGHV4-34-negative

cases.[116] IGHV4-34-positive HCL and HCL-variant lack *BRAF* V600E mutation and are associated with more aggressive disease.[116]

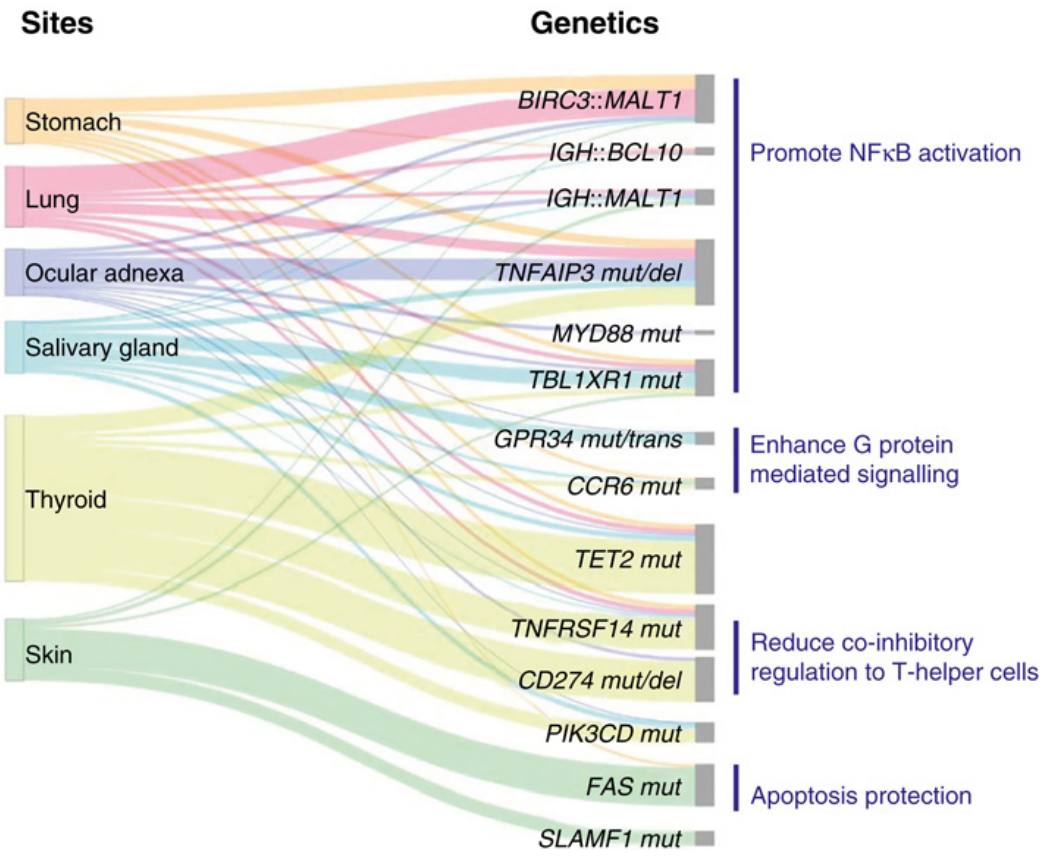

FIGURE 5-6 Recurrent genetic abnormalities in extranodal marginal zone lymphoma (EMZL).Note the association of certain abnormalities with various anatomic sites. Because many of the genes involved in EMZL have not been uniformly investigated in these different anatomic locations, only those genetic abnormalities that are recurrent and fundamental to the understanding of the pathogenesis of these lymphomas are depicted. The height of the boxes under sites does not reflect the frequencies of these lymphomas. *del,* Deletion; *mut,* mutation; *trans,* translocation. *Reproduced and modified with permission from Alaggio R, Amador C,*

Diffuse Large B-Cell Lymphoma

There are numerous subtypes of DLBCL, with the most common category, DLBCL, not otherwise specified (NOS), classified according to its cell of origin (COO) by gene expression profiling (GEP) into the germinal center B-cell (GCB) and activated B-cell (ABC) subtypes, though 10% to 20% of cases are unclassifiable.[117] Because GEP is not widely available for clinical use, surrogate immunohistochemical algorithms have been developed for its classification. This COO–based classification is relevant for prognosis and was thought to be of value in prediction of response to therapy: the 5-year OS of patients treated with R-CHOP is longer in patients with the GCB subtype of DLBCL,[118] while DLBCLs of the ABC subtype show frequent response to BTK inhibitors.[117,119] Molecular approaches have helped define novel DLBCL genomic subgroups.[119-123] Among these, GEP studies performed on the GCB subtype of DLBCL identified an association of the double-hit signature (DHIT) in GCB cases with an outcome similar to that of cases of the ABC subtype.[124,125]

The most frequently translocated genes in DLBCL are *BCL6* (20%–30%), *BCL2* (13%–20%), and *MYC* (8%–15%) (**Table 5-3**),[125-127] with the IG loci (IGH, IGK, and IGL) their predominant partners.[127,128] Partners of *MYC* other than the IG loci include

PAX5, BCL6, BCL11A, IKZF1, and *BTG1*.[127] *BCL2* and *MYC* translocations associate with the GCB subtype, while *BCL2* amplifications, *BCL6* translocations, and *CDKN2A* deletions are more frequent in the ABC subtype (**Table 5-3**).[125,127,129,130]

The mutational profile in the ABC subtype of DLBCL includes frequent mutations in *CD79B/A, CARD11, MYD88, BCOR, ETV6, PRDM1/BLIMP1, PIM1, CDKN2B,* and *CDKN2A,* while in the GCB subtype the most frequent mutations include *EZH2, KMT2D, CREBBP, BCL2, TNFRSF14*, *B2M, FOXO1, ACTB, SOCS1, GNA13,* and *GNA12* (**Table 5-3**).[129,130] DLBCLs of immune privileged sites (including those of the CNS and testes), a group of lymphomas that shares immunophenotypic and genomic features with the ABC subtype of DLBCL, are characterized by concomitant *MYD88* and *CD79B* mutations.[73,131]

DLBCL can also be further stratified into distinct genomic subgroups with the GenClass and LymphGen algorithms (MCD, N1, BN2, EZB, A53, and ST2)[117,124] or in genetic clusters (1 through 5),[128] within which cases share genetic features, GEP signatures, and clinical outcomes. Certain subgroups identified with the GenClass algorithm have cluster equivalents (MCD/C5, EZB/C3, BN2/C1).[126,127,132] An additional molecular classification based on massively parallel sequencing results identified five molecular subtypes (*MYD88, BCL2, SOCS1/SGK1, TET2/SGK1,* and *NOTCH2*), along with an unclassified group (**Fig. 5-7**). MCD, N1, and A53 subgroups, and EZB and ST2 subgroups, tend to predominantly contain ABC and GCB cases, respectively, whereas BN2 associates with all three GEP-defined subgroups.[117,124] The majority of DLBCLs with a DHIT signature are either EZB or genetically composite cases

of EZB and A53, and frequently bear *MYC* translocations, amplifications or mutations, *TP53* mutations or deletions, and mutations in *GNA13, DDX3X,* and *FOXO1*.[124]

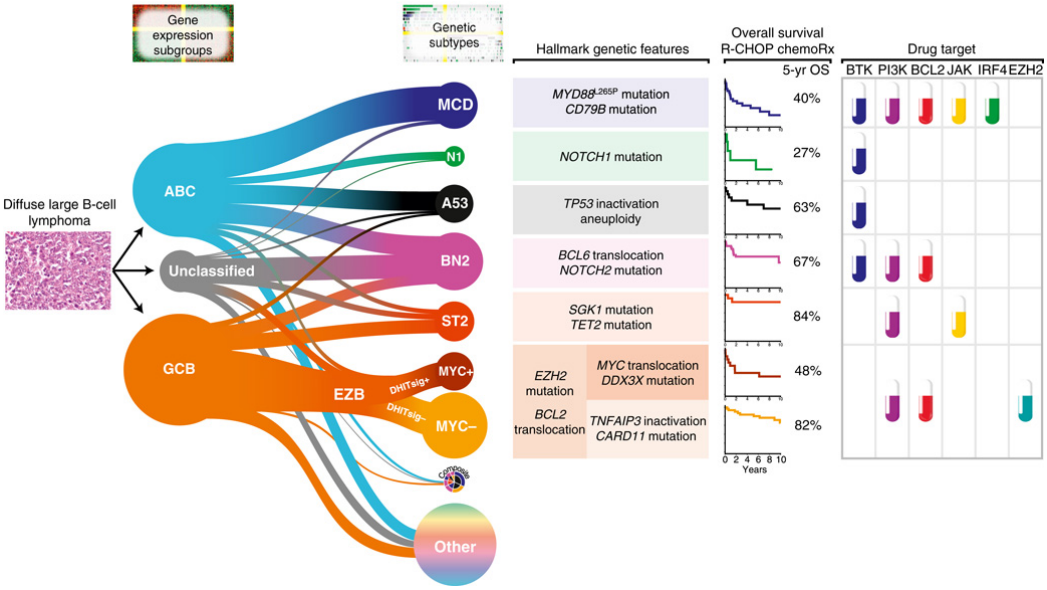

FIGURE 5-7 Genetic subgroups of diffuse large B-cell lymphoma (DLBCL) illustrated using the LymphGen algorithm.This shows the relationships between cell of origin (COO) and the probabilistic assignments to genetics-based subgroups. The size of the subgroup circles approximates the proportions of patients in each group,[117] adjusted for a population-based distribution of COO subgroups. Tumors assigned with high confidence to two or more subgroups are assigned to the composite group, while ~37% of tumors are not assigned to any subgroup with sufficient confidence (Other). The hallmark genetic features are those that are frequent within that subgroup but they are not required for that assignment. Overall survival after R-CHOP chemoimmunotherapy along with inferred drug targets are shown. *Reproduced with permission*

Table 5-3

ABC, Activated B cell; *GCB,* germinal center B cell; *PMBL,* primary mediastinal large B-cell lymphoma.

The genetic classification of DLBCL also helps further refine the prognosis within the GEP-defined subgroups. Within the ABC DLBCLs, the BN2 subgroup has a significantly better survival than in the rest, while in GCB DLBCLs the survival of EZB cases tends to be shorter than in other subgroups.[117,124] In addition, only within the EZB subset of GCB, the survival of cases with a DHIT signature is significantly worse than in those without it.[124] This genetic classification of DLBCL may also help predict therapeutic response (**Fig. 5-7**).[124] Among ABC DLBCLs, impressive outcomes have been observed in young patients with the MCD or N1 subtypes treated with R-CHOP and ibrutinib.[119,132]

DLBCLs with expression of ALK kinase are rare aggressive lymphomas with translocations of *ALK*.[133] The most common partner of *ALK* in these cases is *CLTC* (~70% of cases) because of the t(2;17)(p23;q23).[134] The identification of *ALK* rearrangements in DLBCL is prognostically and therapeutically relevant.[134,135]

Large B-cell lymphoma with 11q aberration (LBL-11q, formerly known as Burkitt-like lymphoma with 11q aberration) typically presents in the young with localized lymphadenopathy, shares morphologic, immunophenotypic, and gene expression features with BL but lacks *MYC* translocations and, instead, carries proximal gains and telomeric losses in 11q.[4,73] Frequent additional CNAs are also identified.[136,137] The most common mutations in LBL-11q involve *BTG2, DDX3X, EP300, ETS1, GNA13, TTN,* and *FAT4,* while the *ID3, TCF3,* and *SMARCA4* mutations commonly found in BL are not observed.[73] In order to identify LBL-11q cases, FISH studies with the 11q probe or copy number arrays are recommended in cases arising in young patients that are morphologically compatible with BL, DLBCL, or HGBL with a GCB immunophenotype, display a very high Ki67 (>90%), and lack a *MYC* translocation.[4,73,133,134]

High-Grade B-Cell Lymphoma, NOS or With MYC and BCL2 or BCL6 Rearrangements

High-grade B-cell lymphomas (HGBL) encompass tumors with morphology of DLBCL, blastoid cytology, and features intermediate between DLBCL and Burkitt lymphoma (BL).[129] Other B-cell lymphomas (e.g., follicular lymphoma or MCL) with *MYC* translocations are excluded from this category.

Among HGBLs with *MYC* and *BCL2* or *BCL6* rearrangements, the majority of cases harbor *BCL2* rearrangements, less commonly *BCL6* rearrangements, and rarely concurrent *BCL2* and *BCL6* rearrangements.[138,139] *MYC* partners include both IG and non-IG genes (*PAX5, IKAROS, BCL6,* and *BCL11A*).[138,139] Although *BCL2* is typically translocated with the IGH enhancer, *BCL6* can involve a

variety of partners, including all three IG loci.[138] Because no morphologic or immunophenotypic features reliably predict *MYC, BCL2,* or *BCL6* translocations, all aggressive B-cell lymphomas with a diffuse pattern should be evaluated by FISH for these abnormalities. A cost-effective approach to the diagnosis of this entity involves initial evaluation for *MYC* rearrangements, with subsequent evaluation for *BCL2* and *BCL6* only in *MYC*-translocated cases. Though break-apart FISH probes are considered the most sensitive for detection of these translocations, false negatives can occur depending on the breakpoint. For this reason, the addition of dual-fusion probes for IGH/*MYC,* IGK/*MYC,* and IGL/*MYC* can improve the sensitivity of the study and identify *MYC* translocations that are missed with the *MYC* break-apart probe. Of note, ~30% of HGBLs with *MYC* and *BCL2* or *BCL6* translocations are not diagnosed as such because of the presence of translocations that are cryptic to FISH studies, or because of focal *MYC* and *MIR17H* copy number gains, or focal deletion of the *PVT1* promoter.[140] HGBLs with *MYC* and *BCL2* or *BCL6* rearrangements recurrently harbor complex karyotypes.[139]

HGBLs with *MYC* and *BCL2* translocations are enriched in mutations affecting *CREBBP, KMT2D, EZH2, TP53,* and *TNFRSF14,* while *CCND3* and *UBE2A* are the most common mutations in HGBLs with *MYC* and *BCL6* translocations.[139,140] In HGBLs with *MYC, BCL2,* and *BCL6* translocations, the most frequent mutations affect *KMT2D, CCND3,* and *IRF8*.[139]

HGBLs with *MYC* and *BCL2* or *BCL6* rearrangements have a worse prognosis with standard therapy than DLBCL, while cases of HGBLs with *MYC* and *BCL6* rearrangements appear to have outcomes

intermediate between HGBLs with *MYC* and *BCL2* rearrangements and DLBCL without *MYC* rearrangement and data suggest that they may not, in fact, reflect a distinct entity.[129]

HGBL, NOS, currently largely a diagnosis of exclusion based upon morphologic features, harbors isolated *MYC, BCL2,* and *BCL6* rearrangements in ~40%, <10%, and <10% of cases, respectively. As in the case of HGBLs with *MYC* and *BCL2* or *BCL6* rearrangements, HGBL, NOS often shows a complex karyotype, a feature that that may help distinguish those with an isolated *MYC* rearrangement from BL (**Table 5-4**). In HGBL, NOS, an isolated *MYC* rearrangement or lack of *MYC, BCL2,* or *BCL6* rearrangements confers a trend toward inferior survival.[141]

Table 5-4

* IG-*MYC,* juxtaposition of *MYC* to one of the immunoglobulin loci: IGH at 14q32, IGK at 2p12, or IGL at 22q11. Non-IG-*MYC* tumors contain a *MYC* rearrangement with juxtaposition to genes other than one of the immunoglobulin loci.

† Simple karyotype: No or only few cytogenetic or chromosomal microarray abnormalities other than the *MYC* rearrangement. Complex karyotype: Six or more abnormalities.

Burkitt Lymphoma

BL is an aggressive germinal center-derived mature B-cell lymphoma characterized by translocations involving *MYC* and IG loci.[142-144] The translocation t(8;14)(q24;q32) is found in 70% to 80% of cases, while t(2;8)(p12;q24) and t(8;22)(q24;q11) are found in 10% to 15%.[145] Although BL usually presents with a simple karyotype, there

is a high prevalence of non-random additional CNAs.[145] Tetrasomy 1q resulting from supernumerary idic(1)(p12) or i(1)(q10) in BL can make it difficult to distinguish immunophenotypically from B-lymphoblastic leukemia/leukemia.[146,147]

MYC is also the most commonly mutated gene in BL.[137,143,144] Other commonly mutated genes are *BACH2, DDX3, DNMT1, HIST1H1E, BCL7, ID3, CCND3, TP53, FBXO11, SMARCA4,* and *TCF3*.[137,143,144] Certain mutations associate with BL subtype and EBV status.[143,144]

FISH studies for the identification of *MYC* translocations are necessary for the diagnosis of the majority of cases of BL. Although *MYC* translocations can be identified on metaphase analyses, FISH studies are preferred given their faster turnaround time and higher sensitivity, and also because not all t(8;14)(q24;q32) translocations involve *MYC* and IGH.[148] *MYC* break-apart probes are recommended for the detection of *MYC* rearrangements; however, 4% of *MYC*-positive cases are not detected with this method and a subset of these can be detected with *MYC*/IGH fusion probes instead.[149] Cryptic insertions of *MYC* into IGH and vice versa, functionally equivalent to the *IGH*::*MYC* translocation, have been described.[150,151] In general, the identification of *MYC* translocations by PCR is hampered by the scattering of the breakpoints on both of the affected chromosomes and is hence not used in the clinical setting.[150]

Table 5-5

IGH, Immunoglobulin heavy chain; *SHM,* somatic hypermutation.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) includes classic Hodgkin lymphoma (cHL) and nodular lymphocyte predominant Hodgkin lymphoma (NLPHL), with the latter renamed nodular lymphocyte predominant B-cell lymphoma (NLPBL) by the ICC but not the 5th edition of the WHO classification.[4,73]

In cHL, Hodgkin/Reed-Sternberg (HRS) cells carry clonally rearranged, somatically hypermutated, and class-switched IG, which indicates their B-cell lineage and their passage through the germinal center reaction.[152] Several genomic alterations are responsible for the loss of the B-cell phenotype of the HRS cells, including crippling IG mutations and lack of BCR expression caused by aberrant AID-mediated SHM, and epigenetic silencing through promoter hypermethylation with dysregulation of the expression of genes involved in B-cell differentiation.[152,153]

Multiple genomic abnormalities promote survival and immune escape of HRS cells (**Table 5-5**). Constitutive activation of the NF-κB pathway can be mediated by gain/amplification of *REL, MAP3K14,* and *BCL3,* and deletions and loss-of-function mutations in negative regulators (*TNFAIP3, NFKBIA,* and *NFKBIE*).[152,154] Genomic abnormalities that constitutively activate the JAK-STAT pathway in cHL include *SOCS1* loss-of-function mutations, *STAT6* gain-of-function mutation, *PTPN1* gain-of-function and loss-of-function mutations, and *JAK2* amplification/gain.[154-156] HRS cells evade the immunosurveillance through mutations in *PTPN1* and *B2M,* translocations of *CIITA,* +9p24/9p24 amplification (*PDL1* and *PDL2*), and loss of *TNFRSF14*.[152,154,156] *PDL1* and *PDL2* amplification in HRS cells and the consequent overexpression of

PDL1 and PDL2 has been effectively exploited therapeutically with the use of PD1 blockers.[157] Several other mutations in cHL affect other pathways (**Table 5-5**).[153,156,158]

Metaphase analysis of cHL has demonstrated occasional aneuploidy and hypertetraploidy, but no recurrent or specific chromosomal abnormalities,[159] while comparative genomic hybridization techniques have identified frequent CNAs.[153] Metaphase analyses and CGH studies in NLPHL/NLPBL show frequent complex karyotypes and non-specific CNAs.[160-162] *BCL6* rearrangements are identified in 17% to 50% of cases.[160,163,164] The mutational landscape of the LP cells includes frequent *PAX5, PIM1, MYC, RHOH, SGK1, DUSP2, JUNB,* and *SOCS1* mutations[164] and uncommon *TNFAIP3* and *NFKBIA* mutations.[165]

Although biologically intriguing, none of the genomic abnormalities in HL are currently used for routine diagnostic use. Detection and quantitation of cHL–associated ctDNA with techniques such as ddPCR has the potential to complement the prognostic utility of FDG-PET scanning in the evaluation of residual cHL after therapy.[152,153] The detection of specific mutations (e.g., *XPO1* E571K) in plasma cell-free DNA by digital PCR has been proposed as a biomarker for the detection of MRD.[166]

Plasma Cell Neoplasms

Plasma cell neoplasms (PCNs) harbor complex heterogeneous genomic changes occurring during disease progression from monoclonal gammopathy of uncertain significance (MGUS) and smoldering multiple myeloma to multiple myeloma (MM) and plasma cell leukemia.

Genomic abnormalities in PCNs are classified into primary and secondary.[167-169] Primary genomic abnormalities initiate the process of plasma cell immortalization and development of MGUS (which contains these abnormalities in ~50% of cases), while the secondary genomic abnormalities occur later in the disease and determine whether the plasma cell clone progresses to MM or remains at an earlier evolutionary step.[167,169]

Primary genomic abnormalities in PCNs broadly classify cases into the hyperdiploid and non-hyperdiploid groups. The hyperdiploid group (~50% of PCNs) is characterized by trisomy of one or more odd-numbered chromosomes, and more favorable outcomes.[167-169] The non-hyperdiploid group typically harbors the juxtaposition of IGH next to an oncogene such as *CCND1* (11q13) (~20% of MM cases), *CCND3* (6p21) (~2%), *FGFR3* and *NSD2* (4p16) (~15%), *MAF* (16q23) (5%–10%), or *MAFB* (20q12) (~1%).[167-169] While t(4;14)(p16.3;q32.3), t(14;16)(q32.3;q23), and t(14;20)(q32;q12) have poor prognosis, the effect of t(11;14)(q13;q32) and t(6;14)(p21;q32) on prognosis is neutral.[168] Despite the association of t(4;14) with poor prognosis, treatment with bortezomib results in improved survival.[168,169] t(11;14)(q13;q32) in MM correlates with small plasma cell morphology, cyclin D1 and CD20 expression, and response to venetoclax.[170]

Secondary genomic abnormalities in PCNs mainly include translocations of *MYC,* CNAs, somatic mutations, and DNA hypomethylation.[167-169] *MYC* translocations (~15% of MM cases) most frequently partner with the IG loci, *FAM46C, FOXO3,* and *BMP6,* and constitute an adverse prognostic factor.[167,168] Among CNAs, deletion of *TP53,* +1q, and del(1p) are the most

frequent.[167] *TP53* deletion is associated with increased risk of mutation of the remaining *TP53* allele, rapid disease progression, and poor prognosis, particularly if the fraction of myeloma cells with del(17p) is >55%.[167,168] del(1p) and +1q are collectively seen in almost a quarter of MM, and are also associated with adverse prognosis.[168,171] del(13q) (45%–50% of cases) may lack prognostic significance.[168]

FISH studies have greater sensitivity than metaphase analysis for the detection of cytogenetic abnormalities in PCNs because plasma cells are typically averse to division ex vivo, and their detection rate is enhanced with plasma cell enrichment (CD138 cell selection).[167,169] The results of FISH studies are one of the components of the Revised International Staging System (R-ISS) used for risk stratification. Chromosome 1 abnormalities will likely be incorporated into future MM risk stratification models as high-risk abnormalities.[171,172]

RAS mutations (up to 40% of MM) are frequently subclonal, and predict adverse outcomes.[167,168] *KRAS* mutations associate with *TP53* mutations and t(11;14), while *NRAS* mutations correlate with decreased response to bortezomib.[167] Less-common mutations affect *FAM46C* and *DIS3* (~11% each), *TP53* (8%), and *BRAF* (6%).[167] Constitutively, activation of the NF-κB pathway (caused by *TRAF2, TRAF3, CYLD,* and *BIRC2/BIRC3* loss-of-function mutations, and *NFKB1, NFKB2, CD40, LTBR, TACI,* and *NIK* gain-of-function mutations) occurs in at least 50% of MM, although it does not appear to influence survival.[167,168,173]

Mature T-Cell and NK-Cell Lymphomas/Leukemias

T-Cell Prolymphocytic Leukemia

Metaphase analysis and FISH can help establish the diagnosis of T-cell prolymphocytic leukemia (T-PLL). T-PLL commonly demonstrates complex karyotypes (in up to 80%) and the genomic hallmark inv(14)(q11q32.1) or t(14;14)(q11;q32.1)] (~80% of cases), which involves TRA on 14q11 and the *TCL1A/TCL1B* loci on 14q32.1, and leads to TCL1 overexpression.[174] This TCL1 overexpression can be identified by immunohistochemistry, and in the context of a T-cell neoplasm, these cytogenetic/FISH or immunohistochemistry findings are considered diagnostic of T-PLL. Approximately 20% of cases harbor a t(X;14)(q28;q11) involving *MTCP1* on Xq28 and TRA on 14q11, while rare cases harbor the t(X;7)(q28;q35) with resultant juxtaposition of *MTCP1* next to TRB on 7q35, each resulting in MTCP1 overexpression.[174,175] Recurrent mutations and deletions frequently affect a variety of pathways in T-PLL (**Table 5-6**) such as DNA repair, DNA damage response, proteasomal degradation, JAK-STAT pathway, and epigenetic regulation.[176,177]

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is driven by human T-lymphotropic virus type-1 (HTLV-1) infection, which integrates into the T-cell genome and disrupts gene regulation. The infrequent neoplastic transformation of HTLV-1 infected T-cells requires accumulation of additional genomic abnormalities, which occur progressively.[178,179]

Genomic analyses in ATLL have demonstrated a high frequency of mutations in genes involved in the TR and NF-κB signaling pathways, T-cell trafficking, and immunosurveillance (**Table 5-**

6).[178-180] Gain-of-function *PRKCB* mutations appear to be relatively specific to ATLL.[180] Mutational differences have been described between North American and Japanese cases.[180] Deletions at the *NRXN3* locus are thought to be pathognomonic for ATLL.[181] Frequent *CTLA4*::*CD28* and *ICOS*::*CD28* fusions have been described in Japanese cases.[180,181]

The total number of genomic abnormalities is higher in aggressive (acute and lymphomatous) subtypes, with higher frequency of *TP53* and *IRF4* mutations and CNAs (including *PD-L1* amplifications and *CDKN2A* deletions), than in the indolent (chronic and smoldering) variants, whereas *STAT3* mutations are more characteristic of the latter.[179,182] CNAs of cell cycle-related genes *(CDKN2A, TP53)* and *CD58* predict transformation of chronic into acute forms of ATLL.[180] Genomic studies have classified ATLL into two groups with distinct clinical and prognostic features.[179] Almost all genomic abnormalities recurrently identified in ATLL are subclonal, a finding that suggests that targeted therapies for specific genomic alterations may exert only partial effect.[180] However, the presence of gain-of-function *CCR4* mutations/CCR4 overexpression may predict response to mogamulizumab with improved OS.[180] While the occasional PD-L1 overexpression may serve as the rationale for therapeutic purposes, rapid progression after PD-1 blockade may occur.[180] Analysis of tumor cfDNA is a promising methodology for monitoring the disease, particularly the lymphomatous type of ATLL.[178]

Table 5-6

* Varies depending on immunophenotype; see text for details.

T-Cell Large Granular Lymphocytic Leukemia

Demonstration of T-cell monoclonality, although not specific, is necessary for the diagnosis of T-cell large granular lymphocytic leukemia (T-LGL). This can be achieved through the evaluation of one of the TR genes by PCR or NGS, or by flow cytometry with monoclonal antibodies against the variable regions of the TCR beta chain.[183]

STAT3 mutations are frequent in T-LGL (**Table 5-6**); >70% involve hotspots Y640 and D661 in the SH2 domain[175,184] and they are linked to symptomatic disease and reduced OS.[184] While *STAT3* Y640F mutations are thought to predict complete response to treatment with methotrexate, cases with other *STAT3* mutations or without *STAT3* mutations display variable therapeutic response.[175] Both the presence and number of *STAT3* mutations correlate with concomitant rheumatoid arthritis.[175] *STAT5B* mutations are rare in CD8+ CD4– T-LGL,[184] but more common in CD4+ CD8+ and CD4+ CD8– T-LGLs and TCR gamma-delta T-LGLs,[184,185] and may associate with an aggressive clinical course in CD8+ T-LGL[184,186] but not in CD4+ T-LGL.[185] Mutations other than *STAT3* and *STAT5* are less common (**Table 5-6**).[184,187]

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphoma (ALCL) includes four entities: (1) ALCL, ALK-positive, (2) ALCL, ALK-negative, (3) primary cutaneous ALCL (PCALCL), and (4) breast implant–associated ALCL (BIA-ALCL).

Anaplastic Large Cell Lymphoma, ALK-Positive

By definition, ALCL ALK-positive has a rearrangement of the *ALK* gene with one of various partner genes, most commonly *NPM1* [t(2;5)(p23;q35)] (>80%)] or *TPM3* [t(1;2)(q25;p23)] (13%).[175,188,189] Other partners are rare (≤1%).[188,189] FISH/karyotypic evaluation for *ALK* translocation is not necessary for diagnosis of ALCL ALK-positive as long as ALK immunohistochemical positivity is demonstrated in a mature T-cell lymphoma. The ALK immunohistochemical patterns vary with the fusion partner.[188] RT-PCR assays for the detection of *ALK* rearrangements are of limited diagnostic value but they may play a role in the identification of measurable disseminated/residual disease.[190] A variety of genes are mutated in ALCL ALK-positive (**Table 5-6**).[188,191] While the prognosis of ALCL ALK-positive is favorable, cases with *TP53* mutations or measurable disseminated/residual disease are associated with inferior outcomes.[190,191]

Anaplastic Large Cell Lymphoma, ALK-Negative

By definition, ALCL ALK-negative lacks *ALK* rearrangements and ALK expression. Instead, *IRF4-DUSP22* and *TP63* translocations have been described in 18% to 30% and 8% of cases, respectively.[188,189] Rarely, these translocations coexist.[192,193] *IRF4-DUSP22* most commonly translocates with *FRA7H* [t(6;7)(p25.3;q32.3)], while the most common partner of *TP63* is *TBL1RXR1* [inv(3)(q26q28)].[194] Rare cases of ALCL ALK-negative harbor other fusion genes such as *NFKB2*::*ROS1*, *NCOR2*::*ROS1, NFKB2*::*TYK2,* and *PABPC4*::*TYK2*.[175,188,194] *IRF4-DUSP22* and *TP63* translocations are not specific for ALCL ALK-

negative.[188,195] Because of the genomic proximity of the *TP63* and *TBL1RXR1* loci, FISH with dual-fusion probes for *TBL1RXR1* and *TP63* is recommended in those cases in which the results of the FISH studies with a break-apart *TP63* probe cases are positive or equivocal.[196] Of note, immunohistochemistry for p63 is not specific, and therefore cannot replace FISH studies.[194]

STAT3, JAK1, and *MSC* mutations are common in ALCL ALK-negative (**Table 5-6**),[188,191,194] while they lack *STAT5B, JAK3,* or *RHOA* mutations.[197] *MSC* E116K mutations are nearly exclusively seen in *IRF4-DUSP22*-translocated cases.[194,198] ALCL ALK-negative with *IRF4-DUSP22* translocations correlates with a favorable prognosis, similar to that of ALCL ALK-positive, whereas translocations of *TP63* predict an adverse outcome.[194] Those without either translocation have an intermediate prognosis. *STAT3* and *TP53* mutations and loss of *TP53* and *PRDM1/BLIMP1* predict inferior outcomes in ALCL ALK-negative.[175,191]

Extranodal NK/T-Cell Lymphoma, Nasal Type

Gene mutations in extranodal NK/T-cell lymphoma, nasal type (ENKTL) mainly affect the JAK/STAT pathway, NF-κB pathway, epigenetic modifiers, the RNA helicase family, the RAS/MAP kinase pathway, tumor suppressors, immune evasion, NOTCH signaling, and cell-cell signaling, among others (**Table 5-6**).[199,200] Although most studies have not found or evaluated differences in the genomic landscapes of ENKTL of T-cell lineage versus NK-cell lineage, some have demonstrated distinct profiles, with ENKTL of NK-cell lineage harboring mutations/CNVs of *STAT3, DDX3X, KMT2C, JAK2, KMT2D, EP300, STAT5B,* and *STAT5A,* and amplification of

9p24.1/*PD-L1/2,* with ENKTL of T-cell lineage displaying mutations/CNVs of *EPHA1, TP53, ARID1A, PTPRQ, NCOR2, PPFIA2, BCOR, PTPRK,* and *HDAC9,* without amplification of 9p24.1/*PD-L1/2*.[201,202] TR gene rearrangement studies show evidence of monoclonality in up to 40% of cases of ENKTLs, even if cases do not express TCR proteins,[199] and can be used to differentiate NK from T-cell lineage.[201] Rare intravascular NK/T-cell lymphomas carry *HIST1H2AM, HIST1H2BE, HIST1H2BN,* and a variety of other mutations.[203]

Follicular Helper T-Cell Lymphomas

Three types of follicular helper T-cell lymphomas (FHTL) are recognized: (1) FHTL, angioimmunoblastic type, also referred to as angioimmunoblastic T-cell lymphoma (AITL); (2) FHTL, follicular type; and (3) FHTL, NOS.[4] AITL is characterized by high-frequency mutations in epigenetic modifiers (*TET2, IDH2* R172K, and *DNMT3A* R882H), in *RHOA,* and in members of the T-cell signaling pathway (*CD28* T195/D124 and *PLCG1*) (**Table 5-6**).[204,205] *RHOA* G17V mutations account for >90% of all *RHOA* mutations and most co-occur with *TET2, DNMT3A,* or *IDH2* mutations.[175,206] Among T-cell lymphomas, *RHOA* G17V and *IDH2* R172K mutations are exclusively found in FHTL.[205,206] AITL with *TET2* or *DNMT3A* mutations may develop from a background of clonal hematopoiesis.[207,208] The non-specific *CTLA4*::*CD28* gene fusion has been identified in >50% of AITL in an Asian cohort.[205,209] While the *ITK*::*SYK* fusion is extremely rare in AITL, and more prevalent in other FHTLs, gains of *ITK* and *SYK* have been identified in 38% and 14% of AITL, respectively.[204]

Peripheral T-Cell Lymphoma, Not Otherwise Specified

GEP studies have identified three peripheral T-cell lymphoma, NOS (PTCL-NOS) subgroups (GATA3, TBX21, and unclassified) with distinct signatures and prognoses.[210-212] An immunohistochemistry algorithm can also be used to classify PTCL-NOS into these subgroups.[211,212] Although the GATA3 subgroup has an inferior clinical outcome than the TBX21 subgroup, a subset within the TBX21 subgroup with a cytotoxic gene signature also has poor clinical outcomes.[210,211] The distinction between these subgroups is relevant for prognostication and possibly therapy selection.[212]

The most frequently mutated genes in PTCL-NOS include tumor suppressor genes, epigenetics modifiers, *VAV1,* and genes of the NOTCH and JAK/STAT pathways (**Table 5-6**).[206,213,214] *RHOA, DNMT3A* or *TET2* mutations are less frequent in PTCL-NOS than in T-cell lymphomas with TFH phenotype, while *IDH2* mutations are absent.[206,213] The vast majority of the *RHOA* mutations found in PTCL-NOS are of non-G17V type. Deletions of *PTEN* and *CDKN2A* are frequent in PTCL-NOS and, if concurrent, they appear to be highly specific for PTCL-NOS.[206,215] Alterations of *TP53* and *CDKN2A,* and mutations in *FAT1, IKZF2,* genes associated with immune evasion, epigenetics modifiers, and genes of the TCR signaling/NF-κB pathways correlate with an adverse prognosis.[206,213,215]

Hepatosplenic T-Cell Lymphoma

Mutations in chromatin-modifying genes are seen in >60% of hepatosplenic T-cell lymphoma (HSTL), while other less-frequent mutations affect genes of the JAK/STAT and PI3K-AKT-mTOR

pathways, *TP53, UBR5,* and *IDH2* (**Table 5-6**).[216] The most common chromosomal abnormalities in HSTL involve chromosome 7 (47%–100%), mainly isochromosome 7q [i(7)(q10)], typically with −7p and +7q, followed by +8 or 8q amplifications (31%–87%), with these CNAs being associated with worse outcomes.[217,218]

Primary Intestinal T-Cell Lymphomas

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is closely, but not exclusively, linked to celiac disease (CD)[219,220] and often preceded by type 2 refractory CD (RCD) and, infrequently, type 1 RCD.[220,221] While in RCD, type 1 TR gene rearrangement studies by PCR most commonly yield polyclonal results, and genetic or gene sequencing analyses reveal no abnormalities, in RCD type 2 monoclonal TR gene rearrangements, CNAs, and *JAK1* and *STAT3* mutations are frequent,[219,221] noting that clonal TR gene rearrangements in small intestinal biopsies are not specific for RCD type 2.[222] No CNAs appear to be specific for EATL, as they can also be found in MEITL.[220,223] However, losses of 3p21.31 (SETD2) have not been described in EATL, a fact which may aid in the distinction from MEITL.[224,225] Mutations in EATL mainly involve the JAK/STAT and RAS pathways, while a small proportion of cases exhibit *SETD2* loss-of-function mutations (**Table 5-6**).[220,223,226] The mutational profile of EATL substantially overlaps with that of MEITL.

Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL), unlike EATL, shows no association with CD.[219] Mutations in MEITL

mainly involve the JAK/STAT, RAS/RAF/MAPK, and G-protein-coupled receptor pathways, *TP53,* and chromatin modifier/potential tumor suppressor genes (**Table 5-6**).[220,223] The mutational profile of MEITL significantly overlaps with that of EATL.[223,224,227] The most common CNAs in MEITL include loss of 3p21 *(SETD2)*, a feature that distinguishes it from EATL, and 9p21.3 *(CDK2A/B)*.[223,224,227]

Cutaneous T-Cell Lymphoma

Primary Cutaneous Anaplastic Large Cell Lymphoma

IRF4-DUSP22 and *TP63* translocations can be found in 20% to 30% and 5% of cases, respectively.[188,189] Although PCALCL has traditionally been considered to lack *ALK* translocations,[194] rare primary cutaneous tumors associated with insect bites that resemble PCALCL may harbor these translocations.[188] *JUNB* amplification has been noted in the majority of PCALCL,[228] while *STAT3, JAK1,* and *MSC* mutations are found in minor subsets (**Table 5-6**).[198] Although the presence of a *IRF4-DUSP22* translocations does not appear to effect prognosis,[188] *TP63* translocations may correlate with aggressive behavior.[189]

Mycosis Fungoides

TR gene rearrangement studies are frequently positive for monoclonality in mycosis fungoides (MF), although the specificity and sensitivity of these studies are relatively low in early MF, particularly when reviewed in the absence of immunophenotypic results.[229] The dominant clone may be accompanied by additional reactive clones.[230] The specificity of the TR gene rearrangement

studies in blood in early-stage disease can be improved by comparing the results to those from diagnostic skin biopsies.[231] Concurrent monoclonal TR gene rearrangements in skin and lymph nodes predict inferior outcomes.[231] Mutations in MF involve epigenetic modifier genes, and genes of various signaling pathways, including *MAKP1, STAT3,* and *PREX2,* among others (**Table 5-6**).[232] MF displays a complex and heterogeneous cytogenetic profile, with deletion of negative regulators of the JAK/STAT pathway *(SOCS1)*, and recurrent translocations of *ARHGAP26, ATXN1, CLEC16A, ELF1, EYS, RBPJ, RPS6KA3, SLC24A2,* and *SSH2,* many of which lead to deletion of genes involved in cell cycle control, chromatin regulation, and the PI3K pathway.[175]

Sézary Syndrome

Sézary syndrome (SS) is a rare aggressive leukemic form of cutaneous T-cell lymphoma. Inferior OS can be predicted if TR gene rearrangement studies document monoclonality in both skin and lymph nodes.[231] The most frequently mutated genes are *TP53, PLCG1,* epigenetic modifier genes, and genes of several signaling pathways (**Table 5-6**).[232] A variety of fusions have been identified: *TPR*::*MET, MYBL1*::*TOX*, *DNAJC15*::*ZMYM2*.[233]

Precursor Lymphoid Neoplasms

B-Lymphoblastic Leukemia/Lymphoma

Nascent genomic interrogation has led to the discovery of increasing numbers of distinct categories of B-lymphoblastic leukemia/lymphoma (B-ALL/LBL) that are occasionally differently designated by the ICC and WHO classification schemes (Tables **5-7**

and **5-8**). Metaphase analysis and FISH are routinely used to identify some of these recurrent genetic abnormalities, which aid in the diagnosis, risk stratification, and therapy selection. In addition, gene sequencing, including whole transcriptome sequencing, RT-PCR, or commercially available FISH probes can help refine the detection of B-ALL/LBL subtypes.[4,73] Fundamental strides have been made in deepening our understanding of the role of the genomic landscape affecting outcomes in B-ALL/LBL and they may continue to further inform future classification schemes.[2,34]

Although almost all cases of B-ALL/LBL demonstrate monoclonal IGH rearrangements by PCR, concurrent illegitimate monoclonal TR gene rearrangements are also frequently observed.[235] Therefore such analyses are unreliable for the assignment of the lineage of lymphoblasts, although they may provide additional targets for MRD assessment.

T-Lymphoblastic Leukemia/Lymphoma

T-ALL/LBL harbor translocations in ~50%, most commonly involving 14q11 (TRA and TRD) 7p14.1(TRG), and 7q34 (TRB) regions, juxtaposing the TR genes to pivotal transcription factor genes, such as *TAL1, TAL2, LYL1, OLIG2, LMO1, LMO2, TLX1 (HOX11), TLX3 (HOX11L2), NKX2-1, NKX2-2, NKX2-5, HOXA, MYC,* and *MYB* (**Table 5-9**).[232,236,237] Also, *ABL1* may be cryptically rearranged with *NUP214, EML1,* and *ETV6*, and the resultant gene fusions may be amenable to TKI therapy.[236] Most frequent mutations and CNAs in T-ALL/LBL involve *NOTCH1, FBXW7,* and *MYB*, genes involved in cell cycle regulation (*CDKN2A* and *CDKN2B*), genes involved in the JAK-STAT, RAS/PI3K/AKT,

and NF-κB pathways; epigenetic modifier genes; transcription regulator genes; and genes involved in mRNA maturation and ribosomal activity (**Table 5-9**).[175,232,236] Among these, activating *NOTCH1* mutations and loss-of-function mutations of FBXW7 are the most frequent,[232,238] followed by del(9p21) and altered methylation of *CDKN2A* and *CDKN2B*.[175] No specific mutations appear to correlate with patient outcome in T-ALL/LBL.[232] Early T-cell precursor ALL (ETP-ALL) is a distinct form of T-ALL/LBL with an immunophenotype and a GEP similar to those of hematopoietic stem cells.[175,236] ETP-ALL harbors mutations in genes of multiple pathways, including early hematopoietic and lymphoid development; RAS, cytokine receptor and kinase signaling and epigenetic regulators.[4,175,236] *DNMT3A* and *RUNX1* mutations in ETP-ALL may predict poor OS.[232] Although almost all cases of T-ALL/LBL demonstrate monoclonal TR gene rearrangements by PCR, concurrent illegitimate monoclonal IGH gene rearrangements may also be identified in ~20% of cases.[238,239]

MYELOID NEOPLASMS

The full spectrum of technologies available in the clinical laboratory is routinely applied to the characterization of myeloid neoplasms. Although these have evolved through classical cytogenetics, FISH, PCR-based approaches, and NGS, they all still largely remain complementary, with each having different roles in different contexts, albeit with some appropriate built-in redundancy that is useful for confirmation of diagnostic aberrations. Broadly considered, the myeloid neoplasms comprise three major groups: AMLs, myeloproliferative neoplasms (MPNs), and myelodysplastic syndromes (MDSs). Others include overlap syndromes, those associated with eosinophilia and specific genetic aberrations, mast cell neoplasms, dendritic cell neoplasms, and those with a germline predisposition.

Acute Myeloid Leukemias

Karyotypic Abnormalities

AML is an extremely heterogeneous disease at the genetic level, with at least 300 different but recurrent structural cytogenetic abnormalities observed.[240] Of all of the parameters that are integrated to yield a final diagnosis and appropriate classification of AML, the most relevant are the genetic abnormalities.[241] Large multicenter cooperative studies and organizations have identified broad prognostic groups based on cytogenetics, although molecular abnormalities have also been appropriately incorporated. In addition to their prognostic relevance, many of the recurrent translocations in AML are used to define specific entities in the ICC and WHO

classification (**Table 5-10**). Accordingly, the identification of these is germane to the contemporary diagnosis of AML. In addition to these recurrent cytogenetic abnormalities, mutational analysis plays a key role in AML classification such that both are now central to contemporary classification in which they are hierarchically stratified (**Fig. 5-8**).[2,242]

t(15;17)(q24.1;q21.2)

Among all acute leukemias, acute promyelocytic leukemia (APL) is the one with the most compelling genotype–morphologic phenotype correlation in that the genetics can frequently be "predicted" on the basis of the characteristic morphology, be it in the classic hypergranular form with abundant Auer rods or in the hypogranular variant with "cottage loaf" or "kagami mochi" nuclei. It also remains paradigmatic with regard to the use of targeted therapy.[243] Accounting for ~5% to 10% of translocations in AML as a whole, the t(15;17)(q24.1;q21.2) is seen in ~99% of APLs. In this prototypic translocation, *RARA* (on 17q21.2) is fused to *PML* (on 15q24.1). Although the involvement of RARA is central to neoplastic transformation, the disruption of PML also plays a role in leukemic transformation. In the approximate 1% of remaining cases, interesting variant translocations are present, with approximately 10 different fusion partners other than *PML*. For all of these, the common denominator is the disruption of the *RARA* gene at 17q21.2, converting a transcriptional activator into a repressor.[244] However, these variants are no longer considered definitional of APL because not all are as exquisitely responsive to all-*trans* retinoic acid (ATRA) and arsenic [i.e., t(11;17)(q23;q21.2), *RARA-ZBTB16*]. Thus from a

molecular diagnostic perspective, it is important to identify these rare variants because not all such patients will benefit from ATRA therapy. t(11;17)-positive leukemic cells tend to have regular nuclei, with an increased number of Pelger-Huët–like cells.

Table 5-9

* *IL7R* and *FLT3* mutations are enriched in early T-cell precursor ALL (ETP-ALL) with the higher frequencies in parentheses reflecting this. They are uncommon in other forms of T-ALL/LBL; conversely, *NOTCH1* and *FBXW7* mutations are rare in ETP-ALL compared with the other forms.

Table 5-10

Acute Myeloid Leukemia Entities Defined by Recurrent Cytogenetic Abnormalities*

§ The other rare recurring translocations and genes involved are t(1;3)(p36.3;q21.3)/*PRDM16*::*RPN1,* t(3;5)(q25.3;q35.1)/*NPM1*::*MLF,* t(8;16)(p11.2;p13.3)/*KAT6A*::*CREBBP,* t(1;22)(p13.3;q13.1)/*RBM15*::*MRTF1,*t(5;11)(q35.2;p15.4)/*NUP98*::*NSD1,* t(11;12)(p15.4;p13.3)/*NUP98*::*KMD5A,* t(11p15.4)/*NUP98* and other partners, t(7;12)(q36.3;p13.2)/*ETV6*::*MNX1,* t(10;11)(p12.3;q14.2)/*PICALM*::*MLLT10,* t(16;21)(p11.2;q22.2)/*FUS*::*ERG,* t(16;21)(q24.3;q22.1)/*RUNX1*::*CBFA2T3,* inv(16)(p13.3q24.3)/*CBFA2T3*::*GLIS2*.

Although typically identifiable by metaphase analysis, the relatively slow turnaround time of this approach and need for prompt initiation of therapy have led to the routine use of more rapid

FISH or RT-PCR. Rarely, the translocation may be cryptic, being detected by FISH or RT-PCR but missed on metaphase analysis.[245] The use of dual-color break-apart FISH probes not only allows the identification of the t(15;17) but also can recognize variant translocations, albeit without identifying the *RARA* partner. With regard to RT-PCR for the common t(15;17), the breakpoints in *RARA* are well conserved in intron 2, whereas there are two major intronic and one intronic breakpoints in the *PML* gene. Thus a single downstream *RARA* primer and two upstream *PML* primers will detect most (>95%) of *PML*::*RARA* fusion transcripts.

FLT3 internal tandem duplication (ITD) mutations are enriched in t(15;17) AML, occurring in 30% to 40% of cases; whereas these mutations are typically associated with a poor prognosis in other settings, their prognostic effect in this context is unclear.[246] By contrast, *FLT3* tyrosine kinase domain (TKD) mutations that occur in 10% are associated with an adverse outcome. Up to 50% of patients with APL may harbor mutations in genes encoding epigenetic modifiers that portend a poor prognosis.[247] Rarely, *RARA* or *PML* mutations occur and can be associated with the development of resistance, and it may become important to test for their presence in relapsing patients.[248,249]

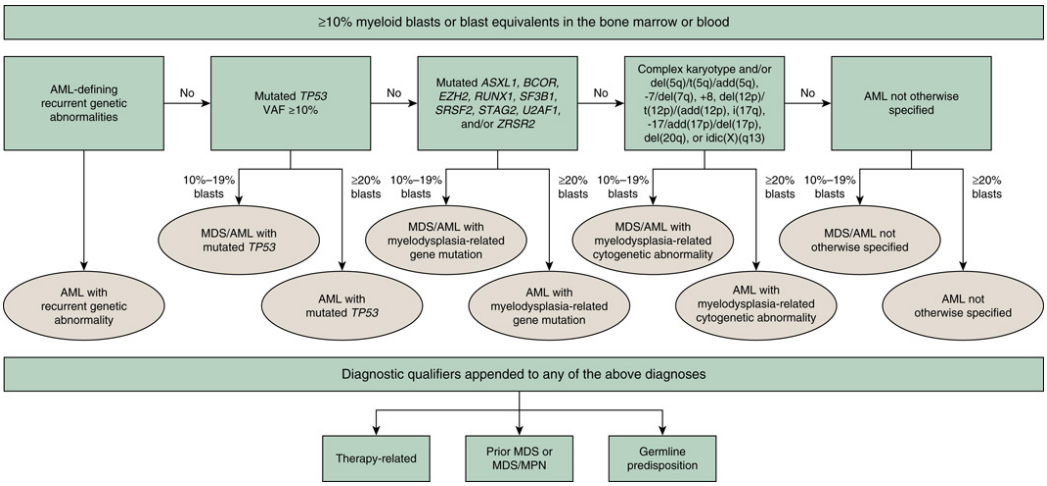

FIGURE 5-8 Hierarchical classification of the International Consensus Classification of acute myeloid leukemia (AML).The classification is hierarchical (i.e., AML with recurrent genetic abnormalities takes precedence over all other categories); among the remaining categories, AML with mutated *TP53* supersedes AML with myelodysplasia-related gene mutations, and the latter supersedes AML with myelodysplasia-related cytogenetic abnormalities. *AML,* Acute myeloid leukemia; *MDS,* myelodysplastic syndrome. *Reproduced with permission from Döhner H, Wei AH, Appelbaum FR, et al. Diagnosis and management of AML in adults: 2022 recommendations from an international expert panel on behalf of the ELN.* Blood. *2022;140[12]:1345-1377.* ***https://doi.org/10.1182/blood.2022016867.***

t(8;21)(q22;q22.1)

This translocation is seen in ~5% to 10% of AMLs. The translocation fuses part of the *RUNX1* gene (formerly *AML1* or *CBPA2*) on 21q22.1 with part of the *RUNX1T1* (formerly *ETO*) gene on 8q22.[250] *RUNX1* is half of the heterodimer core binding factor (CBF) that is a crucial transcription factor in hematopoiesis. This half directly contacts DNA, whereas the β-subunit facilitates DNA binding. The two genes that encode the two components of this CBF transcriptional factor are common targets of translocations in AML and pediatric ALL and are collectively disrupted in ~20% to 25% of each of these major types of acute leukemia. When *RUNX1* is translocated, the subsequently generated fusion protein acts in a dominant negative fashion, inhibiting the transcription of a number of important hematopoietic target genes, including *MPO, GM-CSF, IL-3,* and *TRB*. By contrast, AMLs with *RUNX1*::*RUNX1T1* fusions upregulate expression of B-cell genes, and hence these AMLs typically co-express one or more of CD19, CD79a, PAX5, and TdT.

The breakpoints cluster within a single intron of both genes, so that similar chimeric transcripts are usually generated in every case. Thus a simple RT-PCR assay, with a *RUNX1* primer and a *RUNX1T1* primer, is able to detect this translocation at a molecular level and can be used diagnostically. FISH can also easily detect the translocation. Leukemias harboring a t(8;21) translocation evince particular sensitivity to and substantial benefit from therapeutic regimens containing high-dose cytosine arabinoside. In addition, so-called CBF leukemias [that include those with this translocation and those with inv(16)(p13.2q22)/t(16;16)(p13.3;q22)] show increased sensitivity to monoclonal antibody therapy directed at CD33.

Whereas this good prognostic association appears to be well established in adult AML, this is less clear in pediatric AML. Cooperative mutations commonly seen in *RUNX1*::*RUNXT1* AMLs are those that affect the *KIT* gene, which result in constitutive activation of the encoded receptor tyrosine kinase and are associated with a relatively poor outcome, although this may depend on the site of the mutation, with those in exon 17 adverse while those in exon 8 are not.[251] *ASXL2* mutations are also recurrent in this form of AML (second only to *KIT* mutations); whereas they have no effect on OS, there may be a greater incidence of relapse.[252] *CCND1* and *CCND2* mutations are also enriched in this form of AML.[253] Coexisting del(9q), hyperdiploidy, and hypodiploidy may predict improved survival,[254] while trisomy 8 tends to be associated with an inferior prognosis.[255]

inv(16)(p13.1q22)/(16;16)(p13.1q22)

This pericentric inversion, and the molecularly identical t(16;16), is seen in ~5% to 10% of AMLs. It is characteristically associated with acute myelomonoblastic leukemia with abnormal eosinophils and their precursors that contain abnormally large basophilic granules. The inversion fuses parts of the *CBFB* gene (formerly *PEBP2B*) on 16q22 with parts of one of the myosin heavy chain genes, *MYH11* (previously *SMMHC*) located at 16q11. The inv(16) can sometimes be quite subtle at the karyotypic level and may on occasion be missed, particularly if the metaphase preparations are suboptimal. Of note, +22 is the most common associated abnormality in patients with inv(16) but is uncommon in other situations.[256] Thus the presence of an apparently isolated +22 should alert one to the presence of a

possible cryptic *CBFB*::*MYH11* fusion. Accordingly, molecular studies have a particularly relevant role in the detection of this abnormality. Interestingly, the presence of +22 in an inv(16)-positive AML predicts for a better outcome compared with those lacking +22, according to most but not all studies.[254] Though the presence of a *FLT3*-ITD mutation in core binding factor (CBF) AMLs is associated with inferior outcomes, this is abrogated by the coexistent trisomy 22 in *CBFB*::*MYH11* AML.[257] As noted, AMLs with the *CBFB*::*MYH11* fusion show increased sensitivity to immunotherapy directed at CD33,[258] and hence it is important to detect for this reason.

The inversion/translocation is detectable by both FISH and RT-PCR. Whereas 99% of breakpoints in *CBFB* occur in intron 5 of that gene, the breakpoint heterogeneity is quite marked in the *MYH11* gene, with seven different exons (7 through 13) variably included in the fusion transcripts. This complexity notwithstanding, the most common form, designated type A, accounts for ~90% of cases with this genetic fusion; two other transcripts (types D and E) account for an additional 5%. Whereas +22 might predict a better outcome, the presence of *FLT3*-TKD and *KIT* mutations predicts a worse outcome, while the effect of +8 is unclear.[254] *RAS* mutations are common in this form of AML (~50% of cases) and do not have well established prognostic significance, although some studies suggest a favorable association.[255]

11q23.3 Translocations

KMT2A (formerly *MLL*) at chromosome 11q23.3 is one of the most promiscuous genes in the human leukemic genome and is involved in at least 160 different translocations, and these are seen in both

AML and ALL.[259] One specific translocation, which fuses *KMT2A* with *MLLT3* as a consequence of the t(9;11)(p22;q23.3), is now recognized as a distinct entity with an intermediate prognosis to distinguish it from other *KMT2A* translocations that typically portend an adverse prognosis.[260] In general, *KMT2A* translocations in AML are associated with monoblastic differentiation and prior therapy with topoisomerase II inhibitors.

The breakpoints in *KMT2A* tend to cluster in a relatively small (8.3-kb) area spanning exons 5 to 11, referred to as a breakpoint cluster region. *KMT2A* translocations seen in de novo leukemias tend to cluster in the 5′ region of the breakpoint cluster region, whereas those seen in both infantile B-ALL/LBL and therapy-related AML occur more often in the 3′ region. Although specific fusions are amenable to specific FISH and RT-PCR assays, a single *KMT2A* break-apart FISH probe can be used for screening purposes.

The intermediate prognosis association of the t(9;11) translocation has not been confirmed in pediatric AML; however, other interesting prognostic associations have been observed with other *KMT2A* translocations in this age group.[261] Thus the t(6;11)(q27;q23.3) is associated with a particularly dismal prognosis, whereas the t(1;11)(9q21;q23.3) portends an especially good outcome, with a more than 90% event-free survival.[261]

t(6;9)(p23;q34.1)

This translocation is quite rare, occurring in ~1% of AMLs. Frequently associated with basophilia and multilineage dysplasia, this disease entity has an adverse prognosis. The translocation disrupts the *DEK* gene on chromosome 6p23 and the *NUP214*

(formerly *CAN*) gene on chromosome 9q34.1.[262] The breakpoints cluster within a single intron of both *DEK* and *NUP214,* allowing convenient analysis by RT-PCR. Metaphase analysis and FISH are also used in the diagnosis of this entity. *FLT3*-ITD mutations are highly enriched in AMLs with this translocation, occurring in up to 90% of cases.[263]

inv(3)(q21.3q26.2)

The inv(3) and the related t(3;3) are found in ~1% to 2% of AML cases that may display megakaryocytic differentiation, dysplastic changes (binucleated megakaryocytes), and an elevated platelet count.[264] They are typically associated with a poor clinical outcome. These chromosome 3 abnormalities are centered on the dysregulation of *EVI1* on 3q26, which has a variety of alternative splice forms including one variant that results in the endogenous (nonpathogenic) fusion of *EVI1* with an adjacent gene called *MDS1,* resulting in the gene's name being modified to *MECOM* (*MDS1* and *EVI1* complex locus). In contrast to all the other recurrent translocations in AML, inv(3)/t(3;3) does not generate a fusion protein; rather, it results in the inappropriate overexpression of *MECOM*. The involved gene at 3q21.3 had historically been thought to be *RPN1;* however, subsequent studies incriminated *GATA2* as being more pertinent, with its transcriptional machinery driving unregulated *MECOM* expression. Given the absence of a bona fide fusion gene and transcript, RT-PCR–based assays have been difficult to develop. However, a FISH assay for *MECOM* is available and appears more accurate than conventional chromosomal analysis. The gene encoding the core RNA splicing factor *SF3B1* is mutated in

>30% of AMLs with inv(3)/t(3;3), which leads to aberrant *EVI1* splicing and contributes to its pathogenesis.[265]

t(9;22)(q34.1;q11.2)

This translocation, fusing *BCR* on 22q11.2 and *ABL1* on 9q34.1, more characteristically associated with CML and ALL, may also reflect a distinct subtype of AML.[266,267] These cases tend to have a poor outcome. Deletion of the IGH gene may be a characteristic finding that might help distinguish de novo cases from those that reflect AMLs developing from CML. Metaphase analysis, FISH, and RT-PCR can be used to detect this translocation. FISH on nonblast cells in this form of AML (and ALL) may be valuable in distinguishing de novo AML from CML in blast phase, with the *BCR*::*ABL1* fusion more likely to be seen in differentiating granulocytic cells in the latter, but not in de novo AML.

Rationale for Performing Molecular Genetic Studies for Translocations in AML

Whereas all of the recurrent translocations may be readily discernible with metaphase/karyotypic studies, these cytogenetic analyses have a variable false negativity rate. Some of these are truly cryptic in nature in that they are submicroscopic; however, other false-negative results may have a technical basis. For example, there are well-documented reports of false-negative cytogenetics for the three most frequent translocations in AML, t(15;17)/*PML*::*RARA,* t(8;21)/*RUNX1*::*RUNX1T1,* and inv(16)/*CBFB*::*MYH11*. Given the importance of the detection of each in appropriate AML classification and therapy, it might be prudent to screen all newly diagnosed AMLs for the presence of these lesions, at the molecular

genetic level.[268,269] RT-PCR assays are available, and they may be multiplexed. Novel ligase-dependent PCR assays might allow the simultaneous detection of more than 50 translocations.[270] An additional reason for performing FISH or RT-PCR is the superior turnaround time these assays provide compared with metaphase analysis, so that appropriate therapy can be instituted without substantial delay.[271] Even in those scenarios in which cytogenetics easily detect these translocations at diagnosis, it is reasonable to perform the appropriate molecular genetic studies ab initio. The rationale for this is that a disease-specific molecular lesion needs to be identified so that it can be subsequently exploited as a sensitive target for the detection of MRD after therapy.[272]

Mutations

In addition to gross chromosomal abnormalities including the cytogenetically detectable translocations discussed earlier, some of which require molecular genetic analysis for accurate detection, a variety of subchromosomal lesions (in particular mutations) are frequently encountered in AML.[273-275] They are (unsurprisingly but conveniently) enriched in cytogenetically normal AMLs. Thus these molecular abnormalities can be identified in more than 95% of cytogenetically normal AMLs, which account for ~45% of all AMLs. NGS has led to an explosion in the discovery of mutations that play a role in the pathogenesis of AML and that have diagnostic, prognostic, and therapeutic relevance.[276,277]

Nearly all AMLs have mutation in one of eight categories of genes that are almost certainly relevant for pathogenesis, including *NPM1* (~30%), tumor-suppressor genes (~15%), DNA methylation–related

genes (~45%), signaling genes (~60%), chromatin-modifying genes (~30%), myeloid transcription factor genes (~20%), cohesin complex genes (~15%), and spliceosome complex genes (~15%) (**Fig. 5-9**).[261] Another study, which has identified 16 genetic classes of AML, relies on data from both cytogenetics and mutations in 32 genes.[278] Some of the more frequently detected mutations are summarized in **Table 5-11**, with a subset of these described in more detail here. Patterns of cooperation and mutual exclusivity suggest strong biological relationships among several of the genes and categories. For example, *FLT3, NPM1,* and *DNMT3A* tend to occur together, whereas the transcription factor fusions arising as a consequence of some of the aforementioned translocations and mutations of *NPM1, RUNX1, TP53,* and *CEBPA* are mutually exclusive. *IDH1/IDH2* and *TET2* mutations also tend to be mutually exclusive, although this is not always the case. One study identified 11 classes of AML based upon their genetics, with some overlap with the above, with three new categories emerging[279]: AML with mutations in genes encoding chromatin regulators (such as *ASXL1*), RNA-splicing regulators (such as *SRSF2*), or both (in 18% of patients); AML with *TP53* mutations, chromosomal aneuploidies, or both (in 13%); and, provisionally, AML with *IDH2* (R172) mutations (in 1%). There are currently four AML categories that are defined by the presence of mutations, namely those affecting *NPM1, CEBPA,* and *TP53,* as well as those that have one of nine myelodysplasia-related gene mutations. They will be discussed here, followed by a discussion of a number of other relevant, but not disease-defining, mutations.

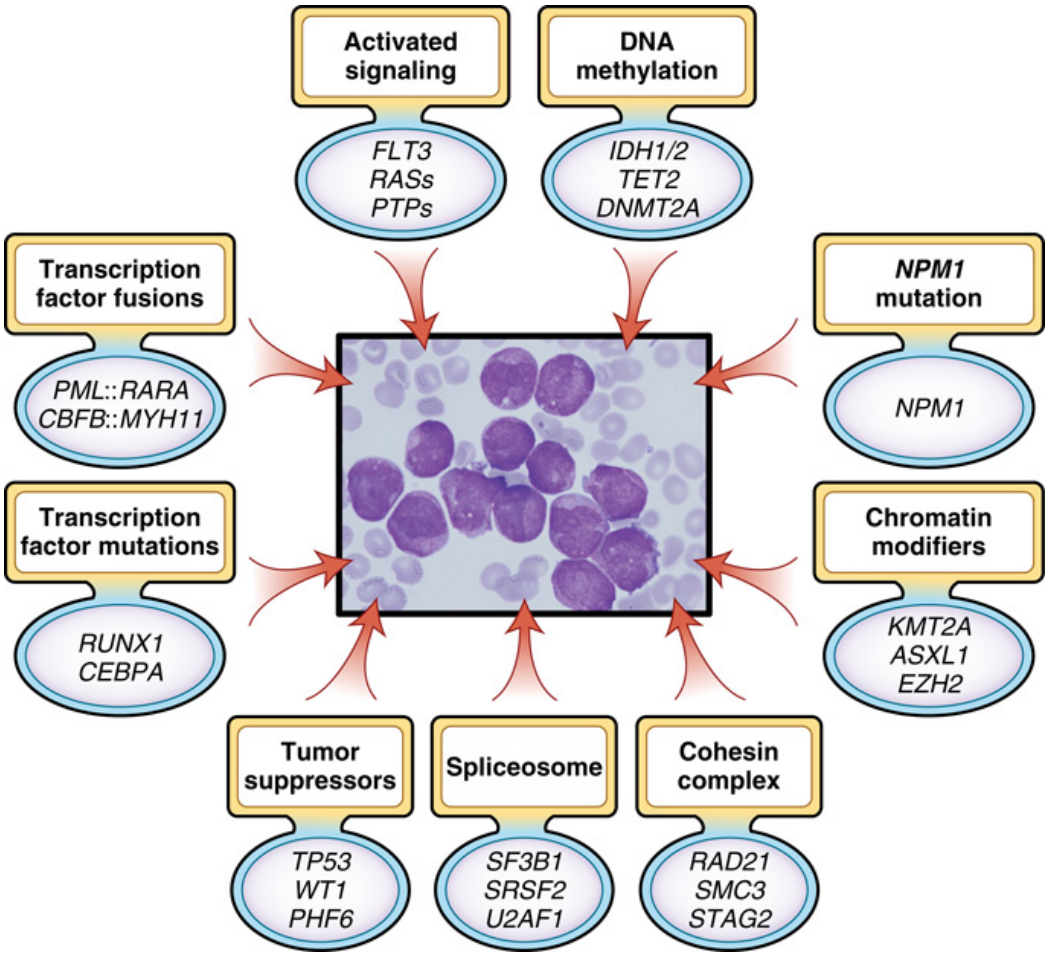

FIGURE 5-9 Molecular basis of acute myeloid leukemia (AML).Virtually all AMLs harbor a mutation in one of eight genetic categories or transcription factor translocations that are central to their pathogenesis. Seven of the eight mutational categories contain a number of genes, and typically no more than one member of each group is mutated in AML. One group contains only a single gene: *NPM1*. The noted recurrent translocations (the ninth category in the figure) lead to the disruption of cellular differentiation

by abrogating the function of transcription factors.

Table 5-11

CBF, Core binding factor; *ITD,* internal tandem duplication.

* Frequency of some mutations may be up to twofold higher in cytogenetically normal AML. See text for details.

NPM1

The gene encoding nucleophosmin *(NPM1)* is, according to most but not all studies, the most frequently mutated gene in AML.[280,281] *NPM1* mutations (typically small insertions of 4 bp, sometimes up to 11 bp) in the coding region of the terminal exon (exon 12 in DNA, designated as exon 11 in RNA), occur in ~ 60% of cytogenetically normal AMLs, equivalent to ~30% of all AMLs. It appears that *NPM1* mutations are orchestrated by the ability of TdT to add N-nucleotides.[282] A normal karyotype is seen in ~82% of *NPM1*-mutated AMLs. The protein functions as a chaperone, actively shuttling between the nucleolus, nucleoplasm, and cytoplasm; however, it is predominantly found in the nucleolus. It is involved in promoting cell growth, in part through its mediation of ribosomal biogenesis and by its functional interactions with the tumor suppressors CDKN2A/p14^{ARF}, *TP53*, and NF-κB. Mutations alter tryptophan residues required for proper nucleolar localization and create a putative nuclear export signal at the C terminus of the protein. Consequently, the mutant nucleophosmin protein is predominantly localized to the cytoplasm and through dimerization

causes the mislocalization of the wild-type protein as well. This leads to the mislocalization and destabilization of $p14^{ARF}$ and to the inhibition of *TP53* activity. In addition to this interesting pathobiology, the mislocalization may be exploited diagnostically because cytoplasmic nucleophosmin can be detected immunohistochemically, ideally with a mutation-specific antibody.[283,284] Some novel (nonexon 12) mutations and gene fusions are missed with standard PCR assays, yet can still be detected immunohistochemically.[285]

NPM1 mutations increase disease-free and OS in patients with AML. This benefit, however, is affected by the *FLT3* status. *FLT3* ITDs are enriched in AMLs with *NPM1* mutations in that they are seen twice as often in this group compared with AMLs with wild-type *NPM1*. Indeed, ~40% of *NPM1*-mutated AMLs also harbor an *FLT3* ITD, and their presence abrogates the good prognostic connotations of *NPM1* mutations. The OS of patients with an AML that is *NPM1* mutation-positive and *FLT3* mutation-negative approaches that of patients with AMLs that harbor karyotypes correlated with a favorable prognosis, such as t(8;21), t(15;17), or inv(16), and for whom bone marrow transplantation may not have survival benefit. It has also been suggested that *NPM1* mutations are only good when accompanied by *IDH2* mutations. Combining the status of these two "dueling" mutations (of *NPM1* and *FLT3*) allows stratification into three prognostic groups. Accordingly, patients may be assigned into good (*FLT3*-ITD−/*NPM1*+), intermediate (*FLT3*-ITD−/*NPM1*− or *FLT3*-ITD+/*NPM1*+), and poor (*FLT3*-ITD +/*NPM1*−) categories. Although typically associated with a good prognosis, one study has suggested that high VAFs (>44%) of mutated *NPM1* predict an

unfavorable outcome.[286] A variety of different but simple molecular assays to detect *NPM1* mutations (either DNA or RNA based) are routinely available in most clinical laboratories. NPM1-positive AMLs tend to lack CD34 expression but express CD33 rather brightly; they are also associated with cuplike nuclear morphology.

CEBPA

CEBPA (CCAAT enhancer binding protein alpha) encodes a key transcription factor that regulates myeloid cell differentiation and proliferation. Mutations of the gene are heterogeneous but are concentrated at the amino and carboxyl terminals of the gene. Mutations are seen in ~10% of all AMLs, typically with relatively well-preserved platelet counts, and are associated with a favorable prognosis. While it was previously noted that this favorable association only occurred when the mutations are biallelic (compound heterozygous, with an N-terminal mutation affecting 1 allele and a C-terminal mutation affecting the other),[287] it has subsequently been demonstrated that only in-frame mutations affecting the bZIP domain (C-terminus) are required to predict a positive outcome and define this entity, without the need for biallelic mutations.[288-290] In the pediatric setting, co-occurring *CSF3R* mutations appear to nullify this favorable prognostic effect.[288] Germline mutations of *CEBPA* predispose to the development of AML. These mutations are associated with a 100% risk for development of AML with a median age at presentation of 24 years; although recurrences (that are clonally distinct) are common, the outcomes are good.[291]

TP53

The gene encoding this prototypic tumor suppressor is mutated in ~5% to 10% of de novo AMLs, but it is mutated much more frequently in the setting of complex cytogenetics (in particular when associated with a monosomal karyotype), prior cytotoxic chemotherapy, increasing age, and in erythroleukemia. AML with mutated *TP53* was recognized as a separate entity within a larger umbrella category of myeloid neoplasms with *TP53* mutations that include MDS and MDS/AML with such mutations.[2] It has been suggested that *TP53* mutations are not directly induced by cytotoxic chemotherapy.[292] Rather, they are likely to reflect rare age-related (or CHIP, see later) mutations that are resistant to chemotherapy and that expand preferentially after treatment. AML with mutated *TP53* is associated with an especially poor outcome. Immunohistochemistry for *TP53* may provide a reasonable surrogate screen for underlying mutations, both missense mutations that lead to overexpression, and truncating mutations that result in lack of expression.[293]

Myelodysplasia-Related Gene Mutations

In addition to the presence of cytogenetic abnormalities that allow for the recognition of a category of AMLs that are myelodysplasia-related, a panel of mutated genes had been identified to be strongly associated with evolution from an underlying MDS, with these two categories (AML with myelodysplasia-related cytogenetic abnormalities and AML with myelodysplasia-related gene mutations) replacing the previous entity of AML-MRC. The genes, mutations of any one of which will allow entry into this category, are *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1,* and

ZRSR2.[279,294,295] Of note, this group now encompasses (and removes as a sole consideration) the previously designated provisional entity of AML with mutated *RUNX1*.

FLT3

FLT3 is a class III receptor tyrosine kinase and IG receptor superfamily member that is expressed by hematopoietic progenitor cells and downregulated during differentiation. Once physiologically activated through *FLT3* ligand binding, phosphorylation of regions in the juxtamembranous domain leads to growth induction and apoptosis inhibition through STAT5 and MAPK signaling. Two major types of genetic abnormalities of *FLT3* have been described: ITD of the juxtamembranous domain and a missense mutation resulting in the amino acid change at D835 that together occur in ~30% of cytogenetically normal AMLs and ~20% of all AMLs.[296] The ITD is more common, occurring in ~23%, with the point mutation seen in ~7% of cytogenetically normal AMLs. As in *NPM1* mutations, TdT appears to be mechanistically involved in *FLT3*-ITD mutations by priming replication slippage.[297] Functionally, these lesions result in the constitutive activation of the TKDs through autophosphorylation, leading to a persistent "on" signal in the transformed leukemic cell; clinically, however, only the ITDs consistently appear to have prognostic relevance.

Importantly, from a clinical perspective, FLT3 dysregulation has been shown to be one of the single most pertinent prognosticators for OS in AML patients. Additionally important, from a molecular diagnostic perspective, these abnormalities are easily discerned by PCR and other mutational detection systems. A number of variables

appear to affect the prognostic associations of *FLT3* ITDs. Thus only when the mutant allele burden is greater than the wild-type allele, that is, >50% (typically a consequence of acquired uniparental disomy), does its prognostic pertinence appear to emerge; however, this cut-off is not universally agreed upon and even very small *FLT3* ITD mutations (clone size of 0.2% to 2%) are important to detect because they may survive chemotherapy and expand over time.[298] Indeed, in the 2022 ELN recommendations allelic ratio (AR) is no longer considered in risk classification.[242] Also, insertion of the ITD into the beta1 sheet of the TKD 1 and, controversially, the length of the mutation are associated with a particularly adverse prognosis,[299,300] although the latter may be overcome with targeted therapy.[301-303] Further, the presence of >1 ITD is an adverse prognosticator and the class of ITD also predicts outcomes with regard to response to FLT3 inhibitors. Thus typical ITDs (in which the mutated sequence matches the wild-type sequence) do better than those that are atypical (where exogenous nucleotides are incorporated).[304] A described third class of *FLT3* mutations reflects deletional mutations.[305] Although the current gold standard for detecting *FLT3* mutations involves PCR with fragment analysis by CE, from which ARs are derived, other technologies are also used, including MPS, in which VAFs are measured, noting that these two metrics (AR and VAF) are not equivalent; in addition, these two approaches have advantages and disadvantages and hence might be best considered complementary rather than equivalent alternative assays.[306] Similar to the association with *NPM1* mutations, blasts of AMLs with *FLT3* mutations tend to show cuplike nuclear invaginations.[307]

FLT3 inhibitors have been used in the therapy of patients with (and sometimes without) such mutations. Interestingly but perhaps unsurprisingly, resistance develops because of the expansion of mutant clones, in particular those occurring in and around D835 and those with gatekeeper mutations affecting F691.[308,309] Resistance to FLT3 inhibition may also occur because of the emergence of RAS pathway mutations, as well as with the acquisition of *BCR*::*ABL1*.[310] Importantly, while *FLT3* mutations are clearly central to the pathogenesis of (and targeted therapy for) AML, they do not define an AML entity because they are not deemed to be primary drivers of the disease, but it is nevertheless essential to test for them for both prognostic and therapeutic reasons.

IDH1/IDH2

IDH1 and IDH2 are NADP-dependent enzymes that convert isocitrate to alpha-ketoglutarate in the Krebs cycle (in the cytoplasm and mitochondria, respectively). The consequence of mutations is the creation of a neomorphic enzyme that generates 2-hydroxyglutarate instead, and this oncometabolite ultimately inhibits the function of TET2, accounting for the usual but not invariable mutual exclusivity of mutations of their respective genes.[311] This may also be the case with *WT1* and the other two mutations so that all three tend to be mutually exclusive.[312] In some studies, IDH2 mutations, particularly those affecting p.R172, associate with improved OS. Inhibitors to both mutant IDH1 and IDH2 are now available for clinical use. As with *FLT3* mutations, while IDH mutations do not define AML entities, they are important to detect to direct targeted therapy. Also as with FLT3 inhibitors,

resistance to these therapies may emerge.[313] Immunohistochemical detection of mutant proteins may provide a useful surrogate for the presence of mutations.[284]

Other Genetic Abnormalities in AML

Whereas a variety of other genetic abnormalities that have biological relevance have been described in AML and contribute to leukemogenesis, none of these is currently routinely evaluated in the clinical setting. These include increased expression of intact genes, copy number variations detected by array comparative genomic hybridization and single nucleotide polymorphism arrays, epigenetic perturbations, and microRNAs.

Myeloproliferative Neoplasms

Genetic studies have a central and ever-expanding role in the diagnosis and classification of the MPNs, not only in the four classical MPNs (CML, polycythemia vera [PV], primary myelofibrosis [PMF], and essential thrombocythemia [ET]) but also in the more recent entries into this umbrella category (chronic neutrophilic leukemia, chronic eosinophilic leukemia, and MPN, unclassifiable) as well as other separately classified chronic myeloid neoplasms (**Fig. 5-10**).[314]

Chronic Myeloid Leukemia

The identification of the Philadelphia chromosome (Ph) in 1960 heralded the era of cancer cytogenetics that has come full circle with the use and unprecedented success of rational, targeted therapy (initially imatinib, as well as other tyrosine kinase inhibitors) directed against the molecular consequence (chimeric *BCR*::*ABL1*

oncoprotein) of the pathognomonic t(9;22)(q34.1;q11.2). This oncoprotein dysregulates multiple pathways that lead to a variety of biological effects, such as increased proliferation, resistance to apoptosis, adhesion defects, and genomic instability, with a latter central to the inexorable disease progression that occurs in untreated patients.[315]

Molecular testing in CML is indicated in three scenarios: at diagnosis, to monitor responses to therapy, and to detect mutations that may induce resistance to therapy. Depending on the denominator, ~95% of patients with a substantial clinical and hematologic diagnostic consideration of CML, in particular based on the complete blood count and peripheral blood smear findings, will be cytogenetically positive for the presence of the defining t(9;22)(q34.1;q11.2); of the ~5% remaining, half (i.e., ~2.5% overall) are positive only at the submicroscopic (molecular genetic) level by either FISH or RT-PCR for the *BCR*::*ABL1* fusion. Whereas the other 2.5% had historically been designated Ph-negative CML, these cases are now classified as atypical CML (aCML) or chronic myelomonocytic leukemia (CMML), both of which are myelodysplastic/MPNs. Accordingly, CML is essentially defined by the presence of a *BCR*::*ABL1* fusion that is usually but not always accompanied by the classical karyotypically determined translocation, in the appropriate clinical and hematologic context.

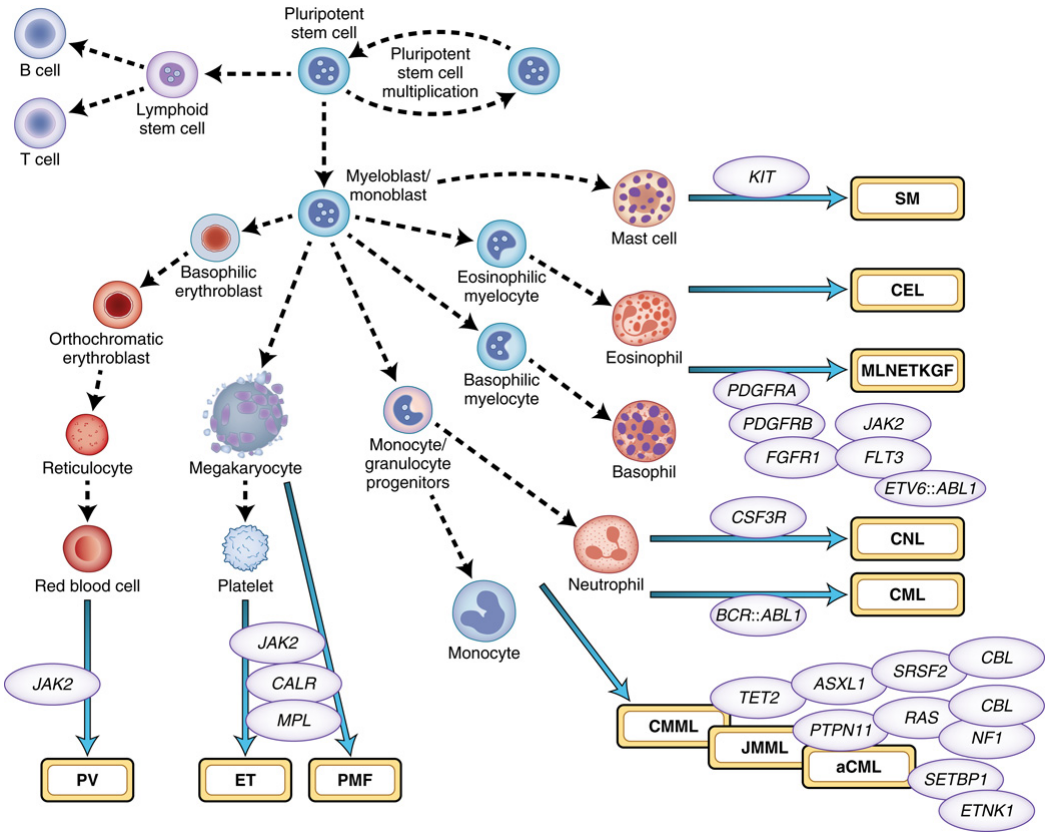

FIGURE 5-10 Molecular basis of the myeloproliferative neoplasms (MPNs) and related disorders.Different recurrent mutations and translocations, mostly occurring in pluripotent hematopoietic stem cells and hence in all neoplastic progeny, are associated, to variable degrees, with the development of myeloproliferative (and related) neoplasms that tend to be associated with the somewhat limited expansion of a specific hematopoietic lineage (*clockwise, from top right:* SM, systemic mastocytosis; CEL, chronic eosinophilic leukemia, the only category currently without a well-defined specific associated molecular

abnormality; MLNETKGF, myeloid and lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions; CNL, chronic neutrophilic leukemia; CML, chronic myeloid leukemia; CMML, chronic myelomonocytic leukemia; JMML, juvenile myelomonocytic leukemia; aCML, atypical chronic myeloid leukemia; PMF, primary myelofibrosis; ET, essential thrombocythemia; PV, polycythemia vera). The detection of these molecular abnormalities is essential for the diagnosis of some of these neoplasms, whereas in others, they can be used as major diagnostic criteria.

Even if the cytogenetic data are unequivocal, it is necessary to document the presence of the fusion by FISH and RT-PCR. This is important not only to indicate that the target of planned tyrosine kinase inhibitor therapy is indeed present but also to discern the specific molecular fingerprint (based on the location of the breakpoints on qualitative RT-PCR analysis) that may be important for the subsequent tracking of MRD. As a corollary, even if there is molecular genetic validation of the diagnosis, it is necessary to perform conventional cytogenetics, both at diagnosis and during the course of the disease, to evaluate for additional chromosomal abnormalities (ACAs) that have prognostic and diagnostic significance (disease metamorphosis to accelerated or blast phase, which is almost invariably heralded by cytogenetically discernible clonal evolution), or for the emergence of Ph-negative clones, which have been reported in ~5% to 10% of patients treated with

imatinib.[316,317] There are six ACAs that may be used as criteria for accelerated phase: an additional Ph chromosome, +8, iso(17q), +19, complex cytogenetics, and abnormalities of 3q26.2. Different ACAs are associated with different frequencies of transformation to blast phase.[318] The emergence of ACAs in Ph-negative clones is of uncertain significance because very few are associated with the development of another overt hematologic neoplasm; however, while −Y may be inconsequential, −7 or del(7q) may be associated with the development of AML or MDS.[319,320]

Broadly, the major indications for *BCR*::*ABL1* testing are in the specific differential diagnostic contexts of CML versus a leukemoid reaction (noting that morphologic clues ought to be most useful) and in CML versus other MPNs and some other chronic myeloid neoplasms. The translocation is not specific for CML; it is also seen in a number of other leukemias, particularly adult B-ALL/LBL, in which it is the most common cytogenetic abnormality. It can also be seen, albeit rarely, in AML. The breakpoints in the *ABL1* gene are usually consistent in both CML and ALL (typically 5′ of *ABL1* exon 2, but occasionally 5′ of exon 3), but they vary in the *BCR* gene. The breakpoints in the *BCR* gene in CML are usually homogeneous, mostly occurring after exon 13 or exon 14, in the M-bcr region of the gene. Thus a simple qualitative RT-PCR assay with a single upstream *BCR* exon 13 primer and a single downstream *ABL1* exon 2 (a2) primer suffices for the molecular detection of this event in virtually all cases of CML. Although there are abundant studies assessing the effect of the site of the M-bcr breakpoint with variable findings, there appears to be no definitive clinical or biological significance, with some of the differences reflecting technical factors[321]; however,

because of alternative splicing, an intron 14 break may yield transcripts containing both e13 and e14 (equivalent to b2 and b3). Indeed, ALL-type transcripts (e1a2) may also be identified in the context of bona fide CML, unrelated to an e1 breakpoint; rather, this too is a manifestation of alternative splicing. However, rare cases (~1%–2%) of CML do harbor e1 *BCR* breakpoints. Such cases are more likely to be associated with a monocytosis, and they are important to recognize because they may not respond well to tyrosine kinase inhibitors and might have an adverse prognosis, and have the potential to be misdiagnosed as CMML.[322] Another noteworthy additional breakpoint, the μ(micro)-bcr, is that occurring after e19, associated with CML with neutrophilia, which must be distinguished from chronic neutrophilic leukemia. Breakpoints other than those occurring in the regions noted here can lead to alternative product sizes or false-negative molecular results; while these are rare, it is important to be aware of them (that ought to be positive by FISH or karyotyping), since they are not trackable by standard quantitative assays.

Whereas the *BCR*::*ABL1* oncogene has historically been interpreted to be the sole driver of seemingly genetically homogeneous CML, NGS has shown that numerous mutations accompany this in chronic phase. These include those affecting *ASXL1* (which appears to be the most frequently mutated gene in CML), *TET2, RUNX1, DNMT2A, EZH2,* and *TP53,* with *TET2* and *DNMT3A* sometimes detected in *BCR*::*ABL1*-negative ancestral clones, possibly reflecting clonal hematopoieis.[323] Some of these and other mutations are seen in advanced phase, with *RUNX1* (33%)

often mutated in myeloid and *IKZF1* (70%) and *CDKN2A* (50%) deleted in lymphoid blast transformation.

In addition to the value of RT-PCR testing at the time of diagnosis of CML (when a *qualitative* assay is essential to determine the site of the *BCR* breakpoint), such testing is mandated to monitor MRD after therapy in patients treated with tyrosine kinase inhibitors and after stem cell transplantation (SCT). For this monitoring, *quantitative* assays are essential.[324-326] Because there is high concordance between peripheral blood and bone marrow testing, the less invasive former procedure suffices for monitoring MRD. Most patients are RT-PCR-positive in the first 6 months after SCT, and this is not of consequence because graft-versus-leukemia can be slow to develop; by contrast, RT-PCR positivity beyond 6 months after SCT is associated with a high risk of relapse.[327] However, some patients may show persistent low levels of disease up to 10 years after transplantation without relapse. With regard to responses to tyrosine kinase inhibitors, the primary goal for some time has been the attainment of a major molecular response (MMR), defined as a greater than 3-log reduction (equivalent to ≤0.1%) in the amount of transcript compared with a standardized control by 12 or 18 months, although it has also been asserted that this has no added value over and above achieving a complete cytogenetic remission by 12 months in predicting prolonged survival. Earlier goals that have clinical relevance include a greater than 1-log reduction (≤10%) at 3 months, also referred to as early molecular remission (EMR) and a greater than 2-log (≤1%) reduction by 6 months. Some studies suggest that reducing *BCR*::*ABL1* levels by more than 50% by as early as day 10 is a robust predictor of sustained treatment free remission.[328]

Although occasionally still used in the literature, the term *complete molecular remission* should be avoided, with the preferred term being *deep molecular remission (DMR)*, qualified by the sensitivity of the assay; if a greater than 4-log reduction (≤0.01%) is attained this is designated as DMR[4] and if a greater than 4.5-log reduction (≤0.0032%) is attained this is designated as DMR$^{4.5}$. Attainment of sustained DMR is a criterion for consideration of cessation of TKI therapy. In addition to monitoring response to therapy, quantitative monitoring (be it by RT-PCR or ddPCR, with the latter showing greater analytic sensitivity and predictive value[329]) can also be used to predict relapse; this is usually defined as a 10-fold (1 log) or greater increase in *BCR*::*ABL1* levels determined by a minimum of two consecutive analyses, with this being more pertinent when it is associated with loss of MMR. FISH does not play a well-established role in monitoring MRD, but may be of some value in patients with variant breakpoints that may not be amenable to quantitative RT-PCR.

A critical issue with regard to quantitative *BCR*::*ABL1* testing had been tremendous variability in how the assay is performed and limited availability of an international standard to allow expression of levels on the International Scale (IS). This has been overcome by the generation and availability of secondary standards and commercial kits or systems that have been calibrated to WHO-generated reference material.[330] Alternatively, clinical laboratories could use the secondary reference materials to align their laboratory-developed *BCR*::*ABL1* test to the IS, through a conversion factor, which is analogous to the international normalized ratio used in coagulation testing.[331] Other emerging technologies in addition to

ddPCR include DNA (rather than RNA/cDNA) patient-specific PCR that might be able to detect 7-log reductions.[332]

A large number (>50) of mutations in the *ABL1* component of the fusion gene have been described, which may lead to resistance to imatinib and other tyrosine kinase inhibitors.[333] However, only a handful (approximately six) of these mutations are common and together account for approximately two-thirds of cases. Nevertheless, different mutations result in variable degrees of resistance to specific TKIs. Many laboratories are now able to test for these mutations, the presence of which may then mandate a change in therapy. This change may not necessarily be the need to switch to an alternative tyrosine kinase inhibitor, such as second-generation agents like dasatinib or nilotinib; some mutations will respond to increasing the dose of imatinib, whereas others might be best dealt with by SCT or the use of a third-generation drug like ponatinib or novel agents such as asciminib for the T315I mutation. Compound mutations are emerging as a therapeutic challenge, with some of these conferring ponatinib resistance.[334] There are a number of defined triggers for mutation testing, including the loss of hematologic, cytogenetic, or molecular responses. Despite its relative insensitivity (~10%–20%), Sanger sequencing had been the preferred technology for mutational analysis; however, this is now being superseded by NGS to afford the early detection of minor clones that are poised to expand.[335] Testing is indicated in response to the noted triggers and seems not yet to be of value at initial diagnosis in patients in the chronic phase, although it is in the accelerated and blast phase.

Classic Myeloproliferative Neoplasms Other Than Chronic Myeloid Leukemia

Three of the other classical MPNs, namely PV, ET, and PMF, are variably associated with three hallmark driver mutations: *JAK2, CALR,* and *MPL*.[314,336,337]

JAK2 encodes an intracellular kinase that mediates signal transduction from cytokine receptors, including the erythropoietin receptor in red cell precursors and the thrombopoietin receptor in megakaryocyte precursors. *JAK2* V617F mutations occur in the vast majority (over 90%) of patients with PV and ~60% of patients with ET and PMF. *JAK2* V617F mutations lead to ligand-independent proliferation of cells that harbor them and are central to the genesis of these MPNs. Putative explanations as to how the same mutation leads to three distinctive neoplasms include the amount of the mutant allele with acquired uniparental disomy more commonly observed in PV than in ET and PMF, the cellular target of the initiating mutation, the presence of additional mutations, and the order in which additional mutations (in particular those affecting *TET2* or *DNMT3A*) develop.[338]

JAK2 V617F mutations occur in exon 14 of the gene; different mutations, occurring in exon 12, are also seen in PV but not in ET and PMF. Thus almost 100% of patients with PV harbor a *JAK2* mutation, either in exon 14 or exon 12 (~4%). Although qualitative assays suffice, there might be a role for quantitative testing for *JAK2* mutations because measurement of VAF at diagnosis may become relevant and, more important, to gauge response to therapy; while JAK2 inhibitors typically fail to elicit a substantial reduction in mutational levels, testing for molecular responses and MRD is of value in the SCT setting and with the use of interferon.

Mutations in *CALR* (encoding calreticulin, a calcium-binding protein that interacts with the endoplasmic reticulum) occur in ~20% to 25% of cases of PMF and ET but not in PV. There are two major mutations, type 1 (a 52-bp deletion, ~65% of cases) and type 2 (a 5-bp insertion, ~32% of cases), that might have different clinicopathologic associations, with PMF more likely with type 1 and ET more likely with type 2 mutations.[339] A minor subset of cases of ET (1%–4%) and PMF (5%–8%) harbor mutations in the *MPL* gene, which encodes the thrombopoietin receptor.

Patients with *CALR* mutations appear to have a less-aggressive form of PMF with a median survival of approximately 18 years compared with those with mutations of *JAK2* or *MPL;* by contrast, those PMFs that are triple-negative, namely, lacking mutations in all three of these genes (now accounting for only ~5% to 10% of patients), tend to have a more aggressive clinical course with a median survival of only approximately 3 years.[340] In PMF, type 1 (or type 1-like) *CALR* mutations are associated with better outcomes than those with type 2 (or type 2-like) *CALR* mutations.[341]

The mutations in these three genes tend to be focused in particular regions of the genes. Thus *JAK2* mutations are primarily located in exons 12 and 14, *CALR* mutations in exon 9, and *MPL* mutations in exon 10. Accordingly, most mutational assays target these specific regions. However, such an approach may lead to occasional activating (so-called “noncanonical”) mutations being missed.

A variety of other mutations have been described in MPNs, with virtually all harboring one or more of these mutations in addition to one of the three hallmark mutations. Many of these are not restricted to MPNs in that they are also seen to variable degrees in other

myeloid neoplasms, such as AML and MDS. Certain additional mutations in PMF are considered “high molecular risk” and predict poor outcomes; they include those affecting *ASXL1, EZH2, SRSF2, TF53, IDH1,* and *IDH2*.[342] Other mutations that negatively affect prognosis include those of *RAS, TET2,* and *U2AF1* (in particular *Q157* mutations).[343] Either single gene assays or multitarget NGS panels may be used to detect these mutations and facilitate the diagnosis of these MPNs. It is important for these assays to be highly sensitive, with the ability to detect VAFs as low as 1%. While single gene assays can be used, panels may be of added value because they can establish clonality in triple-negative MPNs and identify additional mutations that are prognostically pertinent. It may also be of value to perform *BCR*::*ABL1* testing to exclude CML. It has provocatively been suggested that these non-CML MPNs could be classified (with an associated individualized prognosis) in the absence of morphology and bone marrow studies, with eight genomic subgroups: (1) *TP53* disruption or aneuploidy; (2) chromatin or spliceosome mutation; (3) *CALR* mutation; (4) *MPL* mutation; (5) homozygous *JAK2* or *NFE2* mutation; (6) heterozygous *JAK2* mutation; (7) other driver mutation such as *TET2* or *DNMT3A;* and (8) no known driver mutation.[344]

Despite the major advances derived from these molecular abnormalities, there is still a role for metaphase analysis. Thus certain karyotypic abnormalities in PMF are reported to have prognostic implications. For example, +9, −13q, and −20q tend to portend a favorable outcome, whereas abnormalities of chromosomes 5, 7, inv(3), 11q23, and 17 (among others) predict an adverse prognosis.

Chronic Neutrophilic Leukemia

This MPN that may display toxically granulated neutrophils is associated with *CSF3R* mutations in the majority of cases.[345] The gene encodes the granulocyte colony-stimulating factor receptor. As is becoming thematic, a number of other mutations are present, including *SETBP1, SRSF2,* and *ASXL1,* some of which might be prognostically detrimental. There are two major classes of acquired *CSF3R* mutations; most in chronic neutrophilic leukemia are membrane proximal (typically T618I), whereas those that are intracytoplasmic are rare. These have therapeutic (and prognostic, with T618I being adverse) relevance because the former are sensitive to JAK2 inhibitors (such as ruxolitinib), whereas the C-terminal truncating mutations (that are activating because of the loss of negatively regulating elements) respond to dasatinib (that is also effective in CML).[346] *CSF3R* mutations are not present in all cases (80%–90% have these mutations), so their absence does not exclude the diagnosis; nevertheless, this should prompt careful review of the diagnosis. C-terminal truncating mutations also develop in patients with severe congenital neutropenia that typically occurs as a consequence of germline *ELANE* mutations. When acquired *CSF3R* mutations arise in the setting of severe congenital neutropenia, they are associated with the development of acute leukemia.

Chronic Eosinophilic Leukemia, Not Otherwise Specified

This is an MPN with eosinophilia that does not meet criteria for other MPNs and in particular must be distinguished from myeloid and lymphoid neoplasms associated with eosinophilia and tyrosine kinase gene fusions. Though they do not have any of these specific

disease-defining genetic abnormalities, they do have another clonal genetic aberration detected by targeted MPS analysis[347] and are often accompanied by morphologic abnormalities.[348] By contrast, idiopathic hypereosinophilic syndrome is likely a constellation of non-neoplastic and nonfamilial disorders with eosinophilia and end organ damage but without an identified genetic lesion. There is also a lymphoid variant of hypereosinophilic syndrome associated with an indolent expansion of sometimes monoclonal CD3-negative CD4-positive T cells.[349]

Myeloid and Lymphoid Neoplasms Associated With Eosinophilia and Tyrosine Kinase Gene Fusions

This group of neoplasms was previously referred to as myeloid and lymphoid neoplasms associated with eosinophilia and gene rearrangements. The initially recognized group comprised three members with translocations involving one of *PDGFRA, PDGFRB,* or *FGFR1*.[350] The first two are especially important to recognize as they are sensitive, sometimes exquisitely so, to imatinib. All three can be detected with appropriate FISH probes, which are particularly valuable in detecting *PDGFRA* rearrangements that are often cytogenetically cryptic. Subsequent additions to this category include those with t(8;9) that fuses *JAK2* with *PCM1* (other *JAK2*-rearranged neoplasms, including those involving *ETV6* or *BCR,* show less distinctive features but are considered to be genetic variants[351]), t(9;12) that fuses *ETV6* with *ABL1,* and those with *FLT3* translocations,[352] the most common being t(12;13), which involves *ETV6*.

Mast Cell Neoplasms

These include a spectrum of numerous different disease subtypes, with variable frequencies of sometimes different *KIT* mutations.[353] Whereas the hallmark D816V mutation affecting the second intracellular TKD (exon 17) is particularly common (~90% of adult cases) in the various forms of systemic mastocytosis (SM), this mutation is seen in only ~30% of cases with pediatric/primary cutaneous mastocytosis that, by contrast, are more likely to have *KIT* mutations affecting the extracellular domain, encoded by exons 8 and 9. D816V mutations are resistant to imatinib but respond to other kinase inhibitors, such as midostaurin. Rare SM patients with a different *KIT* mutation (in the juxtamembranous or extracellular domain) or with no *KIT* mutation may respond to imatinib. Highly sensitive allele-specific oligonucleotide or ddPCR assays can detect the hallmark mutation in the peripheral blood of most patients with SM, and quantitative assays measuring allelic burden can be used to monitor the natural course of the disease or during therapy. Quantification is also prognostic at the time of diagnosis as the allelic burden is a surrogate for the degree of multilineage involvement, which is a key criterion for disease progression. Standard NGS panels are considered to have insufficient sensitivity to detect mutations in many patients with SM. Additional mutations seen in SM include those affecting *SRSF2, ASXL1, RUNX1, NRAS, DNMT3A,* and *EZH2* that are associated with more aggressive disease.

Myelodysplastic Syndromes/Myeloproliferative Neoplasms

These reflect a group of neoplasms that display features of both MDS (see later) and MPN, and include CMML, aCML, and MDS/MPN

with thrombocytosis and *SF3B1* mutation. Juvenile myelomonocytic leukemia (JMML) is included in this category by the WHO[354] but not the ICC.[2] CMML is associated with a variety of mutations; the most common are those affecting *SRSF2, CBL, TET2, RUNX1, SETBP1,* and *ASXL1,* with the big three of *TET2, ASXL1,* and *SRSF2* each being mutated in around 50% of cases.[355] Mutations of *ASXL1* predict a poor prognosis. *NPM1* mutations are rarely seen in CMML (3%–5%) and they predict an aggressive clinical course; their presence in this setting of known CMML cannot be used to define de novo AML with an *NPM1* mutation. The myeloproliferative subtype of CMML is often associated with other mutations, such as those affecting the RAS pathway (*NRAS, KRAS,* and *CBL*) and *JAK2* or *SETBP1*. aCML is associated with mutations in *SETBP1,* albeit in only a minority of cases (~25%).[356] *ETNK1* that encodes an ethanolamine kinase is mutated in ~10% of aCMLs and rarely in CMML (3%). JMML is characterized by mutations in the RAS signaling pathway, affecting *PTPN11, NF1, NRAS,* and *KRAS*. The presence of *SETBP1, RUNX1,* and *EZH2* mutations in cases of MDS/MPN may be predictive of failure to respond to hypomethylating agents.[357] MDS/MPN with isolated isochromosome 17q may represent a distinct clinico-biological subset.[358]

Histiocytic and Dendritic Cell Neoplasms

Syndromic diseases such as Langerhans cell histiocytosis (LCH), Erdheim-Chester disease, Rosai-Dorfman-Destombes disease, and juvenile xanthogranuloma were once thought to be reactive inflammatory disorders. However, they are now known to represent

neoplasms with, for example, ~50% of cases of LCH and Erdheim-Chester disease harboring *BRAF* V600E mutations, or other mutations in the RAS-MAPK pathway, including those affecting *MAP2K1*.[359] *MAP2K1* encodes MEK1 that is just downstream of RAF in this signaling pathway. Less commonly encountered are mutations in the PI3K pathway. Rosai-Dorfman-Destombes disease is also enriched in similar mutations.[360] In addition to mutations, fusions affecting *BRAF, ALK,* and *NTRK1* may also be seen in LCH.[361] ALK-positive histiocytosis, with *ALK* fusions, in particular *KIF5B*::*ALK* fusions, is a distinct entity that is frequently characterized by neurologic involvement.[362]

Myelodysplastic Syndromes

The MDSs are clonal hematopoietic stem cell disorders that are mechanistically distinct from most other hematologic malignant neoplasms, with ineffective hematopoiesis accounting for the apparently paradoxical coexistence of peripheral cytopenias despite a typically hypercellular bone marrow.[363] Akin to AML, MDS can arise de novo (primary) or as a result of inciting toxic agents, including some chemotherapeutic drugs, as well as chemical or radiation exposure (secondary). There are characteristic dysplastic morphologic features, present in variable degrees, in both the bone marrow and peripheral blood, associated with a variably expanded blast population.

Recurrent cytogenetic abnormalities are associated with MDS and are an integral component of the diagnosis.[364] Although present in the majority of cases of secondary MDS (>80% of cases), these cytogenetic abnormalities are seen in only ~50% of cases of primary

MDS, thereby limiting their diagnostic utility. In contrast to many of the cytogenetic alterations described in other hematologic malignant neoplasms that are typically balanced translocations without a net gain or loss of genetic material, unbalanced numeric chromosomal abnormalities predominate in MDS, hinting at alternative genetic mechanisms. More commonly identified aberrations include −5/del(5q), −7/del(7q), +8, del(20q), and complex karyotypes. However, neither +8 nor del(20q) can be used to facilitate a diagnosis of MDS. Independent of complex karyotypes, a monosomal karyotype also predicts inferior outcomes as in AML. These cytogenetic features are an integral facet of the International Prognostic Scoring System and have assumed an even greater role in the Revised International Prognostic Scoring System (IPSS-R), in which the number of different cytogenetic aberrations has tripled (**Table 5-12**).

It is generally (but not universally) thought that FISH analysis provides no significant added value over and above a good-quality conventional cytogenetic analysis.[365,366] FISH is of utility, however, only in the context of karyotypic failure. FISH on CD34-enriched peripheral blood cells seems to have added value but is labor-intensive.[367]

Isolated del(5q), which defines a specific subtype of MDS (and currently the only one that is defined by its cytogenetic abnormality), is typically associated with a good prognosis and response to lenalidomide. However, *TP53* mutations are not uncommon in this subtype (seen in ~20% of cases) and predict a poor prognosis, and hence it may be important to test for such mutations even in this form of MDS.[368] Specific genetic targets in MDS with isolated

del(5q) have been sought, and they include *RPS14,*[369] *SPARC, CSNK1A1,*[370] *CTNNA1,* and *LMNB1,* with the latter loss accounting for the characteristic nuclear hypolobation of neutrophils.[371] Of note, not all MDS cases with 5q-negative have MDS with del(5q). In general, MDS with del(5q) targets more distal regions (5q33), where both *RPS14* and *SPARC* reside. In addition, in this entity there can be no more than one additional cytogenetic abnormality [except −7/del(7q)] or multihit *TP53* mutations.[2]

With the advent of high-throughput MPS technologies, it is now possible to evaluate MDS specimens for a number of key mutations that may have relevance diagnostically, prognostically, and therapeutically.[372-374] Point mutations have been identified in more than 90% of patients with MDS. Some of the more frequently mutated genes are detailed in **Table 5-13** and illustrated in **Figure 5-11**. The IPSS-R has been updated to incorporate mutational analysis, is designated the IPSS-M, with M for molecular,[375] and includes an analysis of up to 31 genes (16 of which are considered main effect genes), allowing for six risk categories with an open access online calculator that accounts for missing values (**https://mds-risk-model.com**). The six most frequently mutated genes (seen in >10% of patients) in MDS are *TET2, ASXL1, SF3B1, DNMT3A, SRSF2,* and *RUNX1*. Whereas other studies have identified mutations in *ASXL1, TP53, EZH2, ETV6,* and *RUNX1* as predictors of poor OS, according to the IPPSS-M, *TP53* (multihit), *FLT3,* and *KMT2A* (partial tandem duplication) are the top genetic predictors of adverse outcomes. The frequency of mutations of *IDH1, IDH2, FLT3,* and those in the RAS pathway increases at the time of transformation to AML, with mutations affecting signaling pathways

leading to convergent clonal evolution, a hallmark of progression.[376] Unlike in AML, where a single *TP53* mutation is prognostically adverse, in MDS *TP53* defects need to be multihit to be prognostic and indeed definitional of *TP53* mutated MDS. Multihit *TP53* requires the presence of two or more distinct *TP53* mutations (VAF ≥10%), or a single *TP53* mutation associated with either: (1) a cytogenetic deletion involving the *TP53* locus at 17p13.1; (2) a VAF of >50%; or (3) copy-neutral loss of heterozygosity (LOH) at the 17p *TP53* locus.[377,378] In the absence of LOH information, the presence of a single *TP53* mutation in the context of any complex karyotype is considered equivalent to a multihit *TP53*.

A third category of MDS that is now recognized by virtue of its genetic features [in addition to those with del(5q) and multihit *TP53* mutations] is that associated with *SF3B1* mutations, which defines a more homogeneous group than that originally defined by the presence of ring sideroblasts.[379] Mutations of this spliceosome gene leads to the mis-splicing of several genes, with effects on *MAP3K7* leading to anemia[380] and those on *ABCB7* and *TMEM14C* associated with the characteristic ring sideroblasts.[381] While this form of MDS and *SF3B1* mutations are characteristically associated with a good prognosis, other factors can overcome this association and may indeed lead to poor outcomes; these include scenarios in which the mutation is seen in the context of excess blasts, commutated with *ASXL1, RUNX1,* or *EZH2,* or when the *SF3B1* mutation affects K666 (rare, seen in 1%–2% of cases) rather than the canonical K600 mutation (seen in 97% of cases).[382]

Table 5-12

AML, Acute myeloid leukemia; *NR,* not reached.

Table 5-13

aCML, Atypical chronic myeloid leukemia; *CMML,* chronic myelomonocytic leukemia; *MDS,* myelodysplastic syndromes.

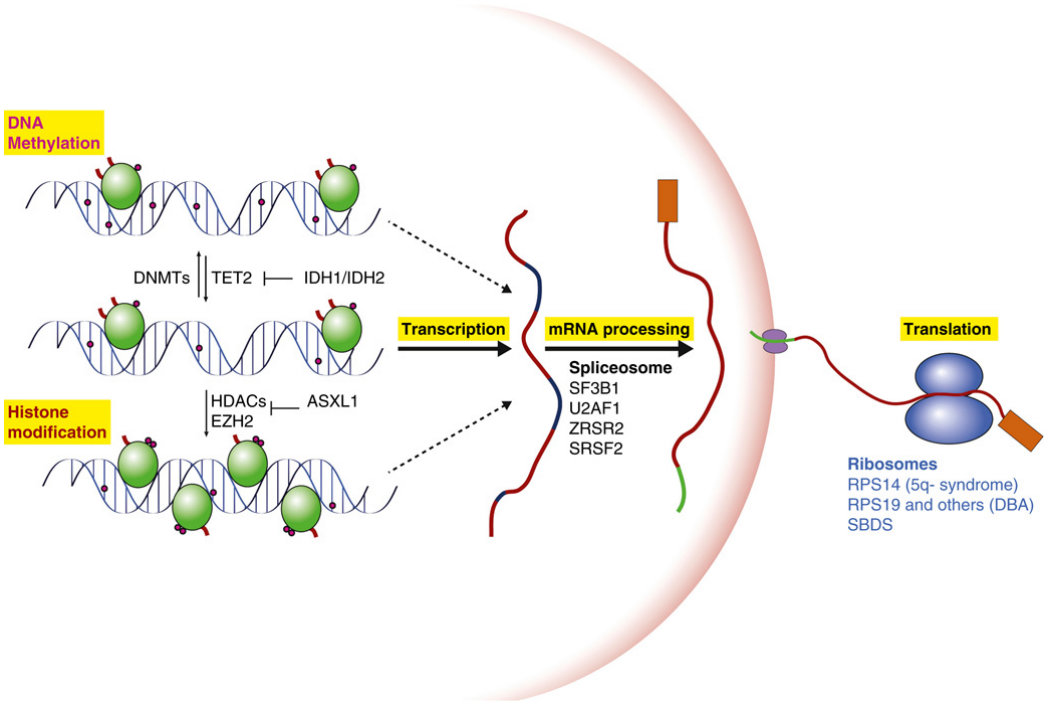

FIGURE 5-11 Molecular basis of the myelodysplastic syndromes (MDSs).Many of the mutations affect the fundamental pathway of transcription, RNA splicing, and ribosomal biogenesis. DNA in a steady state of transcriptional regulation *(middle)* is subject to methylation *(top)* and histone modification *(bottom)*. DNA methyltransferases (DNMTs) methylate DNA, reducing transcription; mutation of *DNMT3A* (one of the genes encoding a DNMT) affects this process. *TET2* mediates a step in the opposite process, removing DNA methylations; mutations of the *TET2* gene lead to a loss of this demethylation function. *IDH1/2* mutations result in altered enzymatic function and production of 2-hydroxyglutarate, which inhibits *TET2*.

Histones *(green balls)* reduce transcription through increased binding. Histone deacetylases (HDACs) and *EZH2* modify histone acetylation *(red lines)* and methylation *(magenta circles),* resulting in increased histone avidity for DNA and reduced transcription. Mutations of *EZH2* and *ASXL1* lead to dysregulation of histone modification. The spliceosome processes mRNA, removing introns *(blue lines)*; genes encoding proteins that constitute the splicing machinery (*SF3B1, U2AF1, ZRSR2,* and *SRSF2*) are mutated in MDS and may result in aberrant splicing. mRNA processing adds the 5′ methyl guanine cap *(tan box)* and the polyalanine tail *(green line)*. Ribosomal proteins, including RPS14 [MDS with del(5q)], RPS19 (Diamond-Blackfan anemia), and SBDS, play roles in ribosomes *(blue ovals)*, translating mRNA into protein; these ribosomal genes are targeted in MDS with del(5q) and in hereditary bone marrow failure syndromes (e.g., Diamond-Blackfan anemia and Shwachman-Diamond syndrome [Shwachman–Bodian–Diamond syndrome]). *Modified with permission Nybakken GE, Bagg A. The genetic basis and expanding role of molecular analysis in the diagnosis, prognosis, and therapeutic design for myelodysplastic syndromes.* J Mol Diagn JMD. *2014;16[2]:145-*

158. https://doi.org/10.1016/j.jmoldx.2013.11.005.

Unsurprisingly, sequencing in morphologically nondiagnostic marrows can identify patients who are at heightened risk for development of MDS; in contrast to the CHIP mutations seen in aging individuals (see "Potential Pitfalls of Molecular Testing" section), these have a higher allelic frequency (~40% versus ~10%) and likelihood of more than one mutation (~65% versus ~10%). Mutational testing on peripheral blood appears to be as informative as that on bone marrow, perhaps precluding the need to perform this invasive procedure for these analyses.[383] *ATRX* mutations in MDS lead to the development of acquired alpha-thalassemia and should be considered when an MDS is associated with microcytosis (in contrast to the usual macrocytosis).

Hematologic Neoplasms With Germline Predisposition

Once considered to be quite rare and restricted to younger individuals, particularly pediatric patients with AML or MDS, such conditions are increasingly recognized in all age groups and to extend beyond myeloid neoplasms, in that it is posited that ~8% of adults with cancer have a pathogenic germline variant.[384] Although not designed to specifically detect *germline* mutations, the widespread adoption of panels used to detect *somatic* mutations has led to an increased awareness and recognition of these entities. Their identification has numerous ramifications, and is crucial for not only correct diagnosis and initial management of the afflicted patient, including the selection of therapeutic conditioning, should SCT be considered, but also for screening of related donors for SCT, and

genetic counseling for both the patient and affected family members.[385] While there may be clues (family history, syndromic stigmata, and findings from somatic panels, such as VAFs of mutated genes >30%, “biallelic” mutations, two mutations in the same gene, and persistence of the mutation at high VAF in remission, among others), many of these disorders may lack some of these features, and hence it has been suggested that germline predisposition risk should be considered for all patients diagnosed with a hematologic neoplasm regardless of age, since some germline predisposition alleles, like those in *DDX41,* can drive hematopoietic malignancies in older age.[386] Indeed, reliance upon the interpretation of VAFs from somatic panels is fraught, because a variety of potentially confounding phenomena including somatic genetic rescue in which correction of the germline mutation may occur.[387] Of course testing for these mutations should be performed on uninvolved specimens uncontaminated by blood, ideally from cultured skin fibroblasts or hair bulbs, since somatic testing panels cannot be relied upon to exclude their consideration.

The ICC category of hematologic neoplasms with germline predisposition includes four major subgroupings,[2] namely those: (1) without a constitutional disorder (e.g., *CEBPA, DDX41*); (2) with a constitutional platelet disorder (e.g., *RUNX1, ANKRD26, ETV6*); (3) with a constitutional disorder affecting multiple organ systems (e.g., *GATA2, SAMD9, SAMD9L*), classical bone marrow failure syndromes (e.g., Fanconi anemia, Shwachman-Diamond syndrome, dyskeratosis congenita), neurofibromatosis, Noonan and Noonan-like syndrome, and Down syndrome; and (4) associated with, in particular, acute lymphoblastic leukemia (e.g., *IKZF, PAX5*). The

recognition of these disorders is an evolving field without clearly established guidelines, but it is anticipated that future studies will lead to the development of a comprehensive list of all predisposition genes.[388,389]

POTENTIAL PITFALLS OF MOLECULAR TESTING

Having detailed the virtues and advantages of molecular analysis in hematologic neoplasms, it is essential to be cognizant of a number of limitations of such testing.

Antigen Receptor Gene Rearrangements

False-positive results may occur for antigen receptor gene rearrangement studies in small samples or samples with very few lymphocytes (pseudoclonality).[390] Routine duplicate testing of these specimen types can identify these spurious positive, and nonreproducible, results. Monoclonal antigen receptor gene rearrangements may also be seen in a variety of reactive and inflammatory conditions that include *H. pylori*–induced gastritis, hepatitis C and other viral infections, Sjögren syndrome, and rheumatoid arthritis. These are typically a reflection of bona fide oligoclones that, unlike pseudoclonality, may remain constant with duplicate testing. Many of these scenarios, of course, are associated to a variable degree with the subsequent development of bona fide (typically B-cell) lymphomas. Other examples in which apparent clonal antigen receptor gene rearrangements are identified, in the absence of neoplasia, include canonical TR gamma chain rearrangements involving the Vγ9 segment that is associated with

aging, immune reconstitution after bone marrow transplantation, and immune response to tumors. An additional caveat is that antigen receptor gene rearrangements may not be specific for definition of lineage of neoplastic populations because in immature lymphoid malignant neoplasms, cross-lineage rearrangements may occur with those of IGH occurring in T-lymphoblastic leukemia and those of TR occurring in B-lymphoblastic leukemia.[391]

False-negative molecular genetic studies of antigen receptor gene rearrangements can be caused by technical or biological factors. Technical factors include oversimplified approaches, for example, the use of single V region consensus primers and the use of CDR3-only upstream primers to detect IGH gene rearrangements that ought not to be in contemporary clinical assays. Whereas PCR is highly sensitive, the consensus primers used amplify rearranged IG genes from normal B cells and TR genes from normal T cells in the sample as well as from the clonal population, and a small clonal population may not be identifiable because of the polyclonal background. Thus the sensitivity of the assay is highly dependent on the proportion of background normal lymphocytes present in the sample. The biological phenomena that may elicit false-negative IGH PCR results are somewhat different, depending on the specific neoplasms. In the context of precursor B cells, a variety of factors may confound the ability to detect IGH gene rearrangements. These include the presence of partial D-J (rather than complete V-D-J) rearrangements, which would be missed with upstream V primers; oligoclonal rearrangements, which are seen in up to one-third of precursor B-cell ALLs; and ongoing rearrangements at the time of relapse. With regard to more mature B-cell neoplasms, passage

through the germinal center, with the induction of SHM, is associated with a greater degree of IGH PCR false negativity, a problem particularly prevalent in FLs. Many of the shortcomings of antigen receptor PCR assays have been overcome with the introduction of the standardized BIOMED-2 reagents, in particular the use of IGH D-J and IGK primers. NGS-based approaches that extend beyond the limited assessment of the size (base pair length) of rearrangements by also determining sequences (base constituents) appear to offer a superior approach for the assessment of these gene rearrangements, and are poised to replace capillary or gel electrophoresis-based assays.[392]

Translocations and Mutations in Normal Individuals

There is an ever-expanding list of leukemia- or lymphoma-associated translocations being detected by ultrasensitive PCR or RT-PCR techniques in "normal" individuals with neither concurrent nor subsequent development of malignant disease (**Table 5-14**).[393] The biological significance of these is uncertain, although they do suggest that many of these translocations are indeed "necessary, but not sufficient" for the full neoplastic phenotype. The t(14;18) fusion, which is evident in the peripheral blood of up to 60% of normal individuals, is positively correlated with age, heavy smoking, hepatitis C virus infection, and pesticide exposure. It has been suggested that once circulating *IGH*::*BCL2* levels exceed 1:10,000, there is indeed a heightened risk (23-fold) for the development of lymphoma. The t(11;14) fusions are less frequent, occurring in ~5% of normal individuals, and they can persist for long periods.

From a clinical laboratory perspective, the presence of such translocations in the normal population should elicit some caution but certainly not undue concern. The reasons for this include the fact that many of these have been detected only with hypersensitive assays detecting these fusions at levels so low (~10^{-6} to 10^{-8}, equivalent to 0.0001% to 0.000001%) that they are irrelevant diagnostically and unlikely to be relevant even in the context of contemporary MRD testing, in which approximately 10^{-4} to 10^{-5} appears to be the usual degree of sensitivity required.

Although biologically fascinating, more potentially troublesome from a diagnostic point of view is the detection of mutations seen in a spectrum of myeloid neoplasms occurring in normal individuals and increasing with age at levels much higher (and thus detectable in many standard assays) compared with the low-level translocations described. Such mutations by definition have VAFs of >2% and occur in the absence of a myeloid neoplasm and cytopenias, and are termed clonal hematopoiesis of indeterminate potential (CHIP).[394] These studies show that approximately ~2% of the general population harbor these mutations in the peripheral blood, with frequencies of less than 1% for age younger than 50 years (although they occur in individuals as young as 25 years), ~10% in those older than 65 years, and ~20% in those older than 90 years. With more sensitive assays with lower VAFs, CHIP is virtually universal by middle age. The most frequently mutated genes are *DNMT3A* > *TET2* > *ASXL1* (the top three), *JAK2, TP53, GNAS, PPM1D, BCORL1,* and *SF3B1,* with those affecting *TP53* and *PPM1D* expanding in the setting of cytotoxic therapy (especially platinum-based therapies) with the potential to elicit therapy-related myeloid

neoplasms.[395-397] There are a total of approximately 20 genes that are recurrently mutated in CHIP, as currently defined. Individuals with CHIP mutations have a 10- to 15-fold increased risk for development of a hematologic neoplasm, increased all-cause mortality, and increased risk of inflammation-associated diseases such as cardiovascular disease, gout, and chronic obstructive pulmonary disease (COPD).[398,399] These observations underscore the fact that the detection of these mutations cannot be used to diagnose MDS, although the opposite may be true, namely, that the absence of a mutation may render a diagnosis of MDS unlikely but not impossible. There are three genomic features, particularly in the setting of clonal cytopenias of undetermined significance (CCUS), that are likely to predict an increased likelihood of progression to a neoplasm: (1) the gene affected, such as *U2AF1, SF3B1, SRSF2, IDH1, IDH2,* and *TP53 ,* more risky; (2) the number of genes mutated, with two or more worse than one; and (3) the VAF, when greater than 10%. Whereas CHIP is by definition unaccompanied by cytopenias, CCUS[400] is, and this expands the risk for developing bona fide neoplasms. Because *DNMT3A, ASXL1,* and *TET2* mutations are so frequent in CHIP and MDS, a mutation in one of these genes cannot always be considered diagnostically useful nor indeed of value in tracking MRD in AML. In contrast, genes that are less frequently mutated in CHIP (such as *U2AF1, TP53,* and *RUNX1*) might retain some specificity in the appropriate clinical context. CHIP and CCUS are essentially analogous to MGUS, MBL, and FL-like B cells of undetermined significance in the setting of myeloma, CLL, and FL, respectively, reflecting precursor lesions, albeit with an

apparently relatively low risk (~1%/year) of progressing to an overt neoplasm.

Table 5-14

Examples of Translocations Detected in Normal Individuals

Translocation	Genes Fused	Tumor Association
t(14;18)	*BCL2*::*IGH*	Follicular lymphoma
t(11;14)	*CCND1*::*IGH*	Mantle cell lymphoma
t(8;14)	*MYC*::*IGH*	Burkitt lymphoma
t(9;22)	*BCR*::*ABL1*	Chronic myeloid leukemia, B-lymphoblastic leukemia/lymphoma
t(2;5)	*NPM1*::*ALK*	Anaplastic large cell lymphoma, ALK-positive
inv(2)	*ATIC*::*ALK*	Anaplastic large cell lymphoma, ALK-positive
t(12;21)	*ETV6*::*RUNX1*	B lymphoblastic leukemia/lymphoma

Similar mutations have also been described in up to almost 50% of cases of aplastic anemia, perhaps limiting their use in distinguishing this group of bone marrow failure syndromes from hypocellular MDS. Mutations include those affecting *ASXL1, TET2, DNMT3A, BCORL1,* and *BCOR*. *ASXL1* and *DNMT3A* mutant clones expand

over time and *ASXL1* mutations are (as is characteristic) associated with a poor prognosis and increased risk for development of MDS.[401] *TET2* mutations portend a better prognosis and are associated with longer survival in aplastic anemia.

There is tremendous overlap in diseases in which many of these mutations occur. There is a growing list of mutations that are seen not only in AML, MPN, and MDS but also in lymphoid neoplasms[402] and indeed a number of non-hematologic neoplasms, highlighting the fact that most of the mutations encountered are not disease specific, although clear associations have emerged. In addition, an increasing number of mutations is encountered in what are currently considered to be "benign" diseases, blurring the diagnostic lines between the traditional separation of neoplastic versus reactive.[403] The presence of CHIP can also cause confusion in the interpretation of ctDNA studies and solid tumor sequencing panels, with the latter potentially confounded by blood contamination. This highlights the important fact that most if not all molecular abnormalities should never be interpreted in isolation, and the need to correlate all molecular data with available morphologic and immunophenotypic data cannot be overemphasized.

SUMMARY AND CONCLUSIONS

Insights into the vast spectrum of genetic abnormalities that are required to initiate and to sustain hematologic neoplasms continue to evolve from fragmented accounts based on restricted lines of investigation into a much more comprehensive view of how the multitude of facets (gene fusions and dysregulation through gross chromosomal abnormalities, mutations, epigenetic transcription

control through DNA and chromatin modifications, and alterations in the noncoding genome, among others) interact. Disruptive technologies such as NGS have dramatically altered our understanding by facilitating an assessment of the panoply of genetic aberrations that drive hematologic neoplasms, opening the door to a more refined manner in which we can diagnose, prognosticate, monitor, and treat these neoplasms with tumor-specific and precision therapies.

Acknowledgments

The authors express their profound appreciation to Insuk Choe, JD for excellent editorial assistance.

Pearls and Pitfalls

- The incremental adoption of disruptive technologies in the evaluation of hematologic neoplasms has facilitated our understanding of the genetic basis of many of these neoplasms. Not only is the judicious use of these tools central to the diagnosis of a subset of lymphomas, leukemias, and other hematologic neoplasms, but they also inform prognosis and targeted therapeutic approaches.
- Despite the high throughput, precision, and sensitivity of nascent technologies such as NGS, time-honored tools, such as conventional metaphase cytogenetic analysis, still retain diagnostic and prognostic relevance in contemporary practice.

- Some hematologic neoplasms are essentially defined, in the appropriate clinicopathologic context, by specific generic aberrations, such as the *BCR*::*ABL1* fusion in chronic myeloid leukemia. In contrast, others, although highly associated with a hallmark genetic abnormality, such as the t(14;18)/*IGH*::*BCL2* in follicular lymphoma, can be diagnosed in the absence of this abnormality, which is also not diagnostically specific for follicular lymphoma.
- Certain mutations, initially described in the setting of a specific neoplasm, for example, acute myeloid leukemia (AML), have subsequently been detected not only in a spectrum of other myeloid neoplasms (such as the myelodysplastic syndromes [MDSs] and myeloproliferative neoplasms [MPNs]) but also in lymphoid and in non-hematologic neoplasms, thus highlighting the notion that these mutations cannot be exclusively used to render specific diagnoses and should be interpreted in combination with other pathologic data in appropriate clinical contexts.
- The increasing detection of a plethora of disease-associated genetic aberrations in normal (but occasionally restricted, e.g., the aging) populations reinforces the need for the rational use and contextual interpretation of the ever-expanding menu of molecular tests.

Myeloproliferative Neoplasms

Myelodysplastic Syndromes

Acute Myeloid Leukemia

Precursor Lymphoid Neoplasms

TYPES OF CHROMOSOMAL ABERRATIONS IN HEMATOLOGIC MALIGNANCIES

Introduction to Human Chromosomes

In 1888, Waldeyer was first to introduce the term *chromosome* (meaning “stainable body,” from the Greek *chroma,* meaning “color,” and *soma,* meaning “body”). Waldeyer referred to Walther Flemming, who coined the terms *chromatin* and *mitosis* in 1879 at Kiel University. Flemming was also first to describe germinal centers. Since the pioneering studies by Flemming and Waldeyer, a wealth of knowledge on the composition and function of chromosomes has emerged. Each chromosome consists of a DNA double helix bearing a linear sequence of genes, coiled and recoiled around aggregated proteins called *histones*. Two sister chromatids (each constituting half of a chromosome) are joined together at a junction called a *centromere* (primary constriction). The full chromosome containing both joined sister chromatids becomes visible only during mitosis, in a phase known as *metaphase*. Regular human cells have 23 pairs of chromosomes (22 pairs of autosomes, numbered consecutively from 1 to 22, and 1 pair of sex chromosomes, i.e., XX in females and XY in males). Thus a normal human somatic cell has two complements of 23 chromosomes (2n) for a total of 46 chromosomes, in contrast to a germ cell, which only

has one chromosomal complement (1n) of 23 chromosomes. By convention, chromosomes are numbered in descending order according to their size and the position of the centromere (arm ratio) and are arranged into seven groups (from A to G) (Denver classification). On the basis of the centromere location, there are three main types of chromosomes: *metacentric,* with their arms roughly equal in length; *submetacentric,* with one arm clearly shorter than the other; and *acrocentric,* with a centromere located near one end of the chromosome. A *band* is defined as part of the chromosome that is clearly distinguishable from its adjacent parts by appearing darker or lighter with one or more banding techniques. This banding pattern, to some extent, reflects the base pair and histone composition of the different chromosome parts. Bands are grouped in regions delimited by specific landmarks and numbered consecutively from the centromere outward along each chromosome arm, with the first number specifying region and the second band within this region; if sub-bands are discernible, they are numbered with the third number (and fourth in some instances) placed behind a period. Letters *p* (from French, *petite*) and *q* are used to designate, respectively, the short and long arm of each chromosome. For designation of a particular band, four items are required: (1) chromosome number, (2) arm designation (*p* or *q*), (3) region number, and (4) band number within that region. For details on banding patterns, naming of chromosomes, and their parts, please refer to the International System of Cytogenetic Nomenclature (ISCN).[1]

Chromosomal aberrations (or abnormalities) are changes in the number of chromosomes (numerical abnormalities; also named

aneuploidy when one or a few chromosomes are gained or lost) or in their structure (structural abnormalities). In cancer cytogenetics, somatic (i.e., acquired, tumor-associated) aberrations have to be clearly differentiated from constitutional (i.e., germline) abnormalities. In principle, a chromosomal alteration—particularly if detected in all cells of an investigated individual—could represent a constitutional aberration, as long as its constitutional appearance is compatible with life.[2] Some common examples of constitutional alterations recurrently detected during tumor genetic workup are numeric changes in the sex chromosomes (e.g., XXY in patients with Klinefelter's syndrome), Robertsonian translocations [e.g., t(13;14)(q10;q10)], balanced translocations in phenotypically normal carriers [e.g., t(11;22)(q23;q11)], trisomy 21 in individuals with Down syndrome, or germline uniparental disomy (i.e., two different chromosomes from the same parent). The constitutional nature of a suspected abnormality should be confirmed or refuted with cytogenetic analysis of phytohemagglutinin (PHA)-stimulated culture of blood and/or cultured fibroblasts, or another alternative cell system (e.g., buccal swap, sedimented cells from urine). Moreover, occasionally somatically acquired alterations may also occur independently from tumorigenesis. Examples include loss of the Y chromosome in marrow or blood of older male patients or T-cell receptor (TR) gene loci rearrangements.

Clones and Clonal Evolution

A *clone* is a cell population derived from a single progenitor cell. At the cytogenetic level, a clone is defined as two metaphase cells with the same structural abnormality or gain of the same chromosome, or

three cells with loss of the same chromosome. The presence of a cytogenetically aberrant clone (or clones) at diagnosis usually indicates a neoplastic process. However, a clone does not necessarily prove the presence of a neoplastic disease, as occasionally, a clonal abnormality may be present in non-neoplastic cells, such as in the case of the aforementioned clonal loss of chromosome Y during aging. Moreover, a tumor population is not always homogeneous, and in addition to the most basic clone of a tumor cell population, termed *stemline,* one or more subclones (termed *sidelines*), containing new abnormalities in addition to the ones present in the stemline, can appear during tumor development (clonal evolution). Non-clonal aberrations (i.e., those occurring in single cells) are usually not listed in the karyotype description, but if they are indicated, it is done separately from the clonal abnormalities. A single-cell abnormality can sometimes be judged to be of a clonal origin if it represents a typical, cancer-associated aberration and/or its clonality is corroborated by alternative techniques (e.g., fluorescence in situ hybridization [FISH]), or it is found at other time points (e.g., at relapse).

Chromosomal instability is a transient or persistent state that causes a series of mutational events leading to gross genetic alterations. Multiple whole chromosome gains and losses and structural abnormalities present in more than one clone and in non-clonal cells are common manifestations of genomic instability. Determination of chromosomal instability requires approaches capable of monitoring cell-to-cell variability and/or the rate of both numerical and structural chromosomal changes. The most commonly used methods to determine chromosomal instability are

conventional cytogenetics, FISH, or copy number (CN) array-based procedures.[3] Nevertheless, new more molecular-oriented technologies like optical mapping or genome sequencing approaches (particularly using long reads) might increasingly supplement the conventional (molecular) cytogenetics technologies in the future.

Alterations of Cell Ploidy

Cell ploidy alterations are changes in the number of chromosome complements. As outlined earlier, the basic set of human chromosomes is called *haploid* and contains 23 chromosomes: one copy of each of the 22 autosomes and one sex chromosome. A haploid chromosome set is characteristic for germ cells. A normal somatic human cell has two haploid sets and is called *diploid* (2n = 46 chromosomes). Cells with an increased number of chromosome sets are called *triploid* (3n = 69 chromosomes), *tetraploid* (4n = 92 chromosomes), and so on (**Table 6-1**).

Systematic cytogenetic analysis of solid tumors and hematologic malignancies has revealed that the chromosome number in cancer cells can be highly variable, ranging from hypodiploidy (<46 chromosomes) to tetraploidy (4n = 92) or even pentaploidy (5n = 115), hexaploidy (6n = 138), or octaploidy (8n = 184). The modal number is the most common chromosome number in a tumor cell population. All changes in chromosome number should be expressed in relation to the appropriate ploidy level. A hyperdiploid karyotype characterizing a subset of acute lymphoblastic leukemia (ALL) patients is thought to arise from a single-step mechanism. Unscheduled tetraploidy can arise by one of three main mechanisms: cell fusion, mitotic slippage, or a failure to undergo cytokinesis.

Maintenance of heterozygosity has been demonstrated, suggesting that the hyperdiploidy does not arise from a near-haploid precursor.

Table 6-1

Relationship Between Modal Number and Ploidy Level

Ploidy Level	Modal Number	Number of Chromosomes
Near-haploidy	23±	≤34
Hypohaploidy		<23
Hyperhaploidy		24–34
Near-diploidy	46±	35–57
Hypodiploidy		35–45
Hypertriploidy		45–57
Near-triploidy	69±	58–80
Hypotriploidy		58–68
Hypertriploidy		70–80
Near-tetraploidy	92±	81–103
Hypotetraploidy		81–91
Hypertetraploidy		93–103
Near-pentaploidy	115±	104–126
Hypopentaploidy		104–114
Hyperpentaploidy		116–126
Near-hexaploidy	138±	127–149

Ploidy Level	Modal Number	Number of Chromosomes
Hypohexaploidy		127–137
Hyperhexaploidy		139–149
Near-heptaploidy	161±	150–172
Hypoheptaploidy		150–160
Hyperheptaploidy		162–172
Near-octaploidy	184±	173–195
Hypooctaploidy		173–183
Hyperoctaploidy		185–195

Data from McGowan-Jordan J, Hastings RJ, Moore S, eds. *ISCN (2020): An International System for Human Cytogenomic Nomenclature (2020)*. Basel: Karger; 2020.

Aneuploidy: Monosomy and Trisomy

Monosomy is a term to describe the absence of one member of a chromosome pair, resulting in a clone with 45 chromosomes in the case of a single monosomy. Conversely, the term *trisomy* describes the presence of an extra chromosome (three copies instead of one pair); a single trisomy results in cells with 47 chromosomes. In the karyotype, a monosomy is usually denoted with a minus sign (e.g., −7 meaning *monosomy 7*) and a trisomy with a plus sign (e.g., +8 meaning *trisomy 8*).

Balanced Chromosomal Alterations (Reciprocal Translocations, Insertions, and Inversions)

Balanced chromosomal changes include reciprocal translocations, insertions, and inversions. Reciprocal translocations are interchromosomal abnormalities resulting from the exchange of chromosomal material between two chromosomes without apparent gain or loss of chromosome material. Insertions are created when a segment of one chromosome is excised and inserted into one of the arms of another chromosome, whereas inversions constitute intrachromosomal aberrations derived from a 180-degree rotation of a segment within a single chromosome. The majority of recurring reciprocal translocations and inversions in hematologic neoplasms are considered to be primary events. They can lead to generation of gene fusions encoding chimeric transcripts, which contain sequences from both fused genes, or to deregulation of wild-type genes located next to a breakpoint by either promoter substitution or novel regulatory context. Several of these translocations and inversions are highly conserved and can be present in a majority of tumors of a given subtype. This makes various primary genetic alterations valuable diagnostic markers. Few cases carry three-way translocations that similarly involve three chromosomes with one breakpoint in each.

Unbalanced Chromosomal Aberrations (Deletions, Duplications, and Unbalanced Translocations)

In addition to a whole chromosome gain (trisomy), chromosomal segments can be gained through unbalanced translocations or intrachromosomal duplications. Massive gain of a large number of

copies of a small chromosomal region is called *amplification,* which cytogenetically is manifested as a homogeneous staining region (HSR) if the amplicon sticks together at one chromosomal site or as small acentric structures called *double minutes (dmin).* Amplifications are known to activate oncogenes and constitute a genetic mechanism leading to the overexpression of the amplification target gene(s). In this sense, several loci of recurrent amplification have been identified in different leukemia and lymphoma types as amplifications of *REL/BCL11A* at 2p16, *BCL2* at 18q21, or *MYC* at 8q24. The border between chromosome material gain and amplification is sometimes difficult to establish. Complex rearrangements containing amplification of two loci juxtaposed by a chromosomal translocation have been named *complicons.*[4,5]

Structural abnormalities resulting in loss of a chromosomal segment are intrachromosomal deletions and unbalanced translocations. The major consequences of deletions in cancer cells are the loss and/or inactivation of tumor suppressor genes, although occasionally deletions can lead to gene fusions and oncogene activation. The most prominent example of deletions in both lymphoid and myeloid neoplasms with a complex karyotype is loss of the short arm of chromosome 17 (17p), which contains the locus of the tumor suppressor gene *TP53*. Losses of 6q are present in many types of aggressive lymphoma, such as diffuse large B-cell lymphoma (DLBCL), follicular lymphoma (FL), or mantle cell lymphoma (MCL). In patients with these deletions, the other allele of the target gene is frequently inactivated by a mutation. In some other cases, a homozygous deletion (i.e., deletion of both alleles) can occur. This is recurrently the case in chromosomal region 9p21, in which

homozygous deletions involving the *CDKN2A* gene can be detected in several types of lymphoma and ALL.[6,7] However, for many recurring deletions, genes presumed to be targets of deletions have not been hitherto identified. It has been suggested that such deletions can play a role in leukemogenesis through haploinsufficiency, that is, decreased expression of genes mapped to the lost segments because of the presence of only one functional allele following a deletion of the second.[8]

In myeloid and lymphoid neoplasms with reciprocal translocations or inversions as primary abnormalities, unbalanced aberrations associated with gain and loss of chromosome material usually represent secondary genetic events and might be present only in a subset of cells of a given tumor. In contrast, in patients diagnosed with acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) with a complex karyotype, unbalanced aberrations predominate and have presumed primary significance.[8-10]

Copy-Neutral Loss of Heterozygosity

Loss of heterozygosity (LOH) means that a constitutionally heterozygous locus loses one allele. The reason for such loss can be a deletion (which is a copy-associated LOH) or LOH without chromosomal loss because of gain of the other allele in the form of a (partial) isodisomy. For this second kind of event, the term *copy-neutral-LOH* (CN-LOH) has been introduced. In this sense, consequences of loss of one allele and duplication of the mutated allele can be functionally similar to a homozygous mutation. CN-LOH is a recurrent oncogenic event in lymphomas and AML. The regions affected by CN-LOH in lymphomas usually include such

tumor suppressor genes as *TP53*[11] or *TNFRSF14,*[12] whereas in AML, CN-LOH often results in homozygous mutations at loci frequently mutated in this disease, such as *CEBPA, FLT3, RUNX1,* and *WT1*.[13-14] Its identification has been useful for characterizing tumor stages and progression in different cancer types.[13-16] As the gene dosage is not altered, CN-LOH cannot be detected by conventional cytogenetics, FISH, or comparative genomic hybridization (CGH) array analysis.

Chromothripsis

Chromothripsis is a phenomenon identified in cancer cells by whole-genome sequencing that produces catastrophic chromosome reorganization of one or a small number of chromosomes at a single point in time.[17] Some distinctive features of chromothripsis are: (1) alternating regions of CN aberration with a minimal number of CN states (one and two copies in its simplest form); (2) LOH of the lower CN state; (3) derivation of each "new derivative" chromosome from one or a small number of chromosomes. Features 1 and 2 can be assessed by CN array, but this approach does not reveal the full complexity of the interchromosomal rearrangements. Chromothripsis escapes conventional cytogenetic detection but can be suspected in complex karyotypes with one to three chromosomes participating in complex rearrangements. Multicolor FISH (M-FISH) or spectral karyotyping (SKY) can also identify the involvement of a minimal number of chromosomes (feature 3), but at low resolution. Nevertheless, a combination of both CN array and multicolor karyotyping techniques or analysis by Optical Genome Mapping

(OGM) or (long-read) sequencing are currently the possible strategies for detection of chromothripsis in routine diagnosis.[18,19]

Moreover, Baca et al.[20] also introduced the term *chromoplexy* to describe another type of coordinated structural genome rearrangement that, differently from chromothripsis, can occur in different steps in the evolution of the tumor, not in one single catastrophic event, and the breakpoints are unclustered and include multiple chromosomes. These changes have been identified in chronic lymphocytic leukemia (CLL).[21,22]

CONVENTIONAL CYTOGENETIC METHODS

Conventional cytogenetics analysis is based on the study of metaphase chromosomes obtained from viable, dividing cells from bone marrow, peripheral blood, lymphoid tissue, or other tumor-containing tissue with staining techniques. This method has become a routine test in the management of hematologic malignancies. The main banding techniques are those that produce the so-called *quinacrine (Q), Giemsa (G), centromeric (C),* and *reverse (R)* banding. In Q-banding, the chromosomes are stained with quinacrine hydrochloride, which reveals a consistent and reproducible banding pattern of brighter fluorescence in A-T–rich regions and dull fluorescence in G-C–rich regions.[23] Q-banding is especially suitable to identify the Y chromosome in both metaphase and interphase nuclei. In G-banding, the chromosome preparation is subjected to treatment with sodium salt citrate at a warm temperature or to a mild treatment with an enzyme such as trypsin, followed by staining with a weak solution of Giemsa or Wright stain.

This procedure also reveals transverse dark and light bands that correspond, respectively, to the brightly fluorescent and dully fluorescent bands produced by Q-banding.[23,24] Currently, most laboratories routinely use G-banding for the diagnosis of hematologic neoplasms (**Fig. 6-1A**).

There are different techniques to obtain R-banded chromosomes like fluorescent R-banding or incubation of the chromosome preparation in very hot phosphate buffer, followed by Giemsa staining.[25] R-banding yields a banding pattern that is the reverse of G-banding, that is, dark bands in G-banded chromosomes stain light with R-banding, and vice versa. R-banding is useful for identifying deletions or translocations that involve the telomeric regions of chromosomes and the late-replicating, inactive X chromosome.

C-banding involves short treatment of the chromosomes with a weak solution of alkali, such as barium hydroxide, followed by Giemsa staining.[26] C-banding suppresses staining all along the chromosome except at the centromeric heterochromatin regions.

Given the importance of cytogenetic analysis, it is important to obtain chromosome preparations of good quality. Every specimen can have specific culture requirements. For example, precursor B lymphoblastic leukemia/lymphoma (B-ALL) or T lymphoblastic leukemia/lymphoma (T-ALL) specimens that have a high mitotic index can be grown in direct culture for 1 to 6 hours, whereas most neoplasms require a short-term, unstimulated culture (24–48 hours). Stimulation with mitogens (e.g., 3 days) is necessary in such chronic lymphoproliferative disorders as CLL (e.g., with DSP30 or CpG-oligonucleotide/interleukin 2) or T-cell leukemias (with PHA).

Technical details can be obtained from *The AGT Cytogenetics Laboratory Manual,* which is the standard reference.[27]

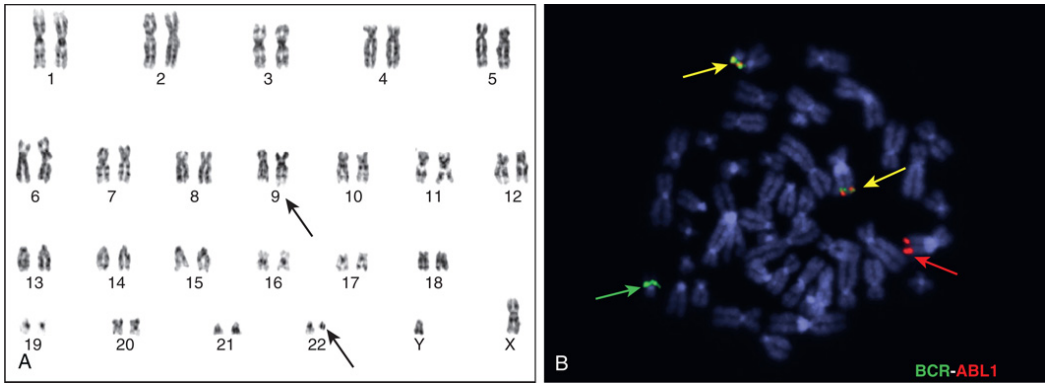

FIGURE 6-1 **A,** G-banded karyotype showing 46,XY,t(9;22)(q34;q11.2). **B,** Fluorescence in situ hybridization (FISH) with dual-color dual-fusion *BCR*::*ABL1* Vysis probe. Fusion is indicated with yellow arrowheads. Kindly provided by Dr. Dolors Costa, Hospital Clínic Barcelona.

To describe chromosomes and their aberrations, the ISCN is applied. It is based on the results of several international conferences, the first of which took place in 1960 in Denver, Colorado. ISCN is periodically updated on the basis of new information and constitutes the widely accepted standard for chromosome and chromosome abnormalities description.[1] In the karyotype description, the first item is the total number of chromosomes followed by sex chromosomes and a description of chromosome abnormalities with ISCN-approved abbreviations. The symbol identifying the type of rearrangement (e.g., t = translocation, inv = inversion, or del = deletion) is followed by the chromosome number(s) involved in this rearrangement placed in parentheses, and

then designation of breakpoints within the rearranged chromosome(s) in a second set of parentheses, for example, inv(16)(p13.1q22). If two or more chromosomes are altered, a semicolon is used to separate their designation. The number of cells constituting each clone is given in square brackets at the end. For example, two clones from a male patient carrying a t(8;21) translocation as a sole abnormality in a stemline and together with a loss of the Y chromosome in a sideline, identified in 13 and 10 metaphase cells, respectively, is reported as follows: 46,XY,t(8;21)(q22;q22)[13]/45,X,−Y,t(8;21)(q22;q22)[10].[1]

Conventional cytogenetic analysis is a powerful tool for characterizing tumor karyotypes. However, it is time-consuming, technically demanding, and requires dividing cells to obtain metaphases. In many hematologic malignancies, particularly lymphomas, the mitotic index is often low and the quality of metaphases poor. In addition, the karyotypes of many advanced lymphoid tumors are highly complex and cannot be completely resolved by conventional cytogenetic analysis. Another limitation of conventional cytogenetic analysis is its inability to distinguish molecularly distinct rearrangements that appear to be cytogenetically identical. For example, the t(14;18)(q32;q21) translocation is observed in FL and extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT), but the genes at 18q21 deregulated by the translocation are different. The fusion product in FL is *IGH*::*BCL2*, whereas in MALT it is *IGH*::*MALT1*. It is important to distinguish between these translocations because each is associated with a distinct histologic subtype. Another limitation of conventional cytogenetic analysis is

its inability to detect cryptic translocations involving telomeric parts of the chromosome, such as the t(6;14)(p25;q32)/*IGH*::*IRF4* translocation typically present in plasma cell myeloma (PCM), also named multiple myeloma (MM),[28] and in a subset of germinal-center–derived B-cell (GCB) lymphomas.[29]

MOLECULAR CYTOGENETIC METHODS

Because of the aforementioned limitations, investigators searched for alternative molecular methods that would enable the analysis of non-dividing cells and offer better resolution. FISH was the first such molecular method developed, and several others, namely SKY or M-FISH, and CN analysis, including CGH array, single-nucleotide polymorphism (SNP) array, and molecular inversion probe (MIP) assays, followed rapidly.[30,31] The applications, advantages, and disadvantages of these methods in comparison to conventional G-banding are summarized in **Table 6-2**.

Fluorescence in Situ Hybridization

In FISH, fluorescently labeled DNA probes are hybridized to interphase nuclei or metaphase spreads prepared for standard cytogenetic analysis. FISH can also be applied to a wide range of cellular preparations such as banded slides, air-dried bone marrow or blood smears, fresh tumor touch prints, frozen or paraffin-embedded tissue sections, or nuclear isolates from fresh or fixed tissues.

A variety of FISH probes, each targeting a specific region or the entire chromosome, are available. Probes routinely used in the analysis of hematologic malignancies include chromosome-specific

enumerator (i.e., mostly centromeric) probes, gene- or locus-specific probes, whole chromosome painting (WCP) probes, arm-specific sequence probes, and telomeric probes.

Chromosome-specific centromeric probes are derived from the highly repetitive, mostly alpha-satellite DNA sequences located within the centromeres. Because the target size is several hundred kilobases (kb) in length, the probes exhibit bright, discrete signals and are easy to evaluate in both metaphase and interphase nuclei. Centromeric probes are useful in identifying numerical abnormalities (aneuploidy), dicentric chromosomes, and the origin of marker chromosomes. Clinically important aberrations such as trisomy 12 in CLL, monosomy 7 in AML, and (high) hyperploidy in ALL—all of which are detected at a lower incidence by conventional cytogenetics owing to low mitotic index or poor morphology—are routinely evaluated by FISH in many clinical laboratories. Another example is the use of differentially labeled probes specific for chromosomes X and Y in monitoring engraftment in sex-mismatched allogeneic stem cell transplantation.

WCP or arm-specific sequence probes use mixtures of fluorescently labeled DNA sequences derived from the entire length of the specific chromosome or one of its arms.[30,31] They are helpful in characterizing complex rearrangements and marker chromosomes. However, cryptic rearrangements affecting terminal regions may remain undetected because of suppression of the repetitive DNA sequences within these regions. The application of chromosome painting probes is limited to metaphase analysis because the signals are often large and diffuse in interphase. Chromosome-specific telomeric or subtelomeric probes are derived

from DNA sequences located at or adjacent to the telomeres and are effective in detecting terminal, interstitial, and cryptic translocations that are below the resolution of conventional cytogenetics and/or are undetectable by WCP.

Gene-specific or locus-specific probes are derived from unique DNA sequences or loci within the chromosome. With banding techniques on highly extended chromosomes, the smallest detectable chromosome abnormality is 2000 to 3000 kb, whereas gene- or locus-specific probes can routinely detect regions as small as 0.1 kb.[31] As such, these probes have wide application in both basic and clinical research. Gene-specific or locus-specific probes have been extremely useful in gene mapping and in defining structural rearrangements, amplifications, and origin of marker chromosomes in both metaphase chromosomes and interphase nuclei.

Table 6-2

* Only with appropriately designed probes.

‡ When present in the form of a homogeneous staining region or double minutes.

In lymphoid malignancies, locus- or gene-specific probes have also been effective in delineating minimal regions of deletion (e.g., on

chromosomes 6q,[32] 11q,[33] and 13q[34]) and in demonstrating monoallelic losses of such genes as *RB1* and *TP53*.

Although the FISH probes can be easily applied to and analyzed on cytogenetic preparations, paraffin-embedded or frozen tissue sections can be difficult to work with and require additional standardization techniques. Loss of signal because of low hybridization efficiency and high non-specific background autofluorescence can lead to atypical signal patterns, making signal interpretation difficult. Nevertheless, adapted FISH protocols have been successfully implemented in the routine diagnosis (**Fig. 6-2**).[35] The major limitation of detecting losses by FISH in paraffin-embedded tissues is that part of the cell can be lost during the sectioning process, leading to false-positive results. Therefore for detection of deletions, the cutoff value (i.e., a minimal percentage of cells with deletion detected for calling the case positive) has to be established at a higher level and appropriate negative controls have to be evaluated.[35] Consequently, commercial FISH probes designed for evaluation of losses usually include an internal FISH hybridization control labeled with a different fluorochrome that usually hybridizes to the centromere of the chromosome with the locus of interest, or to a distal region of the same chromosome expected to be preserved if the deletion occurs. In the analysis of deletions by FISH, the evaluation by two different observers is highly recommended, as it is for the evaluation of translocations.

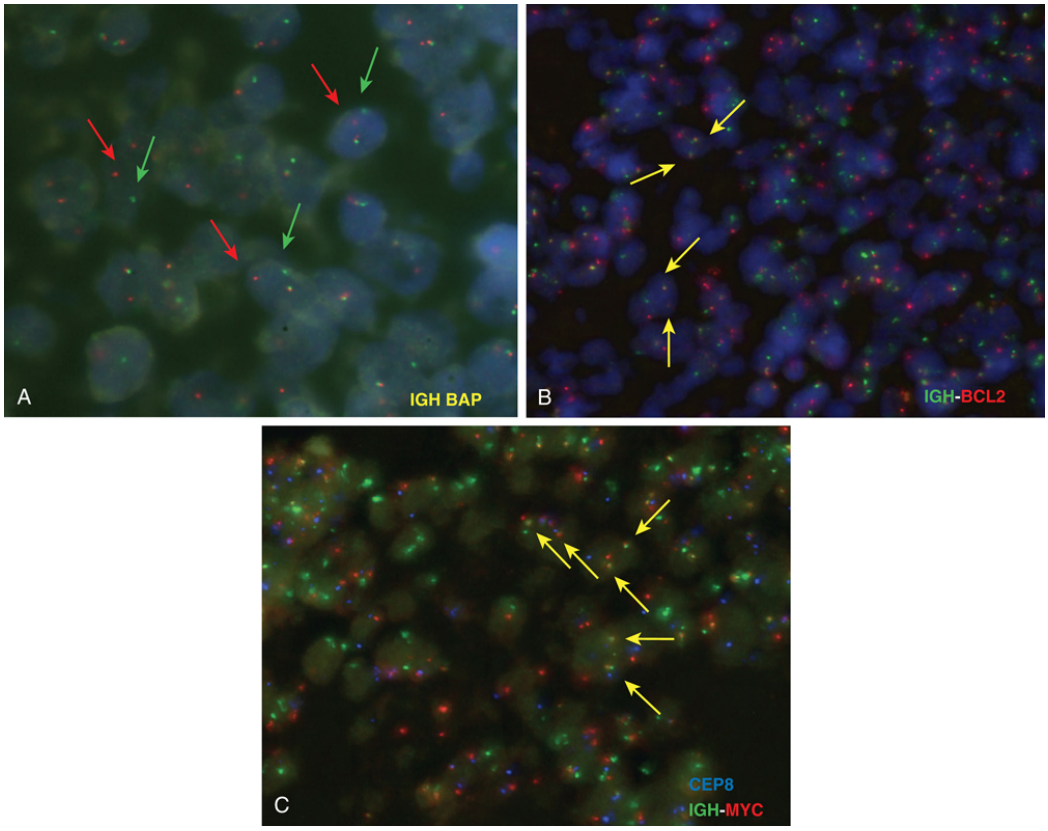

FIGURE 6-2 Fluorescence in situ hybridization (FISH) analysis of 14q32 (IGH)-associated translocations in B-cell lymphomas on formalin-fixed paraffin embedded (FFPE) and frozen material.**A,** Analysis of IGH breaks with break-apart IGH probe (Vysis) on FFPE sections from a mantle cell lymphoma case. Breaks are indicated with green and red arrows. **B** and **C,** FISH analysis with dual-color dual-fusion *IGH*::*BCL2* (Vysis) and *IGH*::*MYC* (three-color DCDF, Vysis) on frozen tissue sections from follicular lymphoma and Burkitt lymphoma cases. Fusions are indicated with yellow arrows. Kindly provided

by Dr. Cristina Lopez, Institute of Human Genetics, Kiel.

For the detection of translocations, two types of FISH probes are widely used, break-apart probes (BAPs) and dual-color dual-fusion (DCDF) probes. The BAPs detect gene rearrangements with differently labeled DNA probes that are complementary to sequences distal and proximal to the breakpoint within the target gene. The DCDF are designed for proving the juxtaposition of two loci and are used for the identification of reciprocal translocations. For this purpose, two DNA probes labeled with different colors located at the respective breakpoints of both translocation partners are used. The juxtaposition of both genes is translated into a third color under the microscope (fusion signal) (**Fig. 6-1B**; **Fig. 6-2B** and **C**). BAP probes are less informative than DCDF probes because although they can reveal breakage within a specific locus, they do not define the other gene involved. In addition, because they flank the locus of interest, small insertions could remain unidentified. Nevertheless, their advantage lies in their ability to detect translocations involving different partners of such promiscuous genes as *MYC, KMT2A* (formerly known as *MLL*), or *BCL6,* and they are easier to evaluate because the separation of two signals is easily recognizable. However, because some normal signals can be vaguely separated when BAP probes are used, the normal signal pattern has to be carefully defined according to probe design, locus interrogated, the material investigated, and so on. On the other hand, a positive result with DCDF probes consists of two fusion signals, an event that is very unlikely to occur by chance. For both kinds of probes, variant

signal constellations caused by complex or unbalanced changes need to be considered.

Among the critical factors affecting an accurate interpretation of FISH is the establishment of proper cutoff values for the different probes used. For DCDF, the cutoff is usually clearly below 5%, but it might be significantly higher for some variant signal patterns, for example, when it is caused by the loss of one derivative chromosome involved in the translocation. On the other hand, because BAPs are variable based on the location of the breakpoints and the probe design, the FISH evaluator needs to visually estimate the relative distance between the different color probes in normal controls. A break is usually recognized if the distance between the two signals is at least twice the estimated signal diameter. Ideally, the BAP cutoff should be between 1% and 5%, although it might be higher, again depending on the probe design and locus investigated.

ISCN standard nomenclature is also established for description of chromosomal changes detected by FISH. In interphase FISH, the abbreviation *nuc ish* is followed by the locus designation in parentheses, a multiplication sign (×), and the number of signals seen: for example, nuc ish(D13S319×2). The presence of an extra signal is reported as nuc ish(D13S319×3), whereas loss of one copy is reported as nuc ish(D13S319×1). If loci of two separate chromosomes are tested and they are juxtaposed (translocation), the results are expressed as follows: nuc ish(ABL1×2),(BCR×2),(ABL1 con BCR×1); or, alternatively, nuc ish(ABL1,BCR)×2(ABL1 con BCR×1).[1]

Probe sets for the detection of most rearrangements associated with specific subtypes of leukemia or lymphoma are now available commercially and routinely used in cytogenetic laboratories to

establish a diagnosis, select therapy, and monitor the effects of therapy. However, it is important to underline that in contrast to conventional cytogenetic analysis, which allows the simultaneous recognition of all microscopically detectable abnormalities in tumor cells regardless of whether they are numerical, structural, balanced, or unbalanced, FISH can be currently used only to detect the presence or confirm the absence of specific abnormalities that the probes used are designed to identify.

Similar to FISH, the chromogenic in situ hybridization (CISH) technique relies on the ability of DNA probes to hybridize specifically to complementary target DNA, but for signal identification CISH uses chromogens instead of the fluorochromes used by FISH. An advantage of CISH is that evaluation can be performed with a conventional bright-field light microscope instead of fluorescence microscopy with multiband pass filters. This allows comparison of CISH results with the tumor area routinely stained. The limitations of CISH include a relatively low number of commercially available probes and, in contrast to FISH, difficulty in evaluating more than two different probes simultaneously.[36]

FISH can also be combined with immunophenotyping, which is particularly useful in identifying the cell lineage of a cytogenetically aberrant neoplastic clone. Simultaneous fluorescence immunophenotyping (FICTION technique) allows visualization of antigen expression of cells with chromosomal aberrations directly correlating phenotypic and genotypic cell features.[37] Different studies have demonstrated the application of combining FISH and cell-sorting techniques, such as magnetic-activated cell sorting (MACS), in the diagnosis of plasma cell myeloma.[38]

Multicolor Fluorescence in Situ Hybridization Techniques

SKY and M-FISH enable the simultaneous visualization of each of 22 pairs of autosomal chromosomes and both sex chromosomes in different colors. To prepare probes used for multicolor hybridizations, flow-sorted chromosomes are labeled with one to five fluorochromes to create a unique color for each chromosome pair. In SKY, image acquisition is based on a combination of epifluorescence microscopy, charge-coupled device imaging, and Fourier spectroscopy.[39] In M-FISH, separate images are captured for each of five fluorochromes with narrow band-pass microscope filters; these images are then combined by dedicated software. Both methods have the ability to characterize complex rearrangements, define marker chromosomes, and identify cryptic translocations (**Fig. 6-3**).[39-41]

Multicolor images of metaphase cells hybridized with the SKY/M-FISH probe mixture are analyzed together with electronically inverted and contrast-enhanced DAPI (4′,6-diamidino-2-phenylindole) images producing G-banding–like patterns that enable specific breakpoint assignments both in interchromosomal and intrachromosomal rearrangements. The final identification of chromosome aberrations and assignment of breakpoints in structural rearrangements is based on a combination of spectral classification and G-banding (**Fig. 6-4**). Additional FISH experiments are often required to clarify ambiguous results, and to confirm or refute the suspected involvement of specific genes located near breakpoints in structural abnormalities. The resolution of SKY/M-FISH for the detection of interchromosomal rearrangements is between 500 and 2000 kb and depends significantly on the quality

of the metaphases and the resolution of the chromosomes involved in the rearrangement. As with banding techniques, subtle, subtelomeric translocations cannot be detected by SKY or M-FISH.

Comparative Genomic Hybridization

CGH is designed to scan the entire genome for gains, losses, and amplifications.[42] In this method, test (tumor) and reference (normal) DNAs are differentially labeled and cohybridized to normal metaphase spreads (chromosomal CGH) or to microarrays (array CGH).

CGH has the advantage of requiring only tumor DNA extracted from either fresh or archived material. The reference DNA does not need to be from the same patient. The tumor DNA is usually labeled with a green fluorochrome (FITC/spectrum-green), and the reference DNA is labeled with a red fluorochrome (TRITC/spectrum-red). The differences in CN between the tumor and normal DNA are reflected by differences in green and red fluorescence along the length of the chromosome. A number of hematologic malignancies have been analyzed by chromosomal CGH to identify genomic imbalances. One valuable finding has been the identification of high-level amplification of genes such as *REL, MYC,* and *BCL2* in B-cell lymphomas.[43-46] The importance of gene amplification as a genetic mechanism in the biology of lymphomas remained unrecognized by studies with banding-analysis alone. A caveat related to this assay is its inability to detect balanced genomic aberrations. Moreover, to be reliably detected, a gain or loss must usually be present in at least 35% of the tumor cells, and the altered regions must be at least 10

Mb. For detection of high-level amplifications, the size of a given amplicon must amount to at least 2 Mb.[47]

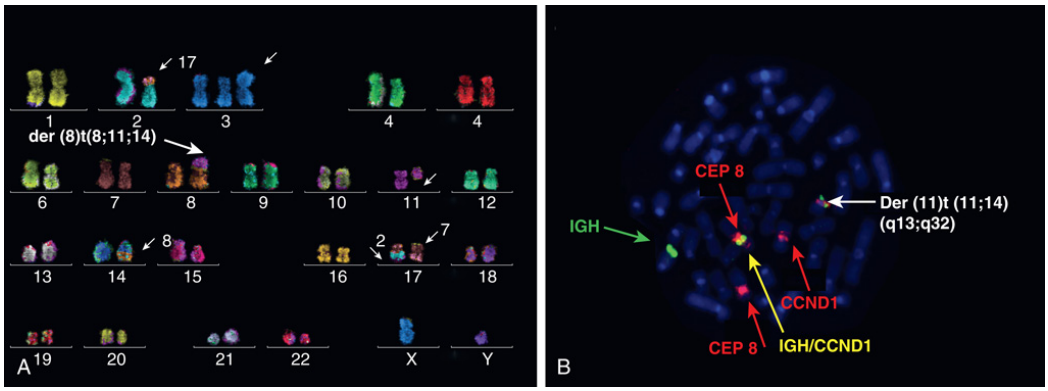

FIGURE 6-3 **A,** Multicolor fluorescence in situ hybridization (M-FISH) of a primary case of mantle cell lymphoma carrying a cryptic t(11;14)(q13;q32) translocation involving chromosome 8. The karyotype was 47,XY,t(2;17)(p11;q13)[6],+3[6],t(8;11;14)(11qter→11q13::14q32::8p11→8qter;11pter→11q13::14q32→14qter;14pter→14q32::8p11→8pter)[6], der(17)t(7;17)(p15;p13)[6],-21[3]/46,XY[2][cp8]. **B,** FISH demonstrating the presence of *IGH*::*CCND1* fusion in derivative chromosome 8. Aberrations are indicated by arrows. From Salaverria I, Espinet B, Carrió A, et al. Multiple recurrent chromosomal breakpoints in mantle cell lymphoma revealed by a combination of molecular cytogenetic techniques. Genes Chromosomes Cancer. 2008;47:1086–1097.

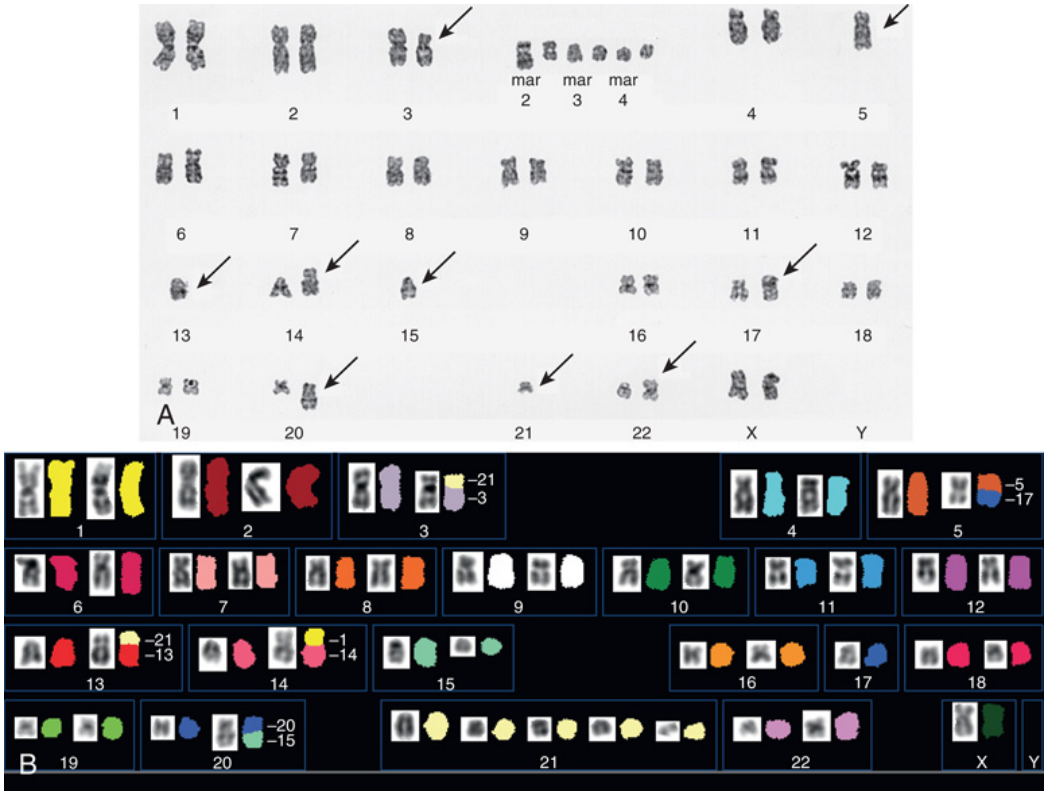

FIGURE 6-4 Standard cytogenetic and spectral karyotyping (SKY) analysis of a complex karyotype detected in a patient with de novo acute myeloid leukemia (AML).**A,** G-banded karyotype interpreted as 48,XX,del(3)(p1?1p2?1), −5, −13,add(14)(p13), −15,add(17)(p11.2),add(20)(q13.?3), −21,i(22)(q10),+mar1,+mar2,+mar3,+mar4. Arrows indicate chromosome abnormalities. **B,** Spectral karyotype from the same patient. Each chromosome is represented twice, by G-banding–like inverted and contrast-enhanced 4′,6-diamidino-2-phenylindole (DAPI)–stained image *(left)* and SKY image shown in spectra-based classification colors *(right)*. SKY enabled

determination of the origin of marker chromosomes and unidentified material in unbalanced translocations. Notably, SKY revealed high-level amplification of 21q material present in der(3)t(3;21), der(13) and four marker chromosomes. The final karyotype interpretation was 48,XX,der(3)t(3;21)(p1?1;q?),der(5)t(5;17)(q11;q1?1),der(13)(21q11→21q22::13p1?1→13qter),der(14)t(1;14)(p32;p11),del(15)(q1?5),−17,der(20)t(15;20)(q15;q13.3),der(21)t(21;21;21),+der(21)t(21;21)x2,+ider(21)t(21;21),idic(22)(p11). Loss of one chromosome X in the depicted cell is random.

Array-Based Copy Number Determination

Genetic complexity of cancer cells requires use of sensitive techniques that facilitate detection of small genomic changes in a mixed cell population and segmental regions of homozygosity. Akin to conventional CGH, CGH arrays rely on the difference in the CN between differentially labeled test and reference DNAs. The spots on the array are either DNA isolated from clones, such as bacterial artificial chromosomes (BACs) containing human genomic DNA or oligonucleotides synthesized directly on the glass slide. For the CGH array, the DNAs are directly labeled with Cy3 and Cy5 fluorescent dyes, for example, with display tumor DNA pseudocolored red and reference DNA green. Again, through competition between test and

control, a scanner detects the ratios of the fluorescence intensities of both dyes at each spot.

High-density oligonucleotide arrays have improved the ability to detect gains and losses of fewer than 5 kb, thus permitting the identification of smaller amplicons and microdeletions that were previously undetectable (**Fig. 6-5A**).[48] Moreover, application of paired germline DNA from the same individual can exclude germline variants, and differences will reflect only somatic lesions acquired by the tumor cells. Nevertheless, one of the limitations of the CGH arrays is that they do not allow detection of regions of homozygosity. The genome-wide SNP arrays rely on oligonucleotide probes corresponding to the allelic variants of selected SNPs covering the whole genome. Hybridization of test DNA to both probe variants indicates heterozygosity, whereas the signal for only one allele is consistent with homozygosity. The fluorescence emitted from individual probes allows the analysis of gene CN (**Fig. 6-5B**, *upper panel*). The major advantage of SNP arrays over other CN platforms is the ability to detect diploid stretches of homozygosity (**Fig. 6-5B**, *lower panel*). The detection of LOH and other chromosomal changes with large numbers of SNP markers has enabled identification of patterns of allelic imbalances with potential prognostic and diagnostic utility.

MIP technology offers a potential solution to the challenges of CN and genotype assessment in formalin-fixed paraffin embedded (FFPE)-derived DNA samples. The small intact target DNA sequence footprint required by MIP probes (~40 base pairs [bp]) makes the MIP platform well suited to work with degraded FFPE DNA.[49] The OncoScan assay uses MIP technology, which has been optimized for

highly degraded FFPE samples (probe interrogation site of just 40 bp). Assay performance has been extensively validated with archived FFPE samples (10 years or older) and has been shown to be compatible with all major solid-tumor tissue types.

Application of these CN technologies, which use only single indirectly labeled tumor DNA for hybridization, has revealed that many normal CN variations occur throughout the genome within the general population.[50] Information on these regional variations must be taken into account when normal DNA from the patient whose tumor sample is tested is not available.

Although many molecular cytogenetic techniques are available, conventional cytogenetics and FISH are the most widely used techniques in the clinic (see **Table 6-2**). Nevertheless, CN arrays initially introduced in prenatal and postnatal diagnosis are increasingly used in the diagnosis of hematologic and oncologic disorders, especially in hematologic malignancies with a low mitotic index that does not allow conventional cytogenetics analysis. Moreover, CN arrays allow the detection of segmental regions of homozygosity and small genomic changes in a mixed cell population, and their use has identified novel genomic abnormalities that escaped detection with other methods. Moreover, CN arrays are a comprehensive tool for identification of chromothripsis, which requires the detection of at least seven switches between two or more CN states detected on an individual chromosome.[51,52]

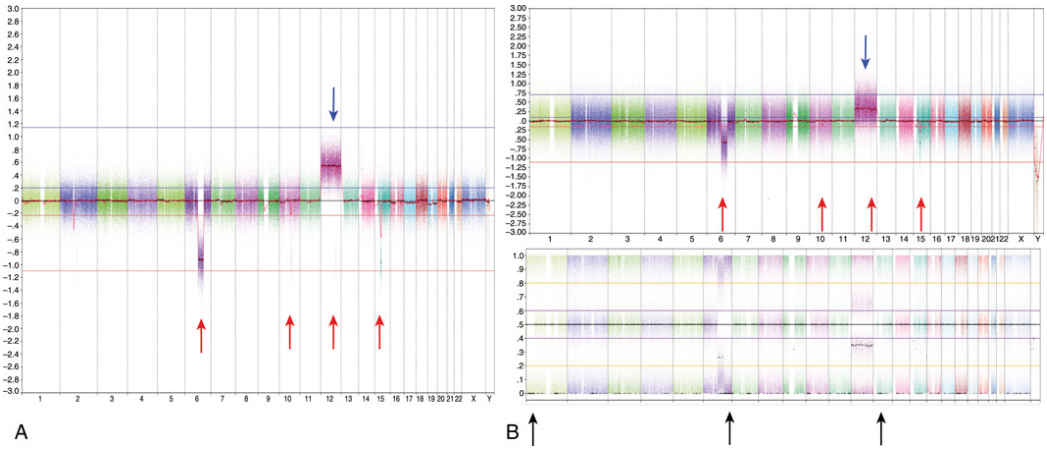

FIGURE 6-5 Copy number profiles for a chronic lymphocytic leukemia case analyzed by both Agilent 1M array CGH **(A)** and SNP–Array, Affymetrix 6.0 **(B)**. Data are displayed as whole-genome "rainbow" plots in which each chromosome is denoted by a different color. **B,** Copy number information *(upper panel)* and allelic ratio information *(lower panel)* are shown. Red arrows indicate losses, blue arrows indicate gains, and black arrows indicate copy-neutral loss-of-heterozygosity regions. Several types of software are available for generation of copy number profiles. In this example, Nexus BioDiscovery (El Segundo, CA) software was used to analyze both types of arrays.

Thus these array-based technologies have become a complementary tool in cases with existing cytogenetic information and are used as the diagnostic tool (together with FISH) in cases without dividing cells. CN arrays specifically designed for analyzing

CN and LOH alterations on DNA from FFPE (MIP-assay) have been introduced.

Optical Genome Mapping

OGM has emerged as a robust technology to diagnose, in a single step numerical and structural, both balanced and unbalanced, chromosome aberrations.[53] This technique relies on high-throughput imaging of high molecular weight DNA (>250 Kb) fluorescently labeled at a specific 6 bp sequence motif that occurs 15 times per 100 Kb in the human genome. The unique labeling pattern allows identification of the genomic location of every molecule, generating a consensus map that can be compared with a reference genome. This approach detects both balanced and unbalanced structural variants from single molecules, from 500 bp resolution and down to 1% allele fraction. In addition, genome coverage depth information is also used for the detection of CN alterations and whole-chromosome aneuploidies. OGM does not require any cell culture before sample processing and results may be available in 4 to 6 days (the time required for the isolation and labeling of the DNA and its subsequent analysis). Several studies used OGM to analyze samples from patients with ALL,[54,55] AML,[56-59] MDS,[58-60] and CLL.[19,61] Thus, it has been suggested that OGM could replace other cytogenetic assays we described (e.g., conventional cytogenetics, FISH, and CN arrays) in the evaluation of hematologic disorders.[19,54,59] However, OGM seems to have some technical and diagnostic limitations. Because OGM uses the CN variation (CNV)-pipeline, which uses quantification of uniquely attributable genetic material to detect variants, the detection of numerical chromosomal

aberrations, triploidy, and higher-order polyploidy is difficult.[53] The other important limitation is the need for a significant amount of fresh and frozen blood cells for its performance because the analysis of previously extracted DNA is not suitable.

Whole Genome Sequencing and Karyotyping

In principle, different types of whole genome sequencing (WGS) analyses ranging from shallow to full, deep genomic sequencing and short-read to long-read analyses are able to also provide a gross karyotype-like overview, with current limitations in repetitive sequence areas like centromeres.[62] Akkari et al.[63] exhaustively reviewed advantages and limitations of several novel technologies, including OGM and WGS.[62] After consideration of clinical, logistic, technical, and financial implications, the authors concluded that despite undisputable clinical usefulness of WGS, the immediate implementation of this technology by clinical laboratories worldwide is rather unlikely. At least in the near future, standard chromosome banding analysis, FISH, and SNP arrays will remain the gold standard of cytogenetic testing in hematologic neoplasms.[63]

CLINICAL RELEVANCE OF CHROMOSOMAL ABNORMALITIES IN HEMATOLOGIC MALIGNANCIES

Detection of chromosomal abnormalities helps to identify distinct disease entities and is useful in establishing diagnosis, classification, prognostication, therapy selection, monitoring of disease progression, and evaluation of response to therapy. Several aberrations and their molecular counterparts have been included in

the previous editions and the 5th edition of the WHO Classification of Hematologic Neoplasms/Haematolymphoid Tumors and the International Consensus Classification of Leukemias and Lymphomas.[64-68] Together with morphology, immunophenotype and clinical features are used to define distinct clinical entities with unique patterns of responses to treatment (**Table 6-3**).[65-68] The most important aberrations will be discussed in the respective chapters. Importantly, cytogenetic investigations are a mandatory part of the diagnostic workup for patients with MDS, AML, ALL, and chronic myeloid leukemia (CML), and are strongly recommended for patients with primary myelofibrosis (PMF) according to recommendations of the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology[69-72] and the European LeukemiaNet (ELN).[73-76] Pretreatment karyotypic findings are among the most important independent prognostic factors in MDS,[77,78] AML,[79-83] and ALL[79,84-87] and, together with molecular genetic findings, are used to determine choice of therapy in patients with these diseases.[88-90] In CML, cytogenetic testing is also recommended for assessment of response to treatment with tyrosine kinase inhibitors along with molecular determination of *BCR*::*ABL1* transcript levels by standardized quantitative reverse-transcription polymerase chain reaction.[72,75]

Myeloproliferative Neoplasms

Among several entities included in the *myeloproliferative neoplasms* category in the current myeloid neoplasms classifications,[66,68] only CML is strongly associated with a specific chromosome abnormality, t(9;22)(q34;q11.2), which creates the *BCR*::*ABL1* fusion gene whose

chimeric protein product is a target of therapy with tyrosine kinase inhibitors. The derivative chromosome 22 generated by the t(9;22) translocation is, for historical reasons, named the *Philadelphia chromosome* and designated as *Ph*. A vast majority of CML patients, approximately 90% to 95%, carry a standard t(9;22) translocation at diagnosis,[91] whereas in the remaining patients, *BCR-ABL1* arises as a result of either three-way or even four-way variant translocations involving, respectively, one additional chromosome, for example, t(1;9;22)(p36;q34;q11.2), or two extra chromosomes, for example, t(3;17;9;22)(q26;q21;q34;q11.2); or through cryptic insertions such as ins(9;22)(q34;q11.2q11.2) or ins(22;9)(q11.2;q34q34).[92] These cryptic insertions can be detected with FISH or PCR.[75] At diagnosis, secondary abnormalities accompanying the t(9;22) translocation or variants, such as –Y, +8, i(17)(q10), +19, and +der(22)t(9;22)(q34;q11.2), are rare and are only detected in approximately 5% to 10% of patients.[93-95] However, their presence has been reported to represent a poor prognostic factor in patients treated with imatinib because patients who harbored any secondary abnormality had lower overall cytogenetic and molecular response rates and longer time to response to therapy.[95] Patients who had the so-called *major route abnormalities,* that is, +8, i(17)(q10), +19 and +der(22)t(9;22), also had significantly shorter progression-free and overall survival (OS).[94] Acquisition of chromosomal abnormalities, especially the major route ones, in a clone with a t(9;22) translocation during therapy with tyrosine kinase inhibitors (i.e., clonal cytogenetic evolution) indicates disease acceleration[75] and has been associated with shorter OS in patients receiving imatinib.[96] On the other hand, clonal chromosome aberrations, most often –Y and +8, occurring in

cells without the t(9;22) translocation in 5% to 10% of CML patients during treatment with a tyrosine kinase inhibitor, appear not to affect patient outcomes. However, acquisition of –7 has been linked to increased risk for developing MDS or AML,[97] thus indicating the need for more-frequent cytogenetic monitoring of such patients.

Table 6-3

* In approximately 90% to 95% of patients, *BCR*::*ABL1* fusion is created by t(9;22)(q34;q11.2), whereas the remaining cases harbor three- or four-way balanced translocations invariably involving chromosomes 9 and 22 and one or two other chromosomes, or carry cryptic insertions or translocations between chromosomes 9 and 22.

† del(5q) can be accompanied by one additional abnormality, with the exception of –7/del(7q).

‡ i(17q) can occur with one other additional abnormality other than –7/del(7q).

§ ≥10% of blasts are required for diagnosis of most listed categories, unless indicated otherwise.

¶ ≥20% of blasts are required for diagnosis. The category of "MDS/AML" will not be used for AML with *BCR*::*ABL1* because of its overlap with progression of *BCR*::*ABL1*-positive CML.

|| Occurs predominantly in infants and children.

Patients with ≥20% of blasts are diagnosed with AML and those with 10% to 19% of blasts with MDS/AML.

** At least 20% blasts are required for diagnosis.

†† At present, subtypes under this heading include AML with rare genetic fusions.

‡‡ To diagnose AML, myelodysplasia-related in patients with 20% of blasts in their bone marrow or blood, the presence of at least one of the listed cytogenetic or molecular abnormalities and/or history of myelodysplastic or myeloproliferative neoplasm are required.

Data from Arber et al.[66] and Khoury et al.[68]

Table 6-4

Data from the Mitelman Database,[92] which consisted of 4846 patients with myelodysplastic syndromes and abnormal karyotype as of October 17, 2022.

Myelodysplastic Syndromes

General Cytogenetic Features

Clonal chromosome abnormalities are found in approximately 52% of patients diagnosed with de novo MDS,[98] but their frequency is higher, 76% to 97%, in treatment-related MDS and AML.[99] The frequencies of abnormal karyotypes in larger series of MDS patients have varied between 38% and 73%,[98] likely because the proportions of patients with particular subtypes of MDS included in these studies differed, as does the incidence of abnormal karyotypes among specific MDS entities.[98]

Cytogenetically, MDS is very heterogeneous, with over 100 chromosome aberrations hitherto recognized as recurrent,[92] but the involvement of specific chromosomes in structural and numerical abnormalities is highly non-random. Tables **6-4** and **6-5** contain lists of the most frequent of these recurrent abnormalities. Balanced rearrangements, such as t(1;3)(p36.3;q21.1), inv(3)(q21q26.2)/t(3;3)(q21;q26.2), t(3;21)(q26.2;q22.1), t(6;9)(p23;q34), and translocations involving the *KMT2A* gene—t(2;11)(p21;q23), t(9;11)(p22;q23), and (11;16)(q23;p13.3)—are relatively rare, and each of

them have also been reported in AML (**Table 6-4**). A vast majority of cytogenetically abnormal MDS patients carry unbalanced abnormalities: deletions, most commonly of 5q, 20q, 7q, 11q, 13q, and 12p; unbalanced translocations, such as der(1;7)(q10;p10) that result in simultaneous 7q loss and 1q gain; isochromosomes, such as i(17)(q10), idic(X)(q13) or i(14)(q10); and whole-chromosome gains (e.g., +8, +21, and +11) and/or losses (e.g., −7, −5, −Y, and −X) (**Table 6-5**).[92]

Table 6-5

* Also described as der(17)t(5;17)(p11-12;p11-13) or der(5;17)(p10;q10).

† Includes a very similar idic(17)(p11).

Data from the Mitelman Database,[92] which consisted of 4846 patients with MDS and abnormal karyotype as of October 17, 2022.

Associations Between Cytogenetic Findings and Clinical Outcome of Myelodysplastic Syndrome Patients

Pretreatment karyotypic findings in MDS patients have been repeatedly associated with both survival and risk for evolution to AML.[77,78,98,100-103] Several recurring abnormalities and a normal karyotype have been incorporated into scoring systems for evaluation of prognosis for MDS patients, which also include hematologic and clinical features in addition to karyotype.[102,103] Introduced in 2012, the Revised International Prognostic Scoring System (IPSS-R)[78] categorizes cytogenetics into five prognostic

subgroups: “very good” indicates an isolated –Y and del(11q) (score value 0); “good” indicates a normal karyotype, isolated del(5q), del(12p), del(20q), and two cytogenetic abnormalities that include del(5q) (score 1); “intermediate” indicates isolated del(7q), +8, +19, i(17)(q10) or any other single- or double-chromosome abnormalities (score 2); “poor” indicates isolated –7, inv(3)(q21q26.2)/t(3;3)(q21;q26.2), del(3q), two chromosome abnormalities that include –7/del(7q), and a complex karyotype with three abnormalities (score 3); and “very poor” indicates a complex karyotype with four or more abnormalities (score 4).[103] The other prognostic variables included in the IPSS-R are percent of bone marrow blasts (scores from 0 to 3), hemoglobin level (scores 0 to 1.5), platelets (scores 0 to 1), and absolute neutrophil counts (scores 0 to 0.5). By combining the risk scores for cytogenetic subgroup, bone marrow blast percentage, and cytopenias, MDS patients can be stratified into five risk groups as follows: “very low,” overall score ≤1.5; “low,” score >1.5 to 3; “intermediate,” score >3 to 4.5; “high,” score >4.5 to 6; and “very high,” score >6. The respective median survival times of patients classified into these risk groups in the study by Greenberg and colleagues[103] were as follows: “very low,” 8.8 years; “low,” 5.3 years; “intermediate,” 3 years; “high,” 1.6 years; and “very high,” 0.8 years. The times for 25% of the patients to undergo evolution to AML were: “very low,” >14.5 (median not reached) years; “low,” 10.8 years; “intermediate,” 3.2 years; “high,” 1.4 years; and “very high,” 0.7 years.[103]

The usefulness of the IPSS-R in predicting clinical outcome in MDS patients has been tested and confirmed by several studies,[104-106] including a study of MDS patients who received allogeneic stem

cell transplantation.[106] Two of these studies[104,105] found IPSS-R to have better predictive power than the earlier IPSS system.[101] This, in part, has been attributed to refinements in cytogenetic categorization of MDS and increasing the effect of cytogenetics within IPSS-R.[103]

Acute Myeloid Leukemia

General Cytogenetic Characteristics

Pretreatment cytogenetic analysis of bone marrow or blood detects clonal chromosome abnormalities in 55% to 60% of adults[79-82] and 76% to 78% of children[107,108] with AML, with the remaining patients having an entirely normal karyotype, that is, cytogenetically normal AML (CN-AML). Moreover, the frequencies of specific chromosome abnormalities differ between adult and childhood AML. For example, balanced rearrangements involving 11q23/*KMT2A* are four times less common in adults than in children,[79] and their incidence decreases with age from approximately 50% in infants younger than 1 year[109] to approximately 40% in children age 1 to 2 years,[110] approximately 9% in older children,[110] approximately 4% of adults in general,[79,82] to less than or equal to 3% of patients older than 60 years.[111,112] Similarly, a cryptic t(5;11)(q35;p15)/*NUP98*::*NSD1* is seven times less frequent in adults than in children,[113] and a rare t(1;22)(p13;q13)/*RBM15*::*MRTFA* translocation does not occur in adults at all, being found mostly in children younger than 2 years.[114] On the other hand, inv(3)(q21q26.2) and t(3;3)(q21;q26.2) are almost never found in childhood AML,[107,108] and del(5q) and other abnormalities resulting in loss of 5q, and complex karyotype with greater than or equal to five aberrations, are more frequent in adults than in children.[79]

Cytogenetically, AML is a remarkably heterogeneous disease, with greater than 300 recurrent abnormalities identified to date.[92] Aberrations that are sometimes found as sole chromosome alterations and are infrequently (or never) detected in other hematologic neoplasms or solid tumors are considered to be primary abnormalities that play an important role in leukemogenesis and often heavily influence clinical characteristics of patients carrying them.[79] The more common presumed primary structural aberrations are listed in Tables **6-6** and **6-7**. They include balanced abnormalities (i.e., reciprocal translocations, inversions, and insertions) (see **Table 6-6**) and those unbalanced ones (deletions, isochromosomes, and unbalanced translocations) that have been recurrently observed as the only chromosome aberrations (see **Table 6-7**). Numerical aberrations can also be considered to be of primary importance when they are found as the sole alteration. The most frequent sole trisomy is +8, detected in approximately 4% of AML patients, followed by +11, +13, +21, and +4, whereas the most common sole monosomy is –7, followed by –Y.

Table 6-6

AML, Acute myeloid leukemia.

* Only those secondary abnormalities that occur in ≥10% of patients with a given primary abnormality are listed.

† This abnormality was also interpreted as ins(3;3)(q21;q21q26).

‡ This translocation was also reported as t(3;5)(q21;q31).

§ –Y is detected in approximately 60% of male patients with t(8;21).

¶ The breakpoints in t(15;17) have been variously assigned to 15q22 or 15q24, and to 17q11, 17q12, 17q21, or 17q22.

|| –X is detected in approximately 33% of female patients with t(8;21).

This abnormality is cryptic, and the Mitelman Database[92] does not list individual patients with this inversion. The numbers provided are from Masetti et al.[148] and Gruber et al.[147]

Data from the Mitelman Database,[92] which consisted of 21,062 patients with AML and abnormal karyotype as of October 17, 2022.

Primary abnormalities can be accompanied by secondary chromosome changes, which are generally less specific, are usually unbalanced, and can occur together with several distinct primary aberrations in AML or even with primary aberrations in other leukemia types or non-hematologic malignant disorders.[79] The most widespread secondary change is +8, which can be recurrently found in AML patients with t(3;5)(q25;q34), t(5;11)(q35;p15), t(9;22)(q34;q11.2), t(12;22)(p12-13;q11-13), t(15;17)(q22;q12-21), inv(16)

(p13.1q22), t(16;21)(q24;q22), and these rearrangements involving 11q23/*KMT2A:* t(4;11)(q21;q23), t(9;11)(p22;q23), ins(10;11)(p11-13;q23q13-25), t(10;11)(p11-13;q23), t(11;17)(q23;q12-21), t(11;17)(q23;q25), and t(11;19)(q23;p13.3) (**Table 6-6**), as well as in patients diagnosed with MDS, ALL, lymphoma, and solid tumors.[92] As shown in **Table 6-6**, secondary abnormalities accompany some primary changes more often than others. For example, at least one secondary alteration is detected in 60% to 70% of patients with inv(3)(q21q26.2)/t(3;3)(q21;q26.2), t(8;21)(q22;q22), or t(9;22)(q34;q11.2), whereas this is the case in only approximately one-third of patients with t(15;17)(q22;q12-21), t(16;21)(p11;q22), or inv(16)(p13.1q22), and in approximately 15% of patients with t(3;5)(q25;q34), t(6;9)(p23;q34), t(6;11)(q27;q23), t(7;11)(p15;p15), or t(11;19)(q23;p13.1).

Table 6-7

Only aberrations reported as the only chromosome alterations in at least three patients with AML are included.

Data from the Mitelman Database,[92] which comprised 21,062 patients with AML and abnormal karyotype as of October 17, 2022.

Correlations Between Cytogenetic Findings and Clinical Outcome of Patients With Acute Myeloid Leukemia

Large collaborative studies conclusively showed that pretreatment cytogenetic findings constitute one of the most important independent determinants for attainment of complete remission (CR), and duration of disease-free survival (DFS) and OS in AML patients,[80-82,107,108,111,112] and proposed prognostic classifications assigning AML patients into favorable, intermediate, or unfavorable risk groups based on the pretreatment karyotype (**Table 6-8**). Although there are some differences among these classifications, several chromosome abnormalities are almost uniformly assigned to these categories: favorable-risk, for example, t(15;17), t(8;21) and inv(16)/t(16;16); intermediate-risk, for example, –Y, +8; and adverse-risk, for example, inv(3) or t(3;3), –7, and a complex karyotype.

Acute Promyelocytic Leukemia With *PML*::*RARA* Fusion/t(15;17)(q22-24.1;q21.2) or With Variant *RARA* Rearrangements

Currently, the most prognostically favorable subset of AML is acute promyelocytic leukemia (APL) with the *PML*::*RARA* fusion/t(15;17) because the use of targeted treatment regimens containing all-*trans*-retinoic acid (ATRA) and/or arsenic trioxide (ATO) result in CR rates of 85% to 100% and a cure rate of up to 97% in studies.[115] It is important to determine whether the newly diagnosed APL patient carries the most common t(15;17)/*PML*::*RARA* or any of the rare variant *RARA* rearrangements, in which chromosomes other than chromosome 15 are involved, for example, t(1;17)

(q42;q21)/*IRF2BP2*::*RARA,* t(3;17)(q26;q21)/*TBL1XR1*::*RARA* or *FNDC3B*::*RARA,* t(4;17)(q12;q21)/*FIP1L1-RARA;* t(5;17)(q35;q21)/*NPM1*::*RARA,* t(11;17)(q23;q21)/*ZBTB16*::*RARA,* t(11;17)(q13;q12-21)/*NUMA1*::*RARA,* t(X;17)(p11.4;q21)/*BCOR*::*RARA,* or a submicroscopic rearrangement of chromosome 17 resulting in the *STAT5B*::*RARA* fusion.[89,92] ATRA has been effective in patients with the classic t(15;17)/*PML*::*RARA* and in patients with variant fusions between *RARA* and the *BCOR, FIP1L1, FNDC3B, IRF2BP2, NPM1, NUMA1,* and *PRKAR1A* genes.[116] In contrast, patients with t(11;17)(q23;q21)/*ZBTB16*::*RARA,* t(3;17)(q26;q21)/*TBL1XR1*::*RARA* and *STAT5B*::*RARA* are resistant to ATRA and have a poorer prognosis. Moreover, thus far only APL with the *PML*::*RARA, TBL1XR1*::*RARA, IRF2BP2*::*RARA, PRKAR1A*::*RARA,* and *FNDC3B*::*RARA* fusions have been responsive to treatment with ATO.[116] The presence of abnormalities secondary to t(15;17) does not seem to affect patient prognosis,[82] although in two studies,[117,118] a complex karyotype with ≥3 aberrations was associated with a lower CR rate[117] and shorter event-free survival (EFS)[118] and OS[117] in patients with APL treated with regimens containing ATO.

"Core Binding Factor" Acute Myeloid Leukemia With *RUNX1*::*RUNX1T1* Fusion/t(8;21)(q22;q22.1) or *CBFB*::*MYH11* Fusion/inv(16)(p13.1q22)/t(16;16)(p13.1;q22)

Two abnormalities consistently associated with a relatively favorable prognosis,[80-82,119-122] especially when repetitive cycles of high-dose cytarabine are administered as postremission therapy,[123,124] are t(8;21)(q22;q22.1) and inv(16)(p13.1q22)/t(16;16)(p13.1;q22). They

are related at the molecular level because the former disrupts the *RUNX1* gene and the latter the *CBFB* gene encoding the α and β subunits, respectively, of the core binding factor (CBF) complex, a heterodimeric transcription factor regulating transcription of genes encoding proteins involved in hematopoietic differentiation. Patients with either cytogenetic rearrangement have similar, high CR rates of 85% to 89% and cure rates of 55% to 60%,[121,122] and their prognosis can be further improved by the addition of dasatinib, a multikinase inhibitor, to intensive chemotherapy.[125,126] The clinical outcome of t(8;21)-positive patients does not seem to be affected by secondary aberrations, whereas in inv(16)/t(16;16)-positive patients, +22 has been associated with a lower relapse risk, longer OS, and, in patients with internal tandem duplication of the *FLT3* gene (*FLT3*-ITD), lengthened relapse-free survival (RFS) and +8 with a shorter OS.[121,122,127] In both cytogenetic types of CBF-AML, *KIT* mutations have been demonstrated to constitute a poor prognostic factor.[128,129]

Acute Myeloid Leukemia With *DEK*::*NUP214* Fusion/t(6;9)(p23.3;q34.1) or With *MECOM* Rearrangement/inv(3)(q21.3q26.2)/t(3;3)(q21.3;q26.2)

Two other rearrangements that denote specific entities within the category of "Acute myeloid leukemia with defining genetic abnormalities" are t(6;9)(p23.3;q34.1)/*DEK*::*NUP214* and MECOM rearrangements by inv(3)(q21.3q26.2)/t(3;3)(q21.3;q26.2), which portend a very poor prognosis.[80-82,120,130,131] In approximately 85% of patients with t(6;9), the translocation is an isolated cytogenetic aberration, but in two-thirds of the patients it is accompanied by a molecular alteration—the *FLT3*-ITD, a known adverse prognostic

factor in AML.[130,131] Nevertheless, the presence or absence of *FLT3*-ITD does not appear to influence a very poor outcome of both adults and children treated with chemotherapy.[130,131] However, patient prognosis can be improved by allogeneic stem cell transplantation,[132,133] which also seems to be the only treatment option for patients with inv(3)/t(3;3),[134] whose clinical outcome has been dismal regardless of the presence of −7, a secondary abnormality present in approximately 50% of patients (**Table 6-6**). However, in one study, patients with −7 fared even poorer than those without.[135]

Table 6-8

abnl, Abnormality; *AMLSG,* German-Austrian Acute Myeloid Leukemia Study Group; *CALGB,* Cancer and Leukemia Group B; *CIR,* cumulative incidence of relapse; *CR,* complete remission; *ECOG,* Eastern Cooperative Oncology Group; *ELN,* European LeukemiaNet; *FLT3*-ITD, internal tandem duplication of the *FLT3* gene; *MRC,* Medical Research Council; *OS,* overall survival; *SWOG,* Southwest Oncology Group.

* The SWOG/ECOG study[80] included patients between 15 and 55 years of age, and the MRC study[82] included patients aged between 16 and 59 years.

† The MRC study[119] included patients aged between 44 and 91 years (median age, 66 years), and the AMLSG study[112] included patients older than 60 years.

‡ All abnormalities that are not listed were considered to have unknown risk.

§ Abnormalities not specified as conferring favorable, intermediate, or adverse risk were not included in the risk-assessment model.

¶ Favorable for a group of 13 patients with del(9q) that included 6 who underwent transplantation off-protocol; intermediate for nontransplanted patients treated with chemotherapy only.

In addition to cytogenetic findings, 2022 ELN classification uses these molecular genetic alterations (irrespective of cytogenetic findings) to categorize patients as follows: mutated *NPM1* without *FLT3*-ITD or bZIP in-frame mutated *CEBPA* into a favorable group; wild-type *NPM1* with *FLT3*-ITD or mutated *NPM1* with *FLT3*-ITD

into an intermediate group; and mutated *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1,* or *ZRSR2* (unless they coexist with favorable-risk AML subtype) and mutated *TP53* at a variant allele fraction of ≥10%.

** Defined as ≥3 unrelated chromosome abnormalities in the absence of other class-defining recurring genetic abnormalities,[73] excludes hyperdiploid karyotypes with ≥3 trisomies (or polysomies) in the absence of structural abnormalities.

†† Defined as a karyotype with ≥2 autosomal monosomies or one autosomal monosomy and ≥1 structural chromosome abnormality other than inv(16)/t(16;16) or t(8;21).

Acute Myeloid Leukemia With *BCR*::*ABL1* Fusion/t(9;22)(q34.1;q11.2)

A poor clinical outcome has also been associated with AML with t(9;22)(q34.1;q11.2)/*BCR*::*ABL1*.[80,82] To date, a diagnosis of AML in patients carrying the t(9;22) translocation has been somewhat controversial because such patients often are considered to suffer not from AML but CML in myeloid blast phase, occurring after an unrecognized chronic phase. Careful comparisons of clinical, cytogenetic, and molecular genetic characteristics of patients with t(9;22)-positive AML and those with CML in myeloid blast crisis revealed several features that help distinguish both entities.[136-138] In contrast to patients with CML, AML patients had a higher percentage of blood blasts[137]; had less likely splenomegaly or peripheral basophilia; rarely[136] or never[137,138] had major route secondary abnormalities characteristic for CML blast phase, but sometimes had

abnormalities of chromosome 7 [−7/del(7q)][136]; and occasionally had *NPM1* mutations (~20%),[137] a cryptic gain of chromosomal material from 19p,[138] frequent loss of the *IKZF1* and/or *CDKN2A* genes, cryptic deletions within the immunoglobulin (IG) and TR genes, and a specific genome signature.[138] Recognition of AML with t(9;22)/*BCR*::*ABL1* is important because of the availability of targeted therapy with tyrosine kinase inhibitors.

Acute Myeloid Leukemia With a Complex Karyotype

Another cytogenetic subset consistently associated with a very poor prognosis is a complex karyotype, found in 10% to 12% of all AML patients (if complex karyotype is defined as ≥3 aberrations), or in 8% to 9% (if defined as ≥5 aberrations).[9] Patients with a complex karyotype had CR rates between 10% and 40% and 5-year OS rates of less than 10%.[9] Notably, *complex karyotype* was defined differently among studies, as ≥5 unrelated chromosome abnormalities,[119] >3 abnormalities,[120] ≥4 abnormalities after exclusion of specific aberrations that confer favorable or adverse prognosis[82] or ≥3 abnormalities, usually excluding t(8;21), inv(16)/t(16;16), and t(15;17).[80,81,112] Complex karyotypes can comprise various numbers of chromosome aberrations in individual patients that occasionally may reach approximately 30, but the occurrence of particular structural and numerical abnormalities is not random.[9] Balanced rearrangements are rare, and most aberrations are unbalanced, leading to loss of chromosome material, most often from chromosome arms (in decreasing order) 5q, 17p, 7q, 18q, 16q, 17q, 12p, 20q, 18p, and 3p. Less frequent recurrent gains, often hidden in marker chromosomes or partially identified abnormalities, mainly

involve 8q, 11q, 21q, 22q, 1p, 9p, and 13q.[9] Approximately 5% of complex karyotype patients have only numerical abnormalities (e.g., +8, +13, +21, +14, +10, and +19), and such patients were reported to have had better OS than patients with a hyperdiploid complex karyotype with one or more structural abnormalities.[139] Moreover, a study designated complex karyotypes with loss of 5q, 7q, and/or 17p as typical, and complex karyotypes with ≥3 abnormalities that do not include loss of 5q, 7q, and/or 17p as atypical, and demonstrated that both pretreatment characteristics and outcomes differ between patients with these two complex karyotype subtypes.[10] Patients with the atypical complex karyotype were younger, had higher white blood cell (WBC) counts and percentages of bone marrow and blood blasts, carried *TP53* mutations less often (10% versus 67%), and more often had tyrosine kinase domain mutations in the *FLT3* gene (*FLT3*-TKD) and mutations in the *MED12, NPM1* and *PHF6* genes than those with the atypical complex karyotype. Relevantly, the former had higher CR rates and longer OS.[10]

Although the molecular consequences of most chromosome alterations found in AML patients with complex karyotypes are still not well-characterized, the association between 17p abnormalities and loss of and/or mutations in the *TP53* gene is well-documented.[140] The presence of *TP53* alterations makes the dismal clinical outcome of patients with a complex karyotype even worse, and it was associated with significantly lower CR rates and shorter RFS and OS compared with patients without *TP53* alterations.[140] In up to 50% of patients with *TP53* mutations, a complex karyotype can be created by chromothripsis.[51] *TP53*-mutated patients with

chromothripsis have a poorer prognosis than those without evidence of chromothripsis.[51]

Acute Myeloid Leukemia *KMT2A* Rearrangement

Patients with the t(9;11)/*KMT2A*::*MLLT3* translocation, which is the most common of more than 120 cytogenetic aberrations disrupting band 11q23 and the *KMT2A* gene,[141] have usually been classified in the intermediate cytogenetic-risk category[73,81,82] because their outcome is better than the outcome of patients with other rearrangements involving 11q23/*KMT2A,*[142,143] who are typically included in the adverse-risk group.[80,82] However, the more favorable prognosis of patients with t(9;11) seems to be characteristic of adults younger than 60 years, whereas t(9;11)-positive patients age 60 years or older have a very poor outcome that is comparable to the outcome of patients with other 11q23/*KMT2A* rearrangements.[83,144,145] In two-thirds of the patients, t(9;11) is the only chromosome change, whereas approximately 20% of patients have a secondary +8 and 4% to 5% of patients harbor secondary +19 or +21.[92] A large pediatric study found that 11q23/*KMT2A* patients with a secondary +8 had a lower relapse incidence, whereas +19 was an independent adverse prognostic factor for not only incidence of relapse but also EFS and OS.[146]

Cytogenetically Normal Acute Myeloid Leukemia

The largest cytogenetic subset of AML is CN-AML. It is detected in 40% to 45% of adults and 22% to 24% of children[79,10,108] and consists of patients without any clonal chromosome abnormality. In childhood AML, a fraction of patients with a normal karyotype on standard cytogenetic analysis may harbor cryptic rearrangements

like a prognostically adverse *NUP98* rearrangement, for example from t(5;11)(q35;p15)/*NUP98*::*NSD1* fusion,[113] or inv(16)(p13.3q24.3)/*CBFA2T3*::*GLIS2,*[147,148] but these rearrangements are very rare (the former) or do not occur (the latter) in adults with AML. As a group, patients with CN-AML have intermediate prognosis in all major cytogenetic-risk classifications because their CR, DFS, and OS rates are worse than those of adequately treated patients with t(8;21), inv(16), or t(15;17), but better than outcomes of patients with unfavorable aberrations.[79,82] However, CN-AML is very heterogeneous molecularly, with several molecular alterations having prognostic significance.[149,150] A favorable outcome was associated with mutations in *NPM1, CEBPA* bZIP in-frame mutations, and high expression of *miR-181a,* whereas adverse prognosis was associated with *FLT3*-ITD, a partial tandem duplication of *KMT2A* [*KMT2A*-PTD]; mutations in *DNMT3A* (both R882 and non-R882 mutations), *IDH1, IDH2* (R172 mutations), *TET2, ASXL1, RUNX1, WT1,* and *BCOR;* expression of *GAS6;* and high expression of *BAALC, ERG, MN1, SPARC, DNMT3B, miR-3151,* and *miR-155*.[149-151] Mutations in *NPM1* and in-frame bZIP *CEBPA* mutations denote separate entities in both the current 5th edition of the WHO Classification of Haematolymphoid Neoplasms[68] and the International Consensus Classification of Myeloid Neoplasms and Acute Leukemias.[66] *RUNX1* mutations occur not only in 6% to 25% of mostly older patients with CN-AML, who usually do not harbor concurrent *NPM1* or *CEBPA* mutations,[152-154] but they also can be detected in up to one-third of AML patients with non-complex karyotypes and such recurrent abnormalities as −7/del(7q), +8, +11, or +21,[152,155] and are especially frequent in patients with sole +13

(~90% of patients).[152] In CN-AML, more than one prognostic mutation and gene-expression change can often be found in the same patient, thus making it necessary to investigate how multiple molecular genetic alterations affect patient prognosis.

The European LeukemiaNet Prognostic Classifications of Acute Myeloid Leukemia

The first ELN genetic-risk classification in 2010 divided AML patients into four genetic groups: favorable, intermediate I, intermediate II, and adverse, based on a combination of pretreatment cytogenetic findings and such molecular genetic markers as *FLT3*-ITD, and *CEBPA* and *NPM1* mutations, which were assessed only in patients with CN-AML.[156] Thereafter, the ability of the four ELN genetic groups to predict treatment outcome has been confirmed[144,157] and shown to be independent from other established prognostic factors.[144] Because percentages of patients younger than 60 years and those age 60 years and older differed in the favorable, intermediate II, and adverse genetic groups, and older patients had poorer outcomes than younger patients for each ELN group, older and younger patients were recommended to be analyzed separately.[144] The ELN classification was first modified in 2017,[158] and again in 2022.[73] The 2022 ELN classification includes only one intermediate group and increased the number of gene mutations, whose testing is no longer limited to patients with CN-AML, in the prognostic stratification of AML.[73] Details of 2022 ELN classification are provided in **Table 6-8**. Whether these changes have improved the ability of outcome prediction of the 2022 ELN genetic-risk classification remains to be determined, although a study found no

advantage of the 2022 ELN classification over the previous one published in 2017.[159]

Precursor Lymphoid Neoplasms

Chromosome abnormalities are one of the most important prognostic factors in ALL. The majority of patients exhibit an abnormal karyotype, and the changes are either numerical (aneuploidy) or structural; the latter consist mainly of translocations and deletions. The recurring abnormalities are associated with morphology and immunophenotype and define subsets of patients with different responses to therapy and prognosis. There are two groups of precursor cell neoplasms presenting as lymphoblastic leukemia/lymphoma (ALL) based on cell lineage: B-cell ALL (B-ALL) and T-cell ALL (T-ALL), respectively. Substantial differences are seen in the incidence of recurring abnormalities between pediatric and adult ALL.[160]

Among the various recurring abnormalities associated with prognosis, ploidy, t(9;22)(q34;q11.2), t(4;11)(q21;q23), t(12;21)(p13;q22), and t(1;19)(q23;p13) are the most important, and, together with clinical features (e.g., age, WBC count), are used in risk assessment and therapeutic decision-making.[79,84-87,161-163]

Some of the other recurring abnormalities associated with poor or intermediate risk are low hyperdiploidy (47 to 50 chromosomes), −5/del(5q), +8, +21, del(1p), del(6q), del/t(9p), and del(12p). Because these abnormalities often occur in addition to other recurring translocations or abnormalities, their true influence on outcome has been difficult to determine. Abnormalities of the TR locus have been described in 4% to 6% of adult T-ALL, and t(10;14)

(q24;q11) is the most common among them. Patients with this translocation have an excellent prognosis when treated with conventional multiagent regimens.[84,162]

B Lymphoblastic Leukemia/Lymphoma

t(9;22)(q34.1;q11.2)/BCR::ABL1

The presence of t(9;22)(q34;q11.2)/*BCR*::*ABL1* in ALL patients is relatively more common in adults than in children (25% versus 9%). In both age groups, the presence of the t(9;22)/*BCR*::*ABL1* translocation has been historically associated with poorer prognosis, though nowadays it offers the option of targeted therapy with tyrosine kinase inhibitors associated with improved outcome. In children, percentage and WBC count and response to therapy can be indicators of more favorable prognosis.

t(v;11)(v;q23)/KMT2A Rearranged

KMT2A rearrangements are the most common findings in leukemia in infants younger than 1 year and are mostly associated with the t(4;11) translocation in this age group. Similar to AML, these rearrangements are less frequent in older children, and their frequency in ALL increases with age in adults. These patients present with high WBC and frequent CNS involvement. Several *KMT2A* translocations have been observed in ALL. The most recurrent partner is *AFF1* (*AF4* at 4q21). Other common partner genes are *MLLT1* (*ENL* at 19p13.3) and *MLLT3* (*AF9* at 9p22). *KMT2A*::*MLLT1* fusions are more frequent in T-ALL. Patients with t(4;11)(q21;q23)/*KMT2A*::*AFF1* have a poor prognosis.[164]

t(12;21)(p13;q22)/ETV6::RUNX1 (TEL::AML1)

The t(12;21)(p13;q22) translocation is common in pediatric patients (age 1 to 10 years) with B-ALL, and it is not seen in T-ALL. Many patients with B-ALL fall into a high-risk group using standard risk factors and are therefore treated aggressively. The presence of t(12;21)(p13;q22) distinguishes a subset of children with a favorable prognosis who thus might benefit from less-toxic and less-intensive therapy. This translocation is not detectable with standard cytogenetic analysis because of the similar morphology of the juxtaposed segments from 12p and 21q, and molecular cytogenetic methods are required to detect this rearrangement.[79,162,163]

t(5;14)(q31;q32)/IGH::IL3

The t(5;14)(q31;q32) translocation juxtaposes the IGH gene to the interleukin-3 gene *(IL3)*. The presence of this translocation is rare, accounting for less than 1% of ALL and is associated with an increase in circulating eosinophils. It is present in both children and adults. Clinical characteristics are similar to other ALLs.[6]

t(1;19)(q23;p13.3)/TCF3(E2A)::PBX1

The t(1;19)(q23;p13.3) translocation identifies a subgroup of patients who are at high risk and typically fail treatment early and thus require intensive multiagent therapy.[165] This translocation is more common in pediatric B-ALL. In one large study, the adverse outcome of B-ALL with t(1;19)(q23;p13.3) remained significant, even after adjustment for recognized adverse clinical features, indicating that it is an independent risk factor.[79,166]

High Hyperdiploidy

High hyperdiploidy denotes karyotypes with multiple chromosome gains and a chromosome number of 50 to 66, usually without structural abnormalities. The distribution of specific extra chromosomes is non-random, with chromosomes X, 4, 14, and 21 being the ones most commonly gained.[167] High hyperdiploidy is common in children and is associated with the most favorable prognosis and cure rates exceeding 90%. Adults, however, do not show the excellent outcome observed in children.

T Lymphoblastic Leukemia/Lymphoma

Translocations Involving T-Cell Receptor Gene Loci

The t(10;14)(q24;q11)/*TR*::*TXL1* translocation occurs in 7% and 30% of childhood and adult T-ALL patients, respectively, whereas the t(5;14)(q11;q35)/*TR*::*TXL3* translocation is present in 30% of childhood patients and 10% to 15% of adult patients. Both translocations have prognostic significance, with t(10;14)/*TR*::*TLX1* being associated with a favorable outcome[168] and t(5;14)/*TR*::*TLX3* with a poorer outcome.[169]

Copy Number Alterations With Prognostic Significance in Acute Lymphoblastic Leukemia

CGH-array analyses of both pediatric and adult B-ALL and T-ALL have shown that the frequencies of genomic gains and losses vary among the cytogenetically defined subgroups.[170,171] Pediatric B-ALL with (high) hyperploidy frequently exhibited genomic amplification, but this was rarely observed in other subgroups. Genomic loss was detected in all subgroups, with the highest frequency noted in the t(12;21)(p13;q22) and hypodiploid subgroups and the lowest

frequency in the 11q23/*KMT2A*-rearranged subgroup. For both adult and pediatric B-ALL, intrachromosomal genomic loss occurred at a higher frequency than gain, and the majority of deletions had an average size of less than 1 Mb, thus being cytogenetically cryptic. Importantly, a high frequency of genomic alterations involving key genes that regulate B-cell differentiation was evident in B-ALL, suggesting that these genomic imbalances play a role in disease pathogenesis. This is evidenced by the microdeletion including the *IKZF1* locus at 7p12, which has now been identified as deleted in more than 80% of the t(9;22)(q34;q11.2) subgroup of ALL patients and is also associated with transformation of CML to ALL (lymphoid blast crisis).[172,173]

Mature Lymphoid Neoplasms

Mature lymphoid neoplasms are an extremely heterogeneous group of diseases. Lymphomas derived from the B-cell lineage constitute 85% of these tumors, and much of the currently available information on cytogenetics comes from these B-cell non-Hodgkin lymphomas (NHLs). The remaining 15% are derived from T-cell or natural killer (NK)-cell lineage and, owing to their rarity and the difficulty of obtaining appropriate tumor samples, remain cytogenetically ill defined. The majority of lymphomas are characterized by complex karyotypes with multiple abnormalities, and a number of recurring translocations, gains, losses, and amplifications have been identified. Although not unique, the recurring translocations are associated with specific diseases (**Table 6-9**). Here we describe in detail the most common recurrent cytogenetic markers associated with the diagnosis of B-cell mature

lymphoid neoplasms, mainly IG translocations that lead to activation of oncogenes.

Mature B-Cell Neoplasms

Absence of Primary Aberrations in Chronic Lymphocytic Leukemia

The majority of mature lymphoid neoplasms are associated with specific IG chromosomal translocations, whereas comparable rearrangements in CLL are rare. Early studies suggesting that t(11;14)(q13.3;q32.3) involving the IGH and *CCND1* locus was common in CLL mainly included cases of leukemic MCL or splenic lymphoma, and the translocation has not been found in *bona fide* CLL. Nevertheless, IG translocations do occur in CLL, albeit at low frequency; approximately less than 2% of all cases have been reported to involve *BCL2, BCL3,* and *BCL11A,* among others. The pathologic consequences of these translocations are deregulated expression of the oncogene caused by the physical juxtaposition of the IG enhancers.[174] Instead, CLL is characterized by a recurrent pattern of chromosomal imbalances, namely deletion in 13q14, gain of 12q13 (mostly as trisomy 12), deletion in 11q22.3, and deletion in 17p13.[175] Several of these changes, particularly the 13q14 deletions, can derive from non-recurrent translocations with breakpoints in the respective regions.[21,176] By conventional cytogenetic analysis, only a subset of cases shows aberrant karyotypes, though this can be enhanced by stimulation (e.g., with CpG oligonucleotides). Nevertheless, particularly the 13q14 losses, which are present in around half of CLL cases, frequently are cytogenetically cryptic. The detection of a complex karyotype in CLL is an indicator of poor

prognosis, mostly linked to deletion of 17p affecting the *TP53* gene.[177,178] Loss or mutation of *TP53* is the most informative unfavorable prognostic marker. Overall, because of its biologic and genetic peculiarities, CLL is more suitable to FISH diagnostics with a panel of probes directed to the recurrent aberrations than it is the domain of conventional cytogenetics. Alternatively, some proposals of array-based diagnostic tools for CLL aberrations have been described.[179-181]

Table 6-9

ABC, Activated B-cell like; *ALK,* anaplastic lymphoma kinase; *GCB,* germinal-center B-cell like; *MALT,* mucosa-associated lymphoid tissue.

* Includes variants t(2;18)(p12;q21) and t(18;22)(q21;q11).

† Mainly translocations of *CCND2* and *CCND3* with immunoglobulin light chains.

‡ Includes variants t(2;8)(p12;q24) and t(8;22)(q24;q11).

§ Includes variants of t(2;5): t(1;2)(q25;p23), inv(2)(p23;q35), t(2;2)(p23;p23), t(2;3)(p23;q21), t(2;19)(p23;p13), and t(X;2)(q11-12;p23).

Plasma Cell Myeloma/Multiple Myeloma Primary Aberrations

PCM, also named MM, is a heterogeneous genetic disease. Cytogenetic studies have shown that many of the specific translocations affect the IGH locus (55% to 70% of tumors), with some being cryptic and detectable only by FISH analysis. The most frequent abnormalities involve these oncogenes: *CCND1* (15% to

18%), *MAF* (5%), *FGFR3/MMSET (NSD2)* (15%), *CCND3* (3%), and *MAFB* (2%).[64] Translocations in the *IRF4* gene have also been described in MM.[28] The remaining cases are mostly hyperdiploid and associated most frequently with gains of chromosomes 5, 9, 15, and 19 and are classified as "MM with recurrent cytogenetic abnormalities." Both IGH rearrangements and hyperdiploidy seem to be early genetic events.[6] Deletion of 13q is the most common change in MM and, if detected by cytogenetics, is associated with poor prognosis. Like CLL, MM is more suitable to FISH diagnostics on immunologically defined plasma cells (e.g., MACS or FICTION) than conventional cytogenetics. FISH panels usually include the detection of the prognostic IGH translocation, hyperploidy, 13q deletions, 17p deletions, and progression markers like *MYC* breaks and 1q gains. In terms of association with prognosis, myeloma cases can be separated in two big groups according to genetic features, a non-hyperdiploid subtype (mainly cases harboring IGH translocations and associated with more aggressive behavior), and a hyperdiploid subtype, a more indolent form of disease.[182]

MYC Translocations: The t(8;14)(q24;q32) Translocation and Variants

The t(8;14)(q24;q32) translocation or its variants, which juxtapose the locus of the *MYC* gene and one of the three IG loci, are present in almost all Burkitt lymphoma (BL) cases. In endemic BL, most *IG*::*MYC* translocations affect the VDJ region because of aberrant somatic hypermutation, whereas in sporadic cases, the translocations are mediated by IG class-switch recombination of the IGH locus at 14q32.[183] The *MYC* breakpoints can be located up to 1

Mb centromeric of *MYC* in t(8;14) and telomeric of *MYC* in t(8;22)(q24;q11) and t(2;8)(p12;q24).[184]

The common functional effect of these translocations is that the *MYC* gene undergoes constitutive expression in tumor cells. The *MYC* translocation is not a genetic lesion exclusive of BL. An *MYC* break has been observed in up to 15% of patients with classical DLBCL, usually associated with complex karyotypes and very poor outcome. Some of these cases can be classified as molecular BL based on gene-expression profiles.[185,186] Other cases frequently carry a t(14;18)(q32;q21) translocation associated with the t(8;14) or variant *MYC* translocation and are clinically aggressive with poor response to current therapies. These cases are called DLBCL/high-grade B-cell lymphoma (HGBL) with *MYC* and *BCL2* rearrangements (or *double-hit lymphomas*) in the WHO 5th edition and just HGBL with *MYC* and *BCL2* rearrangements in the International Consensus Classification (ICC) independently of the cytological variant. Similarly, double hits involving the *MYC* and *BCL6* genes are recurrently observed, which form a group of lymphomas clinically and pathologically distinct from the *MYC* and *BCL2* double hits. Acquisition of an *MYC* translocation has been observed as a secondary event in MCL with blastoid or pleomorphic features, and FL is frequently associated with transformation to DLBCL.[187,188]

Gain and Loss 11q Pattern in High-Grade/Large B-Cell Lymphoma With 11q Aberration(s)

The high-grade/large B-cell lymphoma with 11q aberrations entity, according to the WHO 5th edition and ICC terminology, respectively, defines a subset of tumors with a spectrum of morphology from

intermediate/blastoid or Burkitt-like morphology to large B-cell morphology, germinal center phenotype and very high proliferation (>90%), and negative for *MYC* rearrangements.[65,67,189] Those cases are characterized by a prototypical alteration of chromosome 11 including 11q23.2-q23.3 gain and 11q24-qter loss (**Fig. 6-6A**). Of note, cytogenetic studies have shown that the gained region is frequently inverted.[190,191] This alteration can be detected by specific FISH probes for the commonly gained and lost regions (**Fig. 6-6B**) and an appropriate control. Because isolated cases have been shown to depict single terminal losses or, alternatively, proximal gains together with terminal CN-LOH, the use of CN arrays is recommended.[191-193]

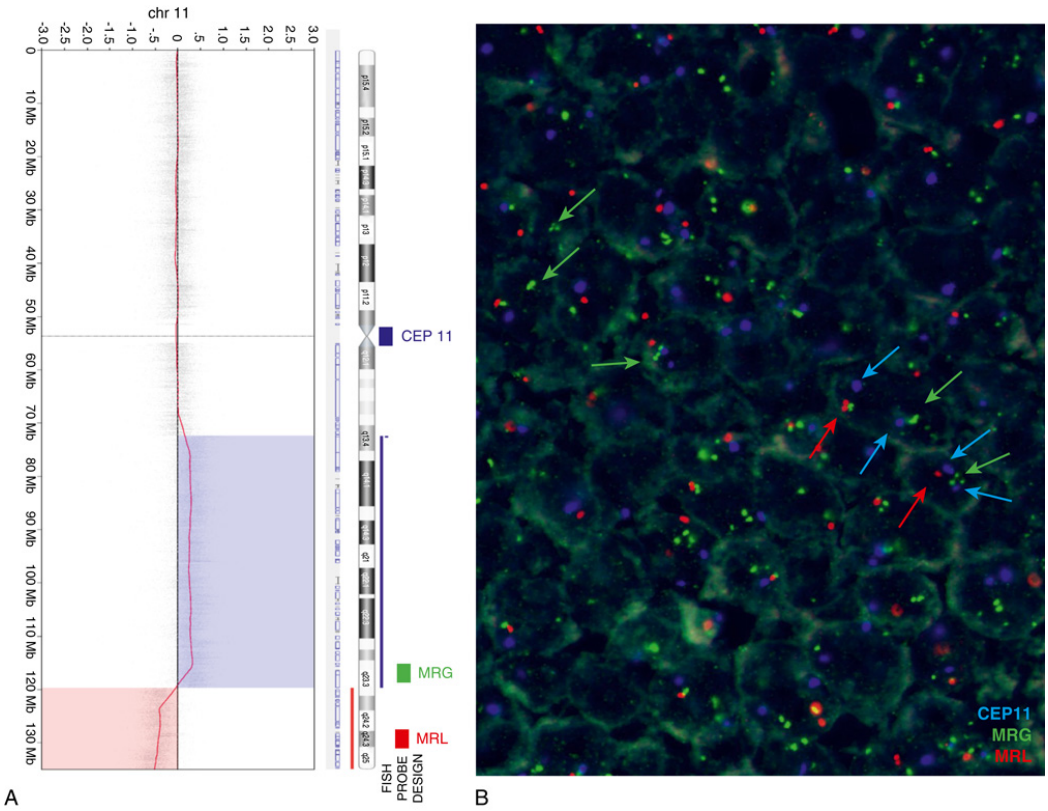

FIGURE 6-6 High-grade/large B-cell lymphoma with 11q aberration(s).**A,** Chromosomal view of chromosome 11 copy number profile analyzed by CytoScan array, depicting gains of 11q13.4-q23.3 in blue and terminal losses of 11q23.3-q25 in red. **B,** FISH constellation of 11q aberration using a custom probe combining CEP11 (spectrum aqua), RP11-414G21 (spectrum green, MRG), and RP11-629A20 (spectrum red, MRL) bac clones. Two blue signals are observed per cell corresponding to the two chr11 centromeres (blue arrows); the presence of three green signals per cell indicates 11q gain (bold green arrows) and the presence of

only one red is indicative of the 11q terminal loss (red arrows). *CEP 11,* Centromeric probe chr11; *MRG,* minimal region of gain; *MRL,* minimal region of loss.

The t(14;18)(q32;q21)*IGH*::*BCL2* Translocation

Around 80% to 90% of FLs carry a t(14;18)(q32;q21) translocation or one of its variants, t(2;18)(p12;q21) or t(18;22)(q21;q11), that juxtaposes the *BCL2* oncogene, an inhibitor of apoptosis, next to the IGH or the IG light chain loci, respectively. This translocation has to be distinguished from the t(14;18)(q32;q21) translocation involving *MALT1* at the same chromosome 18q band (*IGH*::*MALT1*) that occurs in extranodal marginal zone lymphomas. The different involved genes at 18q21 can be recognized by FISH with specific probes. In nodal FL, the translocation is more frequent in grade 1 to 2 than in grade 3, particularly grade 3B, and it is extremely rare or virtually absent in patients with FL younger than 14 years.[194-196] Breakpoints of *BCL2* in translocations with light chain genes are located in the 5′ end of the *BCL2,* similar to *MYC* translocations. Because of their rarity, the clinical implications of the variant translocations are not well defined. About 20% to 30% of DLBCLs show the presence of the t(14;18) translocation. These cases are predominantly centroblastic and belong almost exclusively to the GCB DLBCL subtype.

BCL6 Translocations

Translocations of the 3q27 locus where *BCL6* is localized are found in around 30% of DLBCLs. Translocations of *BCL6* have also been

detected in FL, mainly in grade 3B/follicular large B-cell lymphoma cases, which resemble DLBCL in many features.[197] The breakpoint in 3q27 occurs within the major translocation cluster of *BCL6*. As a result, either one of the three IG genes or a variable non-IG gene is juxtaposed to the coding region of *BCL6*. The variability of the partner chromosomes juxtaposed to *BCL6* suggests that this gene belongs to a group of promiscuous genes. The substitution of *BCL6* promoter by heterologous regulatory sequences causes deregulation of *BCL6* expression in DLBCL carrying these rearrangements. One feature shared by all these promoters linked to rearranged *BCL6* alleles is that they are physiologically active in normal B cells. These translocations could prevent *BCL6* downregulation blocking differentiation from GCB to plasma cell.

IRF4 Translocations

The t(6;14)(p25;q32) translocation juxtaposes the IGH gene to the *IRF4* (formerly *MUM1*) gene, leading to activation of the transcription factor IRF4. This translocation, first described in PCM/MM,[28] has also been observed in a subtype of mature B-cell lymphomas.[29] Specifically, *IGH*::*IRF4* and its variant fusions are associated with a subgroup of GCB lymphomas characterized by FL grade 3 or centroblastic DLBCL morphology, co-expression of IRF4 and BCL6 in the absence of PRDM1/BLIMP1, a specific gene-expression profile, and a disease onset predominantly in the head and neck region of children or young adults (mean age, 12 years).[198] Although the number of cases reported is still limited, *IG*::*IRF4*-positive lymphomas are associated with a significantly better prognosis after treatment.[29,199,200] Deletions of 17p locus,

frequently found in the context of isochromosome 17, and 11q12-qter gains are characteristic of this entity.[201,202] The category of large B-cell lymphoma with *IRF4* rearrangement is included in the current classifications of lymphoid neoplasms to recognize these cases.[65,67]

TBL1XR1::*TP63* Gene Fusion

The *TBL1XR1*::*TP63* gene fusion, initially observed on RNA-sequencing data, has been detected in 5% of *de novo* GCB DLBCLs. The fusion appears exclusive to GCB and was not seen in non-GCB cases examined.[203] The *TBL1XR1*::*TP63* gene fusion is predicted to give rise to a unique chimeric protein, in contrast to the deregulated expression of wild-type *BCL6, BCL2,* and *MYC* that result from other DLBCL translocations. Although the function of this fusion protein is not yet elucidated, the recurrence, subtype enrichment, and conservation of the *TP63* portion of the fusion suggest an important functional role in lymphomas carrying this fusion and may be a novel target for therapeutic intervention.

The t(11;14)(q13;q32)/IGH::CCND1, CCND2 and CCND3 Translocations

Virtually all cases of MCL carry the t(11;14)(q13;q32) translocation, leading to the juxtaposition of the *CCND1* gene at 11q13 to the IGH joining region at 14q32, which results in the constitutive overexpression of cyclin D1. The t(11;14) translocation is detected in approximately 65% of MCLs by conventional cytogenetics, but it can be identified in virtually all cases by FISH with probes involving the IGH and *CCND1* regions. Very few cases with variant *CCND1* translocations with IG light chains have been reported. Similar to other B-cell lymphomas with variant translocations involving

oncogenes, there is also a variation in breakpoints affecting *CCND1* and in the IG light chain translocations in MCL, with breakpoints occurring in the 3′ region of the *CCND1* gene.[188] Chromosomal rearrangements of the *CCND2* locus have been detected in 55% of cyclin D1–negative MCLs. These translocations are mainly with IG light chains (IGK and IGL).[204] In addition, whole-genome/exome sequencing has allowed the identification of cryptic insertions of light chains near *CCND3* that have been associated with cyclin D3 overexpression. By specific FISH probes, including the IGK enhancer region, additional cryptic IGK juxtapositions to *CCND3* and *CCND2* in MCL that overexpressed these cyclins, respectively, have been described.[205] This similar approach has also allowed the identification of cryptic insertions of IG light chains in the *CCND1* locus in MCL expression cyclin D1.[206] From a clinical point of view, detection of these translocations is important to differentiate MCL from other low-grade B-cell lymphomas, in particular when the immunophenotype is inconclusive.

MALT Lymphoma Translocations

There are three translocations associated with MALT lymphoma: t(11;18)(q21;q21)/*API2*::*MALT1,* t(14;18)(q32;q21)/*IGH*::*MALT1,* and t(1;14)(p22;q32)/*IGH*::*BCL10*. All these alterations are associated with activation of the NF-κB pathway, suggesting that this deregulation is essential for MALT lymphoma development. An additional translocation, t(3;14)(p14.1;q32), has also been observed in MALT lymphomas. This translocation brings the *FOXP1* gene under the control of an IGH enhancer, resulting in its overexpression.[207] It has also been observed in other B-cell

neoplasms, mainly DLBCL.[208] In gastric MALT lymphoma, t(11;18)(q21;q21) and t(1;14)(p22;q32) are typically seen in patients with advanced disease who do not respond to antibiotic therapy. In an analysis of 111 patients with *Helicobacter pylori*–positive gastric MALT lymphomas, only 4% of the patients who responded exhibited t(11;18)(q21;q21), as opposed to 67% who failed to respond.[209] Although the t(11;18)(q21;q21) translocation is associated with adverse clinical features, it is seldom found in transformed MALT lymphoma.[210]

Mature T-Cell Neoplasms

Anaplastic large-cell lymphoma (ALCL) anaplastic lymphoma kinase (ALK)-positive is genetically characterized by the t(2;5)(p23;q25) translocation and its variants t(1;2)(q25;p23), inv(2)(p23q35), t(2;2)(p23;p23), t(2;3)(p23;q21), t(2;19)(p23;p13), and t(X;2)(q11-12;p23), which result in expression of the ALK protein. Patients with these tumors are significantly younger (mean age, 22 years) and have a low International Prognostic Index (IPI) score and a more favorable prognosis compared with ALCL ALK-negative.[65,67] Multivariate analysis has shown that the favorable prognosis in patients with ALK-positive systemic ALCL is not merely because of their younger age or low-risk IPI group.[211] A subset of large B-cell lymphomas expressing the ALK kinase with t(2;17)(p23;q23)/*CLTC*::*ALK* or other ALK translocations has also been described.[212,213]

In the subgroup of ALK-negative ALCL, t(6;7)(p25.3;q32.3) disrupting the *IRF4/DUSP22* locus on 6p25.3 and adjoining the *FRA7H* fragile site on 7q32.3 has been identified in 30% of the cases. This translocation has been associated with downregulation of

DUSP22 and upregulation of microRNA miR-29a on 7q32.3.[214] Also, translocations involving *TP63* have been identified in 8% of ALK-negative ALCLs.[215] *DUSP22*-rearranged cases have favorable outcomes similar to ALK-positive ALCLs, whereas *TP63* rearrangements have been associated with poorer outcomes.[216]

Hepatosplenic T-cell lymphomas typically carry gains of chromosomes 7 and 8, mostly presenting as isochromosome 7q and trisomy 8.[217] T-cell prolymphocytic leukemia is characterized in around 80% of cases by an inv(14)(q11q32) or t(14;14)(q11;q32) juxtaposing the *TCL1* oncogene next to the TRA/TRD locus, or by its variant, t(X;14)(q28;q11) involving the *MTCP1* gene in Xq28.[218,219]

Hodgkin Lymphoma

Conventional cytogenetic and FISH studies have shown the presence of aneuploidy and hypertetraploidy in Hodgkin lymphoma (HL) cells. This finding is consistent with the presence of multinucleation in neoplastic cells. Nevertheless, these techniques failed to identify recurrent or specific chromosomal translocations in Hodgkin and Reed-Sternberg (HRS) cells, but IGH breakpoints were observed in 17% of these cases.[220] Moreover, structural chromosomal changes involving the *PDL2* locus in 9p23 or the *C2TA* locus in 16p are common in classic HL.[221] Breaks affecting the *BCL6* locus have also been recurrently described in nodular lymphocyte predominant HL, nowadays also called nodular lymphocyte predominant B-cell lymphoma.[222]

Copy Number Alterations With Prognostic Significance in Lymphoid Neoplasms

Most of the described chromosome translocations in lymphomas are insufficient to induce malignancy by themselves. One evidence is that *BCL2*-translocated and *CCND1*-translocated B cells are circulating at very low levels in the peripheral blood of healthy individuals.[223,224] Studies of genetic alterations other than translocations with conventional cytogenetics, FISH, CGH, CGH array, or SNP array have revealed that patients with the same disease entity may show different secondary genomic alterations. The profile of these alterations is relatively characteristic of each disease, and some of them may have prognostic significance (**Table 6-9**). These regions may contain genes that confer growth advantages, or the possibility of escaping apoptosis or cell-cycle arrest triggered by the genomic instability. In some of these regions, several target tumor-suppressor genes or oncogenes have been identified, such as *TP53* at 17p13, *CDKN2A/B* at 9p21, and *RB1* at 13q14.[225] The genetic profiles of lymphoma entities are constantly being refined based on new technologies becoming available. Moreover, the application of genome-wide analysis to FFPE materials has revealed the genetic profiles of rare subgroups of these diseases. Unfortunately, comparisons of genetic complexity among lymphoma types based on CN array studies are difficult because of different resolution and analysis algorithms.

In CLL, several studies that used FISH to estimate the incidence of del(13q), del(11q), +12, and del(17p) have shown that del(11q) and del(17p) identify subgroups of patients with rapid disease progression and short survival, respectively. Patients with del(13q) as a single defect have the longest survival.[226-228] In FL, cytogenetic studies have repeatedly correlated deletions of 1p and 17p with poor

prognosis.[229,230] Molecular cytogenetics studies including CGH and CGH arrays have shown 6q25-q27 deletions,[231] 9p losses, and gains of 11q as unfavorable prognostic markers.[232] One SNP array study determined that the abnormalities more frequent in transformed FL samples are gains of 3q27.3-q28 and chromosome 11, and losses of 9p21 and 15q, whereas gains of X or Xp and losses of 6q predicted OS.[233] Comparison based on CGH data has shown that MCLs have a higher number of genomic aberrations per tumor than other B-cell malignancies.[225] Gains of 3q, 7p, and 12q, and losses of 17p are significantly more frequent in blastoid and pleomorphic versus classical variants. Alterations in several chromosomal regions were related to poor survival, as gains of 3q26 and 12q14, losses of 8p21, 9p21, 9q22, 13q14, and 17p13, and an increased number of chromosomal imbalances (≥3) have been associated with shorter OS.[234] In addition, the CN profiles of cyclin D1–negative MCL resemble those of cyclin D1–positive cases.[204]

In DLBCL, specific CN alterations were associated with the different molecular subtypes.[235,236] Common findings in activated B-cell (ABC) DLBCLs are frequent gains of 3q, 18q, and 19, and losses of 9p and 6q. GCB-DLBCLs shows gains of the mir-17-92-supercluster on chromosome 13, gains of *REL* on chromosome 2, and losses of 10q including *PTEN*.[237,238] As in other lymphomas, there is evidence that deletions of 17p and 9p21 are associated with poor prognosis.[239] CN studies in BL have described gains of 1q, 8q24, and 12q, and losses of 13q31-q32 and 17p13 as the most frequent alterations.[240-242] Abnormalities in 1q and 7q have been associated with poor outcome.[240] Secondary alterations in MM include −13 or del(13q) found in 50% of the cases. Other secondary aberrations,

such as *TP53* deletions or gain and loss of 1q and 1p have also been observed.[65,67]

Finally, the CN studies in HL are limited because of the low content of the neoplastic HRS cells in the affected tissues. Therefore the information on CN alterations of HL has been historically based on the study of cell lines.[243,244] Nevertheless, improvements in laser-capture microdissection and linear nucleic acid amplification techniques have unraveled a complex pattern of recurrent changes and defined regions of chromosomal gain or loss harboring potential oncogenes and tumor-suppressor genes such as *IKBKB, CD40, MAP3K14, CDKN2B,* and *TNFRSF14*.[245,246] Moreover, gains of 16p11.2-13.3 have been significantly more frequently found in pretreatment and relapse biopsies of unresponsive patients and associated with shortened disease-specific survival.[246]

CONCLUSION

Cytogenetic analysis of leukemias and lymphomas has been instrumental in identifying recurring translocations and inversions, and establishing the principle that these balanced rearrangements cause deregulation of genes at the breakpoints, leading to aberrant cell function and initiation of neoplastic proliferation. By pointing to the genes involved, recurrent chromosome rearrangements have provided critical insights into the biology of neoplastic transformation and normal hematopoiesis.

The introduction of molecular cytogenetic methods has significantly expanded the application of chromosome analysis in both clinical and basic research. In addition to conventional cytogenetics, molecular cytogenetics including FISH and CN arrays

are methods for the routine detection of chromosomal changes in lymphomas. The application of both standard karyotyping and these molecular techniques has also shown that specific chromosome changes are associated with treatment outcomes, thereby enabling therapeutic decisions based on the results of chromosome analysis. This has led to a better understanding of the disease and better patient management.

Pearls and Pitfalls

- Conventional and molecular cytogenetic techniques are key elements in elucidating the pathogenesis of a large number of hematologic neoplasms and providing information relevant to their diagnosis and prognosis.
- The ICC and the 5th edition of the WHO Classification of Haematolymphoid Tumours include a number of entities defined in part by specific genetic abnormalities, particularly chromosome translocations, deletions, and gene mutations. As a result, genetic studies must be a routine part of the diagnostic workup of these neoplasms to adhere to up-to-date classifications.
- Different genetic techniques are available for clinical practice. The most applicable and cost-effective routine screening methods are conventional G-banding and FISH. Other molecular techniques are powerful research tools and can resolve the complexity of genetic alterations in hematologic neoplasms.

- The clinical relevance of many recurring abnormalities observed in complex karyotypes remains contentious. The new array-based molecular genetics technologies now applicable to archived materials are continuously providing new information that will help determine the biologic and clinical significance of these alterations.

Acknowledgments

The authors gratefully acknowledge Dr. Gouri Nanjangud, Dr. Nallasivam Palanisamy, Dr. Jane Houldsworth, and Dr. R.S.K. Chaganti for their many helpful suggestions. IS was supported by a Miguel Servet II contract (MS18/00015) from the Carlos III Health Institute and the European Regional Development Fund "A Way of Making Europe." KM gratefully acknowledges Dr. Clara D. Bloomfield, who died on March 1, 2020, for her constant help and encouragement over the years. The support of the cytogenetic and molecular cytogenetic groups of the authors is gratefully acknowledged as is the continuous support from various granting agencies.

OUTLINE

NORMAL LYMPHOID TISSUES

- **Primary (Central) Lymphoid Tissues**
- **Secondary (Peripheral) Lymphoid Tissues**

B-CELL AND T-CELL DIFFERENTIATION

- **B-Cell Differentiation**
- **T-Cell Differentiation**
- **Differentiation of Cells of the Innate Immune Response**

Lymphoid tissues are the sites where precursor cells mature into immunocompetent lymphoid cells and where immune reactions to antigens occur. The lymphoid tissues and the stages of lymphocyte differentiation and maturation have an anatomy—they occur at

specific sites in the body. They have an architecture—each lymphoid tissue is organized in a specific way, and cellular differentiation and reactions occur in specific sites within this organized tissue. They have a specific cellular morphology—the cells change size, shape, and other features as they mature and react to antigen and other stimuli. They undergo specific genetic and biological changes—lymphoid cells alter their genes, their gene expression, and the proteins they produce and respond to at the various stages of differentiation and maturation. Understanding these normal structures and their alterations during lymphoid cell development and activation and during immune responses is important for pathologists who must diagnose reactive and neoplastic conditions of lymphoid tissues and cells.

Superimposed on this lymphoid tissue anatomy is the biology of the immune system. The function of the immune system is to defend the body against infection. Its cellular components include myeloid cells (granulocytes such as neutrophils, eosinophils, and basophils; monocytes; and histiocytes or macrophages), lymphocytes (T, B, plasma, and natural killer [NK] cells), and professional antigen-presenting cells (histiocytes, dendritic cells, and B cells). There are two distinct types of immune reactions: innate or natural immune responses and acquired or adaptive immune responses (**Box 7-1**).[1]

NORMAL LYMPHOID TISSUES

Lymphoid tissues are divided into two major compartments according to lymphoid cell differentiation stages and functional interactions: central or primary lymphoid tissues and peripheral or secondary lymphoid tissues. The terms *tertiary lymphoid organs*

and *ectopic lymphoid structures* refer to organized lymphoid tissue formed at sites of chronic inflammation. The central lymphoid tissues are the bone marrow and thymus. These organs contain the precursor lymphoid cells and sustain the cells' initial antigen-independent differentiation process from the immature stage to the mature stage, at which they can perform their function in response to antigens. The peripheral or secondary lymphoid organs are the lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT), where the mature lymphoid cells encounter antigens and develop different types of immune responses. These compartments are highly organized microenvironments of different cell populations, vascular structures, and stromal components that maximize the selective interactions between lymphocytes and antigens for the initiation and expansion of the immune responses.[2,3]

Primary (Central) Lymphoid Tissues

Bone Marrow

Bone marrow is the source of self-renewing populations of hematopoietic stem and precursor cells and early common lymphoid B-cell and T-cell precursors. The early B-cell differentiation program continues in the bone marrow, whereas the precursor elements committed to T-cell differentiation migrate to the thymus to complete the T-cell maturation process. Bone marrow is also a repository for plasma cells (and some memory B cells [MBCs]) that migrate back to the bone marrow after being generated in peripheral lymphoid organs and tissues. B-cell development in the bone marrow is dependent on the interactions of precursor lymphoid cells with

stromal cells in different topographic niches, which provide specific contacts and signals to maturing lymphoid cells. The most immature hematopoietic cells are in the endosteal niche close to the interior surface of the bone, where osteogenic cells seem to provide signals for the development of B cells; subsequently, they move to central regions of the bone marrow close to periarteriolar and sinusoidal cells. Cytokines and chemokines influence B-cell differentiation and trafficking in the bone marrow (**Table 7-1**). Two of the major players are CXCL12, also known as stromal cell–derived factor-1 (SDF-1), and its receptor, CXCR4. CXCL12 is expressed by osteoblasts, bone marrow stromal cells, and endothelial cells. CXCR4 is present in hematopoietic stem cells and in early stages of B-cell differentiation, whereas it is downregulated in pre-B cells and mature B cells in peripheral lymphoid organs. CXCR4 is upregulated again in mature cells after antigen stimulation and plasma cell differentiation, which may explain the homing back of these cells to the bone marrow. Late progenitor B (pro-B) and precursor B (pre-B) cells require interleukin (IL)-7 generated by different stromal cells in the endosteal and central niches. Later stages of differentiation in the marrow are less dependent on contact with stromal cells, allowing them to leave these niches and continue their maturation in secondary lymphoid organs.[4]

Box 7-1 Innate and Adaptive Immune Response Systems

Innate

- Defensive system developed very early in evolution.
- Mediated by phagocytes, dendritic cells, NK cells, and some T cells, including γ-δ T cells.
- These cells always respond to antigens in the same way, regardless of prior exposure to the antigen.
- The receptors that recognize antigens in these cells are encoded by the germline DNA without subsequent modifications.
- Antigens recognized by this system contain highly conserved structures that are present on common pathogens but not in host cells.
- Innate immune cells perform their effector functions immediately upon receptor engagement.
- Cells of the innate immune system initiate and regulate adaptive immune responses by presenting antigens and activating signals to T and B cells.

Adaptive

- Immune system developed in vertebrates.
- Mediated by B and T lymphocytes.
- The cell surface antigen receptors (B and T cell receptors) are highly specific and encoded by somatically rearranged immunoglobulin and T-cell receptor loci. B cells typically undergo further affinity selection of their B-cell receptor upon exposure to antigens.
- Cells expressing receptors against self-antigens must be selected against.

- Cells recognizing foreign antigens first proliferate to expand the few antigen-specific B or T cells (clonal selection).
- The adaptive system generates memory cells and improves in efficiency and specificity during the life of the individual owing to repeated exposure to antigens.

Precursor B lymphocytes or lymphoblasts are not easily detected morphologically in normal bone marrow. These cells have round nuclei with dispersed chromatin and small nucleoli. They may be seen more commonly in regenerating bone marrow, where they are called *hematogones*.[5] These cells express immature lymphoid markers, may be numerous—particularly in autoimmune disorders, human immunodeficiency virus, and other viral infections—and are associated with neoplasia. Caution is needed to avoid misinterpreting these cells as neoplastic lymphoid cells.[5]

Thymus

The thymus, located in the anterior mediastinum, is where precursor cells that migrate from the bone marrow undergo maturation and selection to become mature, naïve T cells that can respond to foreign antigens (**Fig. 7-1**). The thymus is critical to the development of a normal T-cell repertoire in early life, and there is evidence that it continues to function in T-cell development throughout life.[1,6]

Table 7-1

The thymus has a central lymphoid compartment—the thymic epithelial space—and a peripheral compartment—the perivascular space.[6] The thymic epithelial space is divided into a cortex and a medulla; each is characterized by specialized epithelium and

accessory cells, which provide the milieu for T-cell maturation. The cortex contains cortical epithelial cells, which are large cells with vesicular chromatin, prominent nucleoli, and pale cytoplasm that form a reticular 3-dimensional supporting meshwork and express high levels of major histocompatibility complex (MHC) class II. Phagocytic histiocytes (macrophages) are also present in the cortex, where they both present antigen and phagocytize apoptotic thymocytes. The medullary epithelial cells are coarser and express MHC classes I and II. In central areas, these cells form spherical whorls with central keratinization known as Hassall corpuscles. The medulla contains dendritic cells that are similar to cutaneous Langerhans cells and lymph node interdigitating dendritic cells. Perivascular spaces are present in both the cortex and medulla.

The lymphocytes of the cortex (cortical thymocytes) range in morphology from medium-sized blastic cells with dispersed chromatin and nucleoli in the outer cortex to somewhat smaller, more mature-appearing round lymphocytes in the inner cortex. The immunophenotype of most cortical thymocytes is that of precursor T cells (TdT positive, CD1a positive, CD4 positive, CD8 positive). Medullary thymocytes are small, mature-appearing lymphocytes with round or slightly irregular nuclei and inconspicuous nucleoli. Lymphocytes in the perivascular spaces resemble those in the medulla.[6] Both have the immunophenotype of mature T cells (TdT^-, $CD1a^-$, $CD3^+$, $CD4^+$, or $CD8^+$).

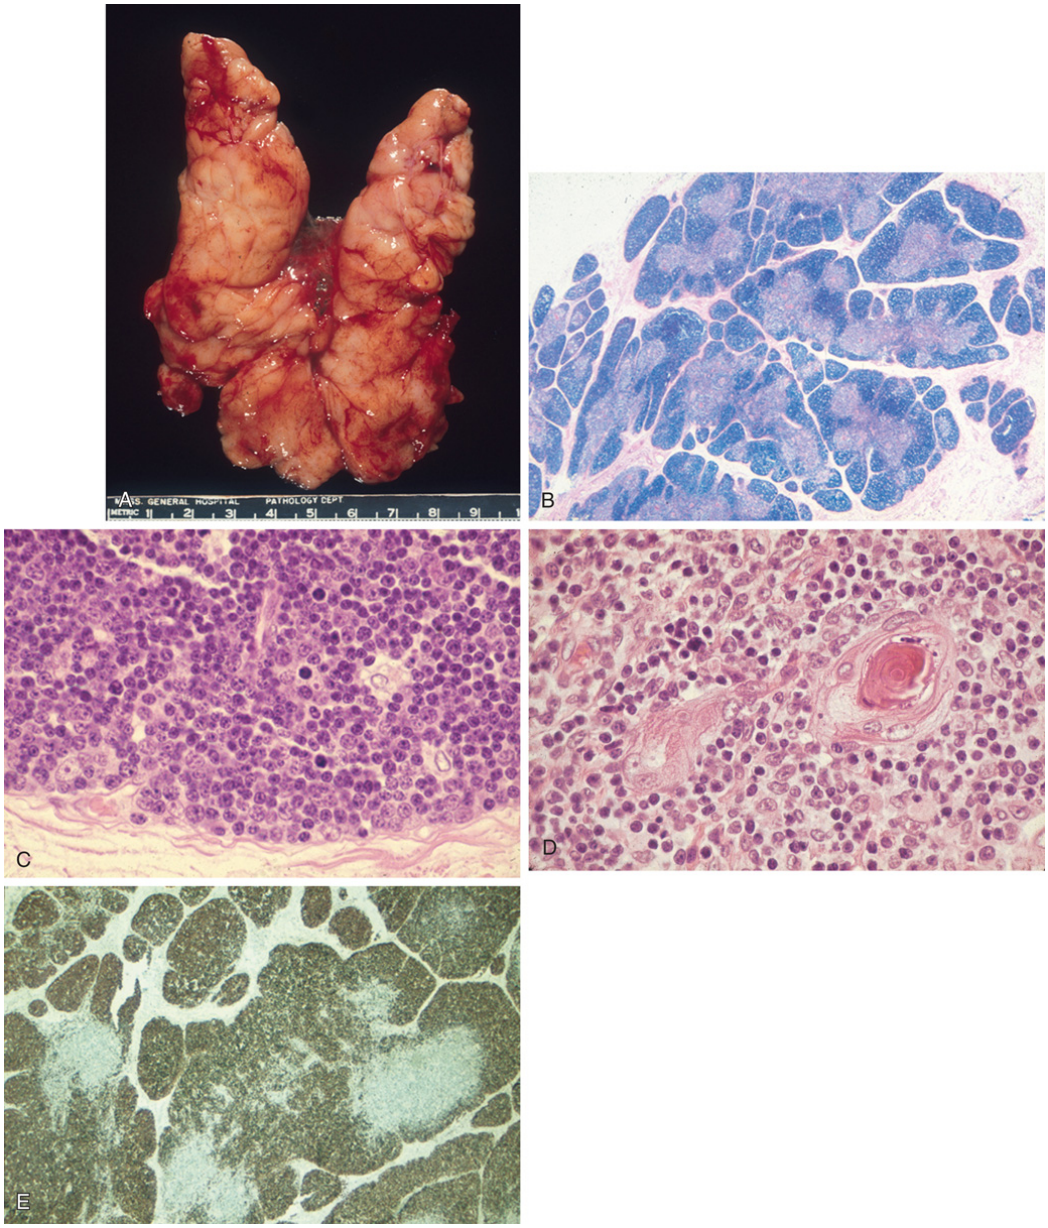

FIGURE 7-1 Thymus.**A,** Gross photograph of the thymus. Two lobes are connected by an isthmus; the surface of the thymus is also lobulated. **B,** Low magnification shows the lobular architecture. The cortex is dark blue, and the medulla is paler, containing keratinized Hassall corpuscles. **C,** The cells of the outer cortex are medium-sized blastic cells with rather

dispersed chromatin. Large oval cortical epithelial cells are visible, with distinct nucleoli and indistinct cytoplasm. **D,** The cells of the medulla are mature-appearing lymphocytes, associated with more spindle-shaped epithelial cells. **E,** With immunostaining for terminal deoxynucleotidyl transferase, the cortical thymocytes are stained, and the medullary thymocytes are negative.

The thymic medulla also contains a particular population of B cells with dendritic morphology that expresses mature B-cell markers CD23, CD37, CD72, CD76, immunoglobulin (Ig)M, and IgD. These cells form rosettes with non-B cells and have been called asteroid cells. The close relationship with T cells and epithelial thymic cells suggests that they may play a functional role in the T-cell differentiation process.[7,8] These asteroid cells may be the cell of origin for primary mediastinal large B-cell lymphoma.

The thymic epithelial space begins to atrophy at 1 year; it shrinks by about 3% per year through middle age and then by 1% per year thereafter[6]; concomitantly, the perivascular space increases. The "fatty infiltration" noted in the adult thymus occurs in the perivascular space.[6]

Secondary (Peripheral) Lymphoid Tissues

Lymph Nodes

Lymph nodes are strategically located at branches of the lymphatic system throughout the body to maximize the capture of antigens and chemokines present in lymph drained from most organs via the

afferent lymphatics (**Fig. 7-2**). The lymph nodes are protected by an external fibrotic capsule with internal prolongations that form trabeculae, providing the basic framework for the organization of the different cellular, vascular, and specialized stromal components.

The cellular compartments are distributed among three discrete but not rigid regions: the cortex, paracortex, and medullary cords. The cortex or cortical area is the B-cell zone and contains the lymphoid follicles; the paracortex contains mainly T cells and T-cell antigen-presenting cells. The medullary cords in the inner area of the lymph node contain B cells, T cells, plasma cells, macrophages, and dendritic cells.

Cortical Area

The initial cortical structure is the primary lymphoid follicle, composed of aggregates of naïve B cells with a small network of follicular dendritic cells (FDCs) (**Fig. 7-2B**).[9-11] The lymphoid cells are small and have round nuclei with dense chromatin and scant cytoplasm. These cells express mature B-cell markers, IgM, IgD, CD21, and CD23. Antigen stimulation of B cells generates the expanded and highly organized secondary lymphoid follicle with a mantle cell corona, a germinal center, and a dense meshwork of FDCs (**Figs. 7-2C–F** and **7-3**).

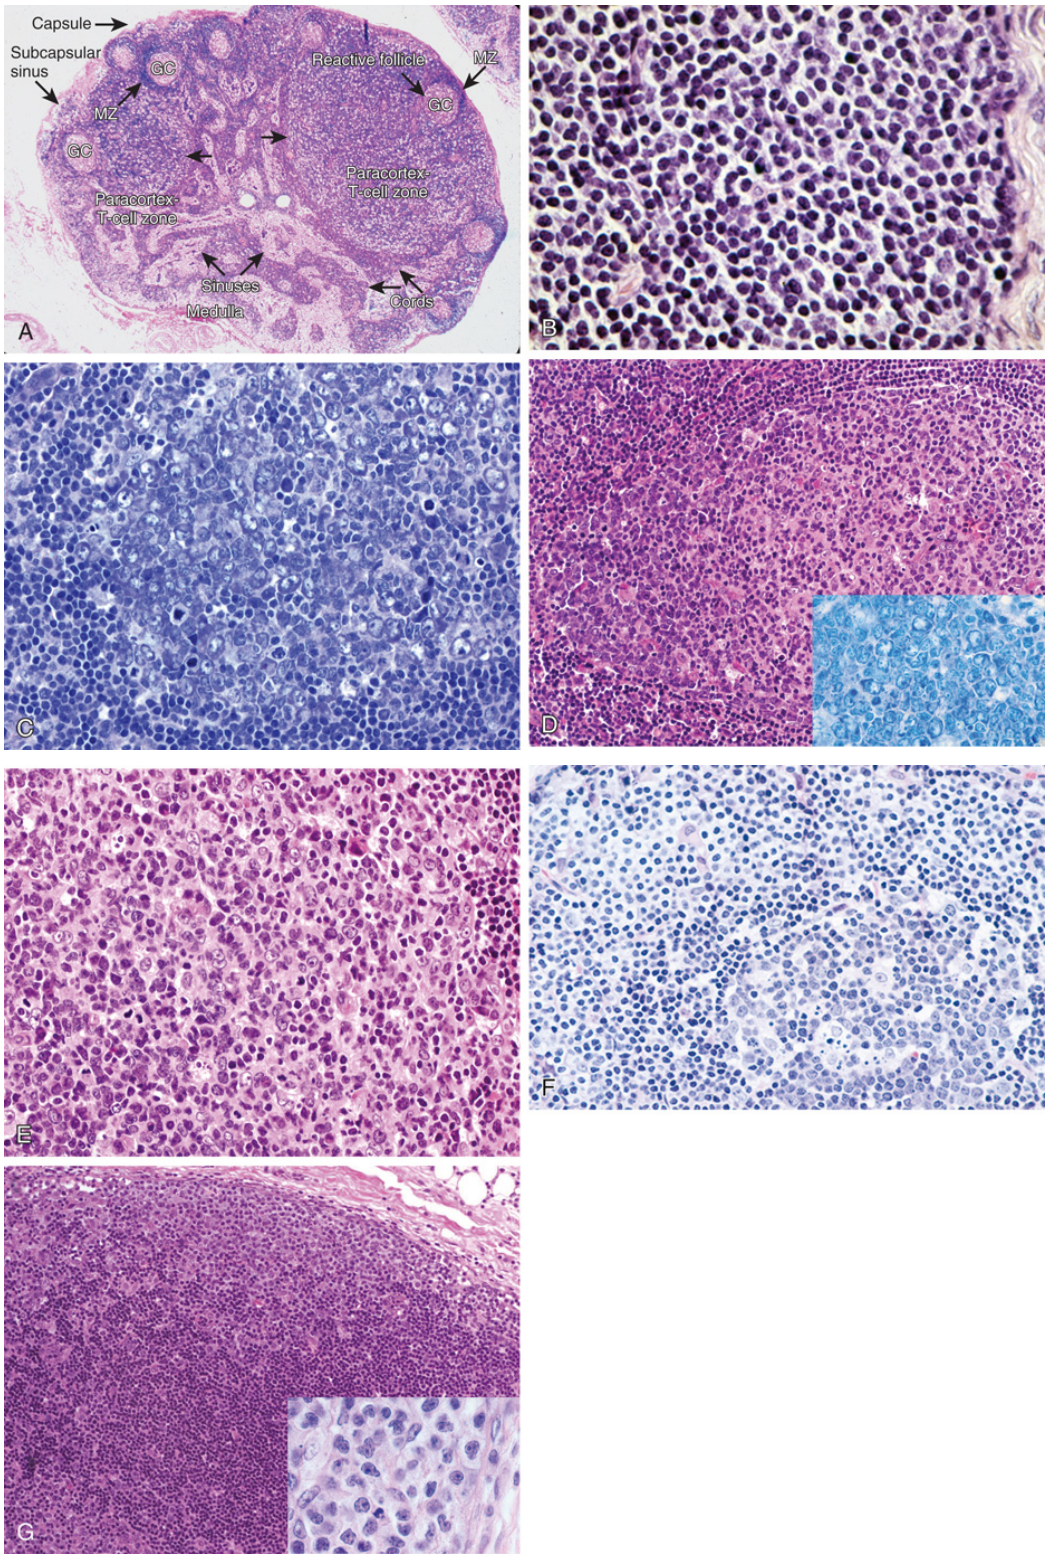

FIGURE 7-2 Lymph node.**A,** Low magnification illustrates the architecture of a

reactive lymph node. Lymph nodes have a capsule, a cortex, a medulla, and sinuses (subcapsular, cortical, and medullary). The sinuses contain histiocytes (macrophages), which take up and process antigens, which are then presented to lymphocytes. The cortex is divided into follicular *(long, thin arrows)* and paracortical *(short, thick arrows)* regions, and the medulla is divided into medullary cords and sinuses. Both T-cell and early B-cell reactions to antigens occur in the paracortex, and the germinal-center reaction occurs in the follicular cortex. Plasma cells and effector T cells generated by immune reactions accumulate in the medullary cords and exit via the medullary sinuses. **B,** Primary follicle composed of small, predominantly round lymphocytes arranged in a cluster that appears somewhat 3-dimensional. These cells express IgM, IgD, and CD23. **C,** Secondary follicle with an early germinal center predominantly contains centroblasts—large blast cells with vesicular chromatin, one to three peripherally located nucleoli, and basophilic cytoplasm. Occasional centrocytes are present—medium-sized cells with dispersed chromatin, inconspicuous nucleoli, and scant cytoplasm that is not basophilic (Giemsa stain). **D,** The germinal center has polarized into a light zone and a dark

zone, surrounded by a mantle zone of small lymphocytes. The dark zone contains mostly centroblasts, with admixed and closely packed centrocytes *(inset)* (Giemsa stain).**E,** The light zone contains centrocytes, numerous T cells, and many follicular dendritic cells with oval, vesicular nuclei that are often bilobed or binucleate. **F,** Follicle from a mesenteric lymph node has an expanded marginal zone composed of cells with centrocyte-like nuclei and pale cytoplasm. **G,** Lymph node with a monocytoid B-cell aggregate forming a pale band beneath the subcapsular sinus. Inset shows the cells at higher magnification; they have folded, monocyte-like nuclei and abundant pale-to-eosinophilic cytoplasm. *GC,* Germinal center; *MZ,* mantle zone.

The mantle zone is composed mainly of the small B cells of the primary lymphoid follicle that are pushed aside by expansion of the germinal center. Like primary follicle B cells, mantle zone B cells express IgM, IgD, CD21, and CD23. Occasional B cells co-expressing CD5 are also located in this area but are difficult to identify in routine histologic sections. The mantle corona also contains MBCs when the outer marginal zone is not developed.

The germinal center is a specialized lymphoid compartment in which the humoral T-cell–dependent immune response occurs.[9-11] This structure sustains the proliferative expansion of antigen-activated B-cell clones and the generation of high-affinity antibodies

by the induction of antigen-driven somatic hypermutation of the Ig heavy and light chain variable region genes. Ig heavy chain constant region genes also undergo the class or isotype switch recombination from IgM and IgD (which can be co-expressed as a result of differential splicing) to IgG, IgA, or IgE. This process is not exclusive to the germinal centers; it may occur in other sites, to a lesser degree, in the T-cell–independent response. The germinal center also provides a microenvironment that selects the antigen-stimulated clones that produce high-affinity antibody, whereas B cells that do not produce high-affinity antibody to the specific antigen undergo apoptosis. Antigen-selected cells then exit the germinal center, becoming MBCs or long-lived plasma cells.

Morphologically, the early germinal center contains predominantly small and large centroblasts. These cells are medium-sized to large-sized B cells with an oval-to-round vesicular nucleus containing one to three small nucleoli close to the nuclear membrane and a narrow rim of basophilic cytoplasm; these features are best seen on Giemsa staining (**Fig. 7-2C**). After several hours or days, the germinal center becomes polarized into two distinctive areas: the dark zone and the light zone (**Fig. 7-2D**). The dark zone is composed predominantly of centroblasts. Mitotic figures are common in this area. Closely packed centrocytes are also present in the dark zone (**Fig. 7-2D**, *inset*). Centrocytes are small-to-large B cells with irregular, sometimes deeply cleaved nuclei, dense chromatin, inconspicuous nucleoli, and scant cytoplasm that is not basophilic on Giemsa staining. Macrophages phagocytizing apoptotic nuclear debris are also present (tingible body macrophages). The light zone contains predominantly quiescent centrocytes.

The light zone also contains a high concentration of FDCs, and their vesicular and often double nuclei with small nucleoli are easily seen in this area (**Fig. 7-2E**). Contrary to other dendritic cells, FDCs are derived from mesenchymal cells and are important organizers of the germinal centers and the T-cell–dependent immune response. These cells express a profile of molecules that attract B and T cells and facilitate the antigen-presenting process. Thus, FDCs secrete CXCL13, a chemokine that recruits B and T cells expressing CXCR5 (**Table 7-1**). They also express CD23, the adhesion molecules ICAM-1 and VCAM-1, and complement receptors (CD21, CD35) that fix immunocomplexes (**Fig. 7-3**). It is important to note that, whereas conventional dendritic cells present antigenic peptides bound to MHC class II molecules to CD4-positive T cells, FDCs do not express MHC class II. Therefore FDCs present unprocessed antigen-antibody immune complexes to the B cells either bound to complement or to membranous Fc receptors.

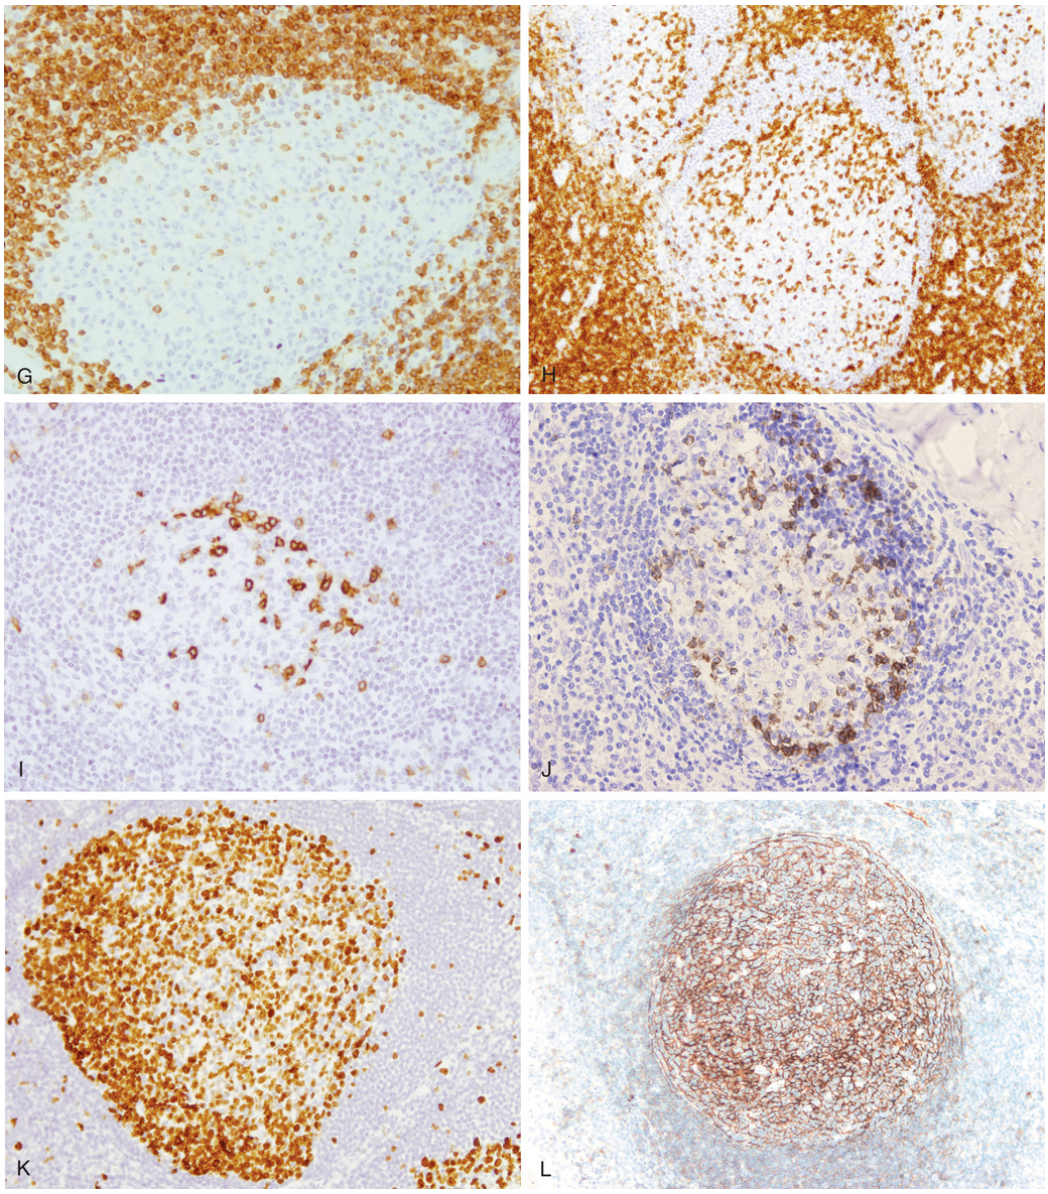

FIGURE 7-3 Secondary follicle.**A,** Reactive follicle with a polarized germinal center *(dark zone to the left and light zone to the right)* and a mantle zone area more developed near the light zone of the germinal center. **B,** Immunostain for CD20 shows staining of both the mantle zone and the germinal center. **C,** Immunostain for IgD shows staining of the mantle zone lymphocytes.

D, CD23 stains follicular dendritic cells (FDCs) predominantly in the light zone in addition to mantle zone B cells. **E,** CD10 highlights the germinal center. **F,** BCL6 shows nuclear staining of most germinal-center cells.**G,** BCL2 is expressed by mantle zone B cells and some intrafollicular T cells, but germinal-center B cells are negative. **H,** CD3 stains the T cells in the paracortex and numerous T cells within the germinal center. They are more numerous in the light zone than in the dark zone and form a crescent at the junction of the germinal center and the mantle zone. **I,** CD57 is expressed by a subset of germinal-center T cells. **J,** CD279 (PD1) is expressed by germinal-center T cells of the follicular helper subset. **K,** The majority of cells in the dark zone are in cycle, staining for Ki-67, whereas fewer cells in the light zone are proliferating. **L,** CD21 stains FDCs predominantly in the light zone and mantle zone B cells.

Phenotypically, both centroblasts and centrocytes express mature B-cell antigens (CD19, CD20, CD22, CD79) and germinal-center markers such as BCL6, CD10, LMO2, MEF2B, and HGAL (**Fig. 7-3**). Centroblasts express Ig at low levels, which may aid in the replacement of the former Ig by modified Ig upon somatic hypermutation. They express high CXCR4 and are negative or low for CD83 and CD86. Surface Ig is re-expressed by centrocytes so that these cells can be selected for having Ig with higher affinity for the

driving antigen. Centrocytes are positive for CD83 and CD86 but negative or low for CXCR4. BCL6 is an essential nuclear zinc-finger transcription factor required for germinal-center formation and the T-cell–dependent immune response. It is expressed in germinal-center B and T follicular helper (T_{FH}) cells but not in naïve B cells, mantle zone B cells, MBCs, plasma cells, or other T cells.[10,12] CD10 is a membrane-associated molecule (also known as common acute lymphoblastic leukemia antigen [CALLA]) that is normally expressed in early pro-B cells in the bone marrow but is lost in naïve cells and re-expressed in germinal-center cells. Its function is not well known, but it seems to be indispensable for germinal-center formation. CD10-positive mature lymphoid cells are restricted to germinal centers, and their identification outside this compartment should suggest the presence of a follicular lymphoid cell-derived neoplasm. LIM-only transcription factor 2 *(LMO2)* and human germinal-center–associated lymphoma *(HGAL)* are more recently identified genes expressed in germinal-center B cells. LMO2 is a transcription factor that plays an important role in hematopoiesis, and in the bone marrow it is normally expressed in myeloid, erythroid, and lymphoid cells, but in peripheral tissues it is only expressed in germinal-center B cells. *HGAL* is a highly evolutionary conserved gene that is highly expressed in the cytoplasm of normal and neoplastic germinal-center B cells, whose function is not well understood.[13,14] Myocyte Enhancer Factor 2B (MEF2B) is a transcription factor that interacts with BCL6 and regulates a gene program involved in germinal center formation, particularly the dark zone.[15] It is expressed exclusively in the nucleus of germinal-center B cells but, contrary to BCL6, it is not detected in germinal-center T cells.[16] An important functional

phenotypic change in germinal-center B cells is the downregulation of the antiapoptotic molecule BCL2, constitutively expressed in naïve and memory lymphoid cells.[9,10] Thus, these cells are susceptible to death through apoptosis, and only the clones binding the specific antigens will be rescued and survive in this microenvironment. Germinal-center B cells also express surface molecules involved in interactions with FDCs and T cells. In particular, CD40, CD86, and CD71 facilitate the association with T cells, whereas CD11a/18 and CD29/49d recognize the FDC ligands CD44, ICAM-1, and VCAM-1.[10-12]

Germinal centers contain specialized subpopulations of T cells that play an important role in the regulation of the B-cell differentiation process and T-cell–mediated immune response (**Fig. 7-3**). T_{FH} cells are mainly localized in the light zone and in the mantle zone area and express CD4, CD57, ICOS, CXCL13, PD-1 (programmed death-1, or CD279), and CXCR5, the receptor for the CXCL13 chemokine also secreted by FDCs.[17] T_{FH} cells promote B-cell differentiation through induction of activation-induced cytidine deaminase (AID) expression by B cells, which is needed for Ig class switch. Germinal centers also contain a subset of T regulatory (Treg) cells that express CD4, CD25, and FOXP3 and play a role in preventing autoimmunity and limiting T-cell–dependent B-cell stimulation. These cells also seem to directly suppress B-cell Ig production and class switch.[18] Treg cells are also found in interfollicular areas.

Marginal zones are sometimes seen around follicles in lymph nodes, although these are usually not as prominent as those in the spleen; they are often more conspicuous in mesenteric lymph nodes (**Fig. 7-2F**). Marginal zone B cells have nuclei that resemble those of

centrocytes but with more abundant pale cytoplasm; they appear to be a mixture of naïve B cells and MBCs. In some reactive conditions, slightly larger B cells with even more abundant pale-to-eosinophilic cytoplasm appear in aggregates between the mantle zone and cortical sinuses; these are known as monocytoid B cells (**Fig. 7-2G**). Neutrophils are frequently intermingled with expanded marginal zone cells. A subset of neutrophils is able to stimulate the antibody production by marginal zone cells, suggesting a possible bridge between innate and adaptive immune response.[19]

Paracortex

The paracortex is the interfollicular T-cell zone (**Fig. 7-2A**). This compartment contains mainly mature T cells and dendritic cells of the interdigitating cell subtype that specialize in presenting antigens to T cells (**Fig. 7-4A**). This area is organized by the production of the chemokines CCL19 and CCL21 by stromal cells of the paracortex, particularly fibroblastic reticulum cells and endothelial cells of the high endothelial venules (HEVs) present in this area. These chemokines recruit the T cells and dendritic cells expressing their receptor, CCR7. The T cells in these areas are heterogeneous, with a predominance of CD4-positive cells; some CD8-positive and Treg cells are also found. The interdigitating cells are positive for S100, MHC class II, CD80, CD86, and CD40 but negative for CD1a, CD21, and CD35; they have complex interdigitating cellular junctions. In some reactive conditions, particularly those associated with rashes, the paracortical areas contain Langerhans cells that have migrated from the skin.

Interfollicular areas also contain isolated large B or T cells with immunoblastic morphology; these cells may be numerous in some reactive conditions. B-immunoblasts are large cells similar in size to centroblasts but with prominent single nucleoli and more abundant basophilic cytoplasm (**Fig. 7-4B**). These cells express mature B-cell markers and abundant cytoplasmic Igs and are considered intermediate steps toward plasma cells. In some reactive situations, these cells may be abundant, express CD30, and downregulate mature B-cell transcription factors such as PAX5, mimicking Hodgkin cells. However, CD15 is negative and polytypic light chain expression is common.[20] A less-frequent subset of large B cells with a dendritic morphology has been identified in nodal T-cell areas.[21] These cells carry Ig somatic mutations and express mature B-cell markers and CD40 but are negative for germinal-center markers (BCL6 and CD10), CD30, and CD27. The functional role of these cells is not known, but they resemble the thymic asteroid cell.

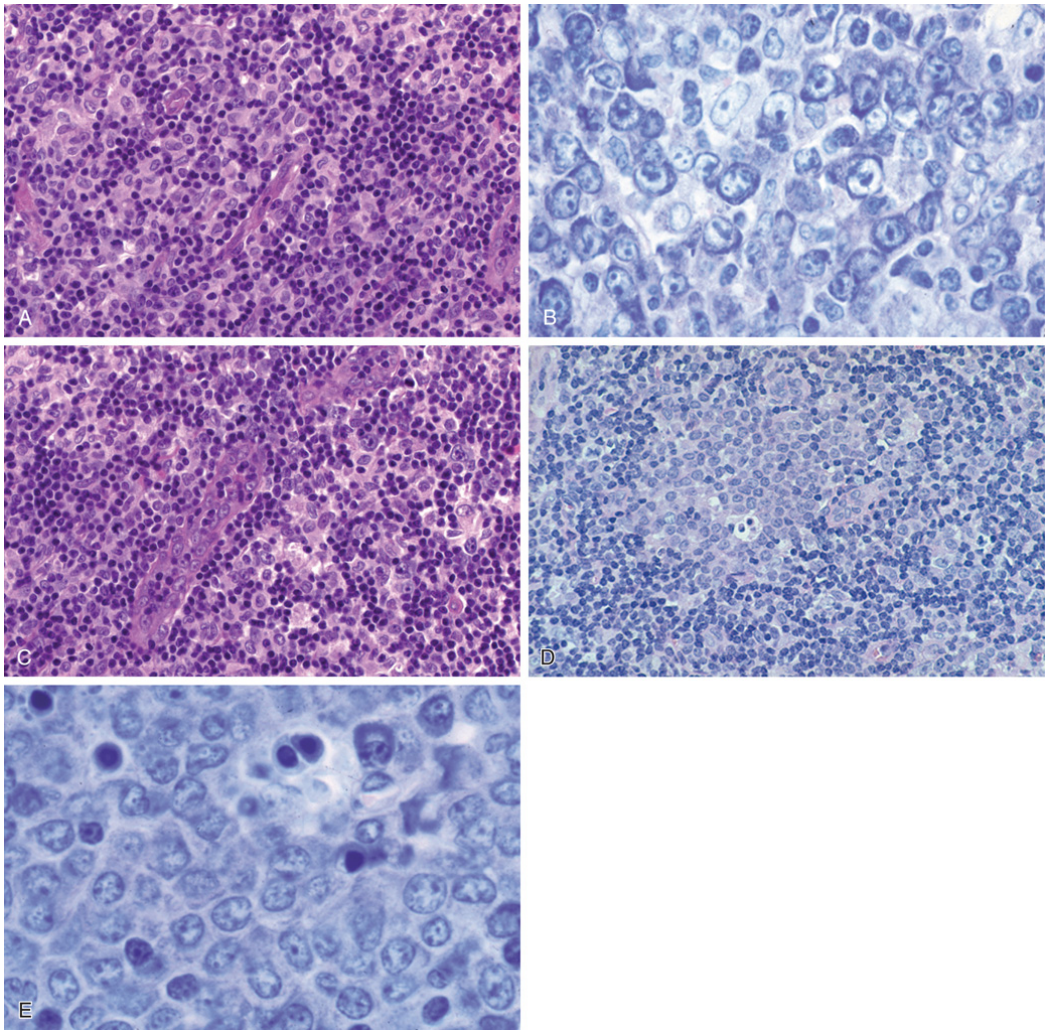

FIGURE 7-4 Lymph node paracortex.**A,** The paracortex contains small, round, evenly spaced lymphocytes and interdigitating dendritic cells with pale, grooved, or irregular nuclei and indistinct cytoplasm; these cells present antigens to T cells and to B cells that may migrate through the paracortex. **B,** In early reactions to antigens, an immunoblastic reaction occurs, and numerous B immunoblasts are present in the paracortex. Immunoblasts are two to three times the size of small lymphocytes and have vesicular chromatin,

single central nucleoli, and abundant basophilic cytoplasm (Giemsa stain). **C,** High endothelial venules (HEVs) are prominent in the paracortex. HEVs have plump endothelial cells, and lymphocytes are typically seen migrating between them. Lymphocytes migrate into the lymph node via the HEVs, which have receptors for lymphocytes on the endothelial cells. **D,** At the junction of the paracortex and the medulla, an aggregate of plasmacytoid dendritic cells is seen. The cells have dispersed chromatin and amphophilic cytoplasm; apoptosis and nuclear dust may be seen. **E,** On Giemsa staining, the cytoplasm is faintly basophilic and eccentric, resembling a plasma cell.

The paracortex contains HEVs, postcapillary venules through which both T and B lymphocytes enter the lymph node from the blood (**Fig. 7-4C**).[22] HEVs have large, plump endothelial cells whose nuclei often appear to virtually occlude the lumen. HEVs are also found in other secondary lymphoid tissues except spleen tissue and in tertiary lymphoid structures. These endothelial cells express adhesion molecules that anchor circulating lymphocytes and also act as tissue-specific recognition molecules (called *addressins*) that bind to specific molecules on the lymphocytes (called *homing receptors*). These include E-selectin, P-selectin, VCAM-1, ICAM-1, ICAM-2, peripheral node addressin (peripheral lymph nodes), and mucosal addressin (mesenteric lymph nodes) cell adhesion molecules (MAdCAMs). The addressins bind to L-selectin (CD62L) and $\alpha_4\beta_7$-

integrins on the lymphocytes. Postcapillary venules in other tissues do not express lymphocyte adhesion molecules unless they are stimulated by inflammatory mediators; however, those in the lymph nodes express them constitutively and thus recruit lymphocytes continuously.[23] The HEVs usually contain lymphocytes both within the lumen and infiltrating between the endothelial cells and the basement membrane.

Under some circumstances, collections of plasmacytoid dendritic cells may be found in the paracortex, usually at its junction with the medullary cords. These are medium-sized cells with dispersed chromatin, small nucleoli, and eccentric, amphophilic cytoplasm; they typically occur in small clusters, sometimes with apoptotic debris and histiocytes, mimicking a small germinal center. These cells produce high amounts of interferon-α and function in the regulation of T-cell responses. They express CD4, CD68, granzyme B, CD123, TCL1, and CLEC4C (BDCA2) and lack specific markers of T-cell, B-cell, or myeloid differentiation.[24-26]

Lymph Node Vasculature and Conduit System

The interaction among lymph, blood, and the different cell components of the lymph node is facilitated by a highly organized vascular system. Blood arrives via arteries at the hilus and branches to reach the subcapsular area and paracortex, where the capillaries form loops and specialize into postcapillary HEVs. Lymph arrives through the afferent lymphatic vessels at the opposite pole of the node, which open to the subcapsular sinus, and flows through the trabecular and medullary sinuses toward the efferent lymph vessels at the hilus. Macrophages in the subcapsular sinuses capture large

antigens, immune complexes, and viruses and may present them to nearby B and T cells in the primary follicles in the cortical areas. Small soluble antigens may diffuse through the sinus wall and reach the cortical areas.[27]

The nodal conduit system is a specialized structure that connects the lymphatic sinuses with the walls of the blood vessels, particularly the HEVs in the paracortex, allowing the rapid movement of small antigenic particles (around 5.5 nm and 70 kDa) and cytokines from the afferent lymph deep into the portal of entry of lymphocytes to the nodal parenchyma.[2,28] This structure consists of small conduits composed of a core of type I and III collagen fibers associated with cross-linked microfibrils of fibromodulin and decorin, all of them surrounded by a basal membrane of laminin and type IV collagen. This entire conduit system is generated and wrapped by fibroblastic reticular cells. These cells are positive for vimentin, smooth muscle actin, desmin, and keratins 8 and 18. They also express CCL19/CCL21, serving as a homing mechanism for B cells and T cells expressing the receptor CCR7.[3] Some studies suggest that these cells may acquire FDC markers under certain T-cell stimuli and may be the origin of the expanded meshwork of FDCs that surrounds the HEV in angioimmunoblastic T-cell lymphoma.[3]

Spleen

The spleen has two major compartments—red pulp and white pulp—related to its two major functions as a blood filter for damaged elements of the blood and a defense against blood-borne pathogens, respectively. The white pulp organization is similar to that of the lymphoid tissue of lymph nodes (**Fig. 7-5A**–F). Follicles and

germinal centers are found in the Malpighian corpuscles, and T cells and interdigitating cells are found in the adjacent periarteriolar lymphoid sheath (PALS). The red pulp also contains antigen-presenting cells; lymphocytes, particularly a subset of γ-δ T lymphocytes; and plasma cells. A distinctive feature of the spleen is the presence of a prominent marginal zone that surrounds both the B-cell and T-cell zones (**Fig. 7-5D**).[29,30]

White Pulp

The B-cell and T-cell areas in the spleen are organized around the branching arterial vessels (**Fig. 7-5A–F**). Similar to the lymph nodes, the T-cell and B-cell compartments are recruited and maintained by specific chemokines. CCL19 and CCL21 are produced mainly by stromal cells in the T-cell areas, and the FDCs secrete CXCL13; these chemokines recruit cells expressing the receptors CCR7 and CXCR5, respectively (**Table 7-1**). T cells surround the arterioles in a discontinuous manner, whereas B-cell follicles may be found adjacent to the T-cell sheaths or directly attached to the arteriole without a T-cell layer (**Fig. 7-5F**). A distinctive area of the splenic white pulp is the marginal zone, which is more evident in follicles with an expanded germinal center and plays a role in T-cell independent immune response with rapid production of plasmablasts. B cells in this area have slightly irregular nuclei, resembling those of centrocytes but with more abundant pale cytoplasm, and express CD21 and IgM, but contrary to mantle cells, IgD expression is negative or weak (**Fig. 7-5D**). The marginal zone has two subpopulations of macrophages that constitute an innate immune barrier: the marginal zone and metallophilic macrophages.

The marginal zone macrophages in the outer area express CD68, C-type lectins (DC-SIGN/SIGNR1), and the scavenger receptor MARCO that can bind bacterial polysaccharide antigens. Metallophilic macrophages are located in the inner area of the marginal zone, express CD169, and can bind sialic acid-containing molecules on immune cells and some pathogens. They also express Toll-like receptors. The human marginal zone is surrounded by a perifollicular area with more widely separated fibers and capillaries sheathed by abundant macrophages that are positive for sialoadhesin. A large amount of the splenic blood passes through this area, where the flow seems to be retarded. This anatomic relationship between an open blood area and the marginal zone seems to facilitate direct contact between blood-borne antigens and B cells.[29,30]

Red Pulp

The red pulp is composed of sinuses and cords (Billroth cords). The sinuses form an interconnected meshwork covered by a layer of specialized sinusoidal endothelial cells (littoral cells) and surrounded by annular fibers of extracellular matrix; these annular fibers may be seen on periodic acid–Schiff staining (**Fig. 7-5G**). The cells have cytoplasmic stress fibers that regulate the passage of blood cells. The capillaries open into the cords, and the blood cells that cannot pass through the sinusoidal cells are destroyed by the abundant macrophages resident in the cords. Sinusoidal blood flows into the venous system. The sinusoidal littoral cells have a specific phenotype with expression of CD8 and factor VIII but negative for CD34 (**Fig. 7-5H**). The red pulp cords also contain plasmablasts and plasma

cells. Upregulation of CXCR4 in these cells may play a role in this movement because it binds to the CXCL12 expressed in the red pulp; on the contrary, CXCR5 and CCR7, which bind to the white pulp chemokines CXCL13, CCL19, and CCL21, are downregulated in these cells (**Table 7-1**).[29,30]

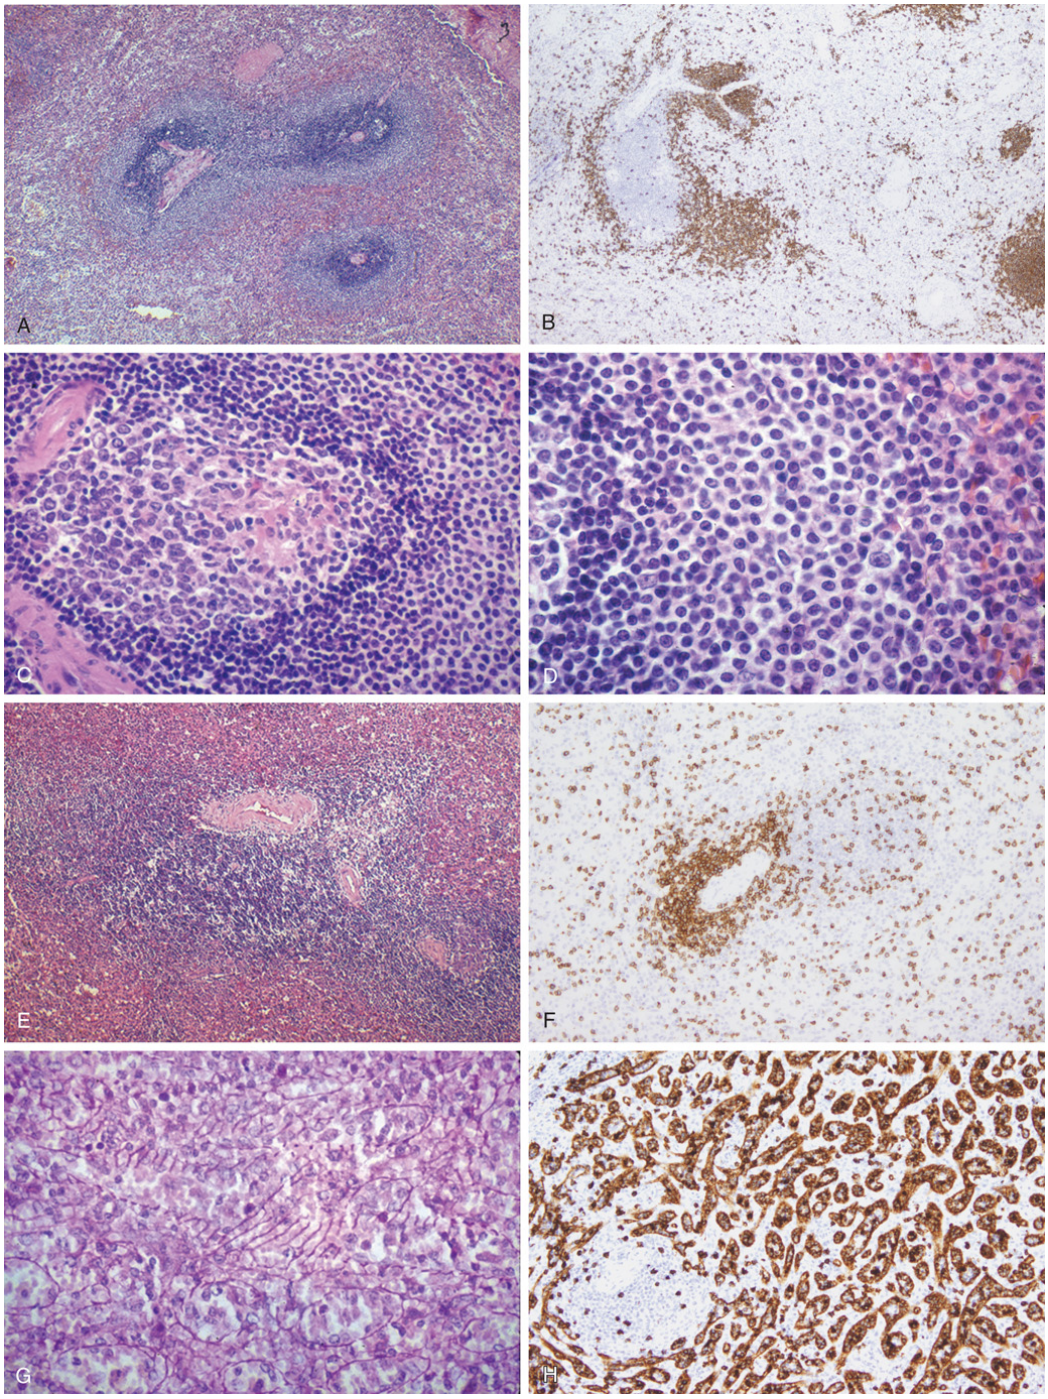

FIGURE 7-5 Spleen.**A,** At low magnification, the white pulp contains a reactive follicle with a germinal center *(left)* and a T-cell zone *(right);* both are surrounded by a pale-staining marginal zone. **B,** CD20 staining highlights the B-cell

nodules. **C,** Splenic follicle contains a germinal center, a mantle zone, and a pale-staining marginal zone composed of medium-sized cells with abundant pale cytoplasm. **D,** Marginal zone area of the B-cell follicle. The cells have pale cytoplasm. **E,** T-cell zone has an appearance similar to that of the nodal paracortex, with interdigitating dendritic cells present in a background of small lymphocytes. **F,** CD3 stains the periarteriolar T cells. **G,** Periodic acid–Schiff stain highlights the basement membrane of the sinuses, which are fenestrated, allowing nucleated red blood cells to be trapped in the cords. **H,** CD8 strongly stains the red pulp sinusoidal cells.

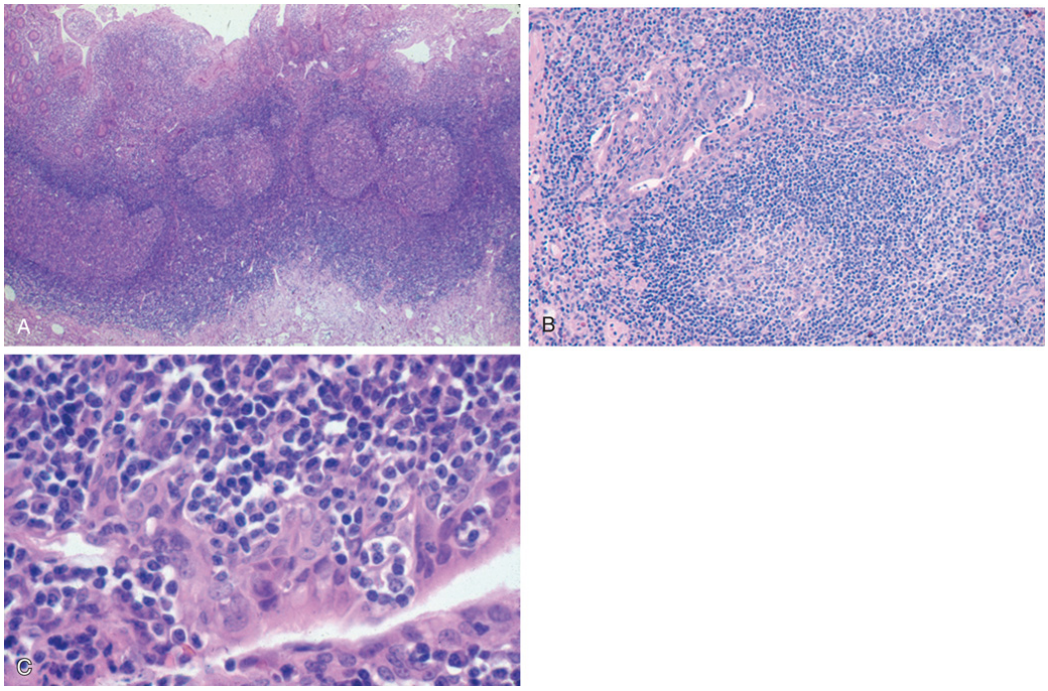

FIGURE 7-6 Mucosa-associated lymphoid tissue (MALT).**A,** Low magnification of Peyer's patches of the terminal ileum shows lymphoid follicles with reactive germinal centers and mantle zones; a pale area of marginal zone cells extends upward into the lamina propria. The overlying mucosa is somewhat flattened and eosinophilic. **B,** Adenoid showing a reactive follicle with pale-staining marginal zone cells extending toward a crypt. **C,** Adenoid showing marginal zone cells within the epithelium (lymphoepithelium).

Mucosa-Associated Lymphoid Tissue and Tertiary Lymphoid Organs

Specialized lymphoid tissue is found in association with certain epithelia, in particular the gastrointestinal tract (gut-associated lymphoid tissue—Peyer's patches of the distal ileum, mucosal lymphoid aggregates in the colon and rectum), the nasopharynx and oropharynx (Waldeyer's ring—adenoids, tonsils), and in some species, the lung (bronchus-associated lymphoid tissue). Collectively, this is known as MALT. In each territory, MALT contains four lymphoid compartments: organized mucosal lymphoid tissue, lamina propria, intraepithelial lymphocytes, and regional (mesenteric) lymph nodes (**Fig. 7-6**).[31] The organized lymphoid tissue is exemplified by Peyer's patches of the terminal ileum and is also found in Waldeyer's ring. The lymphoid follicles are structurally and immunophenotypically similar to those found in lymph nodes. The only difference here is the expanded marginal zone, which tends to reach the superficial epithelium. MALT marginal zone cells are morphologically like those found in the spleen. The interfollicular areas are occupied by T cells and interdigitating dendritic cells. The lamina propria contains mature plasma cells and macrophages and occasional B and T lymphocytes. These plasma cells secrete mainly dimeric IgA, but small populations producing IgM, IgG, and IgE are also present. The dimeric IgA and pentameric IgM are secreted into the intestinal lumen bound to the secretory component, a glycoprotein produced by the enterocytes. The T lymphocytes in the lamina propria are a mixed population of CD4-positive and CD8-positive cells, with a slight predominance (2:1 to 3:1) of the former. Intraepithelial lymphocytes are observed between the epithelial cells and are composed of a heterogeneous population of T cells. The predominant cells are CD3 positive, CD5 positive, and CD8 positive,

whereas 10% to 15% are CD3 positive and double negative for CD4 and CD8. CD3-positive CD4-positive cells are a minority, and only rare cells are CD56 positive.[32] Most of the T cells express the α-β form of the T-cell receptor (TCR), and around 10% of the cells are TCR γ-δ. The epithelium above the Peyer's patches contains clusters of B cells and specialized epithelial cells called membranous or microfold cells (M cells). These cells are also found more dispersed in other parts of the gastrointestinal tract and other mucosal sites, particularly in the epithelium over lymphoid follicles.[33] M cells play a sentinel role for the mucosal immune system by capturing luminal antigens and delivering them to the underlying immune cells. The basic structure of mesenteric lymph nodes is similar to that of other lymph nodes, but the marginal zone surrounding the follicles is usually expanded and visible.

The organization of the immune system in mucosal sites is orchestrated by the coordinated action of several adhesion molecules, chemokines, and their respective receptors. Lymphoid cells that respond to antigens in the MALT acquire homing properties that enable them to return to these tissues.[34,35] This homing is mediated in part by expression of high levels of $\alpha_4\beta_7$-integrin, which binds to MAdCAM-1 on HEVs in gut-associated lymphoid tissue.[23] In addition, the MALT immune cells express $\alpha E\beta_7$-integrin (CD103), whose ligand E-cadherin is expressed on the basolateral surface of the epithelial cells. Epithelial cells also secrete CCL25, which recruits T cells expressing its receptor CCR9 (**Table 7-1**).[36]

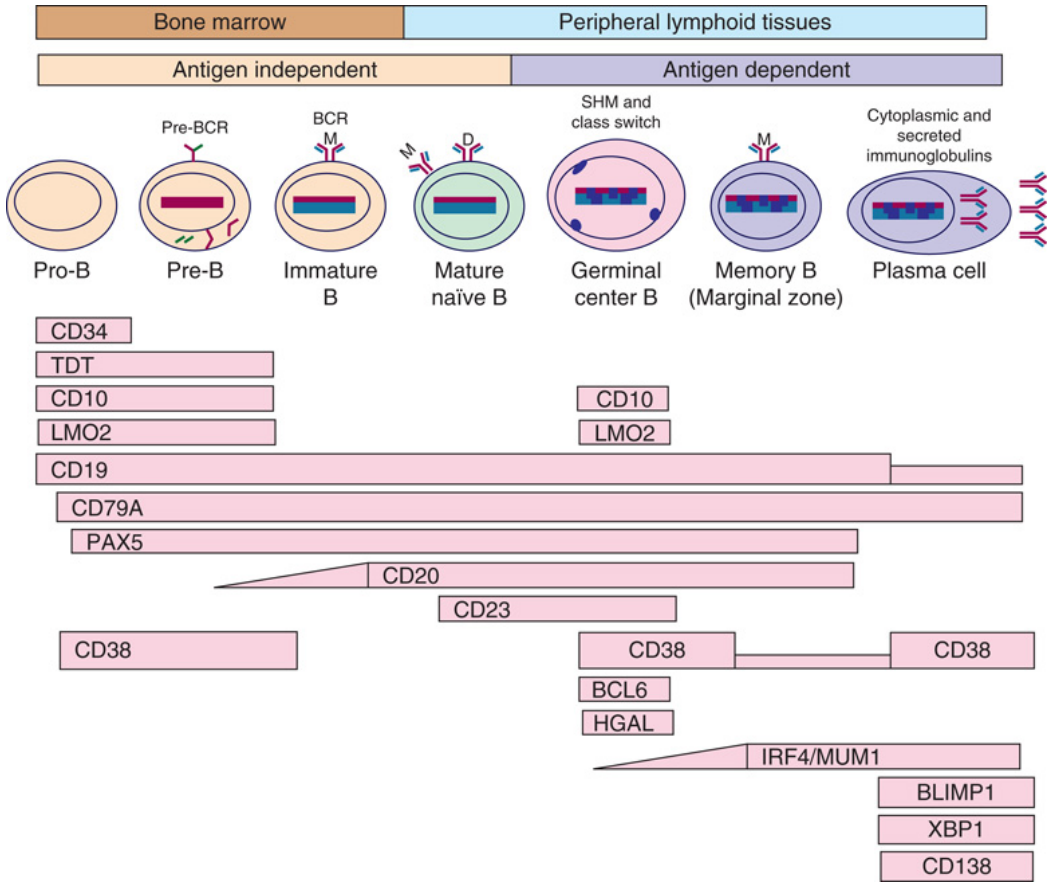

FIGURE 7-7 Schematic diagram of B-cell differentiation.Early B-cell precursors express CD34, terminal deoxynucleotidyl transferase (TDT), LMO2, and CD10. CD19 is an early B-cell differentiation antigen that is maintained during the entire B-cell differentiation program, and its expression is attenuated in plasma cells. CD79A and PAX5 appear at nearly the same time as heavy-chain gene rearrangement. CD20 is not expressed until the stage of light-chain rearrangement. Germinal-center cells are positive for BCL6 and HGAL and re-express CD10, LMO2, and CD38. The plasma cell differentiation

program is characterized by the downregulation of PAX5 and the expression of CD138, BLIMP1, and XBP1. *BCR,* B-cell receptor of mature B cells; *pre-BCR,* pre–B-cell receptor consisting of a heavy chain and the surrogate light chain (which is composed of two linked small peptides, Vpre-B and λ5, represented in *green*); *SHM,* somatic hypermutation; *red bar, IgH* gene rearrangement; *blue bar, IGL* gene rearrangement; *red bar and blue bar with black insertions,* rearranged *IgH* and *IgL* genes with somatic mutations.

Tertiary Lymphoid Organs

Tertiary lymphoid organs are organized lymphoid tissue formed at sites of chronic inflammation to develop an adaptive immune response in front of different causes such as infectious, autoimmune, or neoplastic disorders.[37] They have follicular structures and T-cell compartments with HEV and antigen-presenting cells. Contrary to lymph nodes, these areas are not encapsulated and may resolve once the initial stimuli disappear. The initial steps in the genesis of these structures are the priming of resident fibroblastic cells by inflammatory stimuli such as IL-12, IL-17, and IL-22 with production of CXCL13, CCL19, and CCL21, which will attract lymphoid cells, and progressive formation of follicular structures with FDCs and development of HEV.

B-CELL AND T-CELL DIFFERENTIATION

In both the T-cell and B-cell systems, there are two major phases of differentiation: foreign antigen-independent and foreign-antigen dependent (Figs. **7-7** and **7-8**). Foreign antigen-independent differentiation occurs in the primary lymphoid organs—the bone marrow and thymus—without exposure to foreign antigens. This produces a pool of lymphocytes that are capable of responding to foreign antigens (naïve T and B cells) and in general do not respond to self-antigens or autoantigens. The early stages of foreign antigen-independent differentiation involve hematopoietic stem cells and lymphoblasts (blast or progenitor cells of the entire lymphoid line), which are self-renewing; the latter stages involve resting cells with a finite life span ranging from weeks to years. Naïve B and T cells carry surface molecules that are receptors for antigens (surface Ig and the T-cell receptor, respectively). On exposure to antigens, naïve lymphocytes transform into large, proliferating blast cells (immunoblasts for progenitor cells of immune effector cells or centroblasts for blast cells of the germinal center). These blasts give rise to progeny that are capable of direct activity against the inciting antigen: antigen-specific effector cells. The early stages of both antigen-independent and antigen-dependent differentiation involve proliferating cells; the fully differentiated effector cells do not divide unless they are stimulated by an antigen.

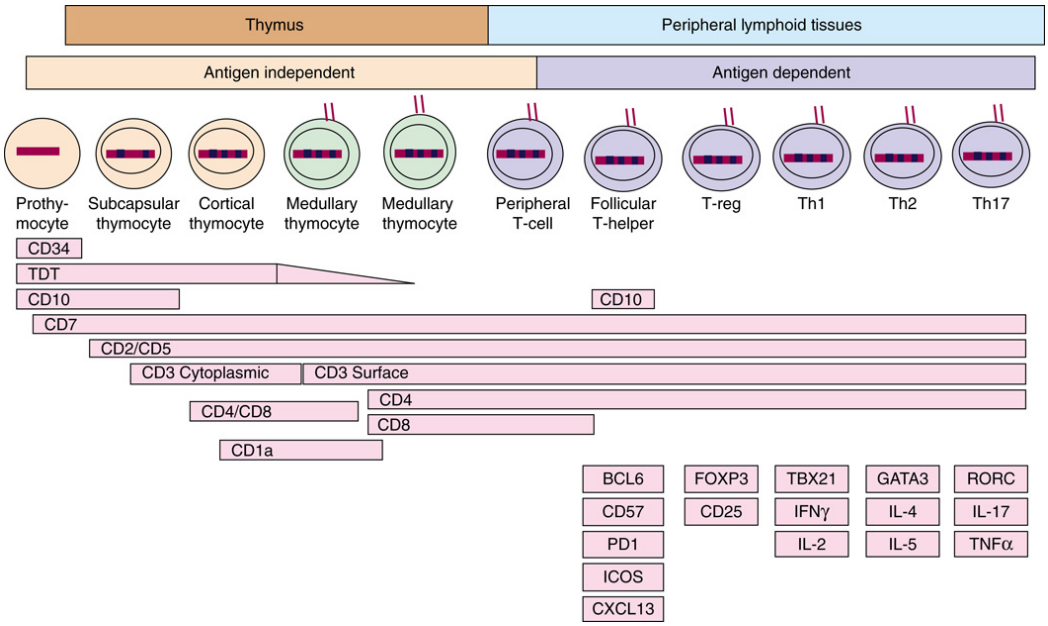

FIGURE 7-8 Schematic diagram of T-cell differentiation.Early T-cell precursors express CD34, terminal deoxynucleotidyl transferase (TDT), and CD10. CD7 is the first T-cell–specific antigen expressed, followed by CD2/CD5 and cytoplasmic CD3. Cortical thymocytes are double positive for CD4 and CD8 and express CD1a. Medullary thymocytes are already positive for either CD4 or CD8 and express surface CD3. Different subpopulations of mature T cells have been recognized. This simplified diagram illustrates follicular T-helper (Th) cells that express CD10, BCL6, CD57, PD1, and ICOS. T-regulatory cells and Th1, Th2, and Th17 CD4-positive cells are characterized by expression of the transcription factors FOXP3, TBX21, GATA3, and RORC, respectively. Germline T-cell receptor (TCR) genes are represented schematically with a

solid red bar. Additional *blue* segments represent gene rearrangements. The TRG gene is the first one rearranged, followed by TRB and TRD. The α-β T cells delete the TRD gene during the TRA rearrangement, as delta segments are included in the TRA locus. The γ-δ T cells may have TRB gene rearrangements without assembly of a complete α-β TCR. These gene rearrangements generate two main populations of T cells—α-β and γ-δ—with expression of the TCR complex in the cell membrane (represented here as *double solid bars*).

B-Cell Differentiation

Antigen-Independent B-Cell Development

Precursor B Cells

Precursor B cells develop from hematopoietic stem cells and differentiate in the bone marrow before they migrate to the peripheral lymphoid tissues as naïve mature B lymphocytes. Fetal early B-cell development occurs in the liver, bone marrow, and spleen, whereas in adults it is restricted to the bone marrow. B-cell differentiation produces a broad repertoire of B-cell antigen receptors by the recombination of the variable (V), diversity (D), and join (J) segments of the Ig genes. In this process, the gene segments V, D, and J are joined to encode the heavy-chain (H) variable region that is then joined to the constant region upon RNA splicing.

Cells in the earliest stages are called pro-B cells; they retain some self-renewal capacity and start the rearrangement of the Ig heavy chain.[1] These cells first carry out DH-JH rearrangements, followed by a VH rearrangement to the DH-JH element. The key enzymes for the V(D)J recombination process are the recombination activating genes *(RAG)* 1 and 2. Some of the common chromosomal translocations in B-cell lymphomas occur at this stage of differentiation when the cell is initiating the Ig rearrangement. As the ends of the rearranging *V*, *D*, and *J* genes are trimmed and additional nongermline encoded nucleotides may be added in the recombination process, there is about a 66% chance that a rearrangement is out-of-frame and thus nonproductive. In such an instance, a second attempt can be made on the second Ig heavy chain allele. If the rearranged V-region gene is in-frame and can be expressed as a μ heavy chain, the cells enter the next pre–B-cell stage in which they synthesize the μ heavy chain protein. At this stage, the cells also synthesize a surrogate light chain composed of two linked small peptides consisting of a variable region ($V_{pre\text{-}B}$) and a constant region (λ5) (pre–B-cell receptor). If this initial receptor is functional, it delivers signals to the cells to proliferate and reactivate the recombination machinery for the kappa light chain gene rearrangements. If no functional kappa light chain rearrangements are generated, the cells perform lambda light chain gene rearrangements. The light chain V-region genes are composed of only two segments, a V and a J segment; D elements are missing. When light-chain rearrangement is complete, a complete surface B-cell receptor (BCR) is expressed as an IgM molecule, and the cell becomes an immature B cell. This population of immature B cells has

a vast repertoire of receptors with different antigen specificities, including recognition of antigens in normal cells of the human body (self-reactive cells). The BCRs that recognize these self-antigens generate negative signals to the cells that are induced to die, to became inactivated (anergic), or to perform novel light chain gene rearrangements to replace the original light chain with a new one (light chain editing). In the latter case, further development is possible if the new BCR is no longer autoreactive. Finally, the mature cells that do not react, or that react with very low affinity, with self-antigens leave the bone marrow, now expressing both IgM and IgD.

The pro-B cell expresses CD19 and the precursor markers CD34, CD10, CD127, and HLA-DR. The transcription factors E2A and EBF are also induced at this stage and regulate the machinery for the BCR rearrangements, particularly RAG1, RAG2, and PAX5, a master transcription factor that maintains the B-cell differentiation program through all the B-cell stages up to the plasma cell differentiation stage.[38] These cells also express the terminal deoxynucleotide transferase (TdT) that mediates the addition of nongermline encoded nucleotides (N nucleotides) during the heavy and light chain rearrangements. Pre-B cells lose CD34 and CD127 expression and upregulate CD79a and CD79b, molecules associated with surface Ig and involved in signal transduction after engagement with antigen,[39,40] analogous to CD3 and the TCR molecule. Expression of MHC class II antigens persists throughout the life of the B cell and is important in interactions with T cells; in contrast, TdT is lost before the cells leave the bone marrow. The mature B-cell antigen CD20 is expressed weakly in pre-B cells and increases in immature B cells.

Naïve B Cells

The newly formed B cells that leave the bone marrow are called *transitional B cells*. These cells already co-express IgM and IgD, are CD5 positive, and show high level expression of CD10, CD24, and CD38. In mice, some of these cells are still autoreactive, express AID, and tend to migrate to the spleen where they may undergo negative selection. The differentiation processes of human transitional B cells into mature B cells are less well understood. The newly formed mature B cells that have not yet encountered foreign antigens are called *naïve B cells*. They have rearranged but unmutated Ig and express IgM/IgD, but they are negative for CD27.[41] Several subpopulations of naïve B cells have been recognized.[42,43] *Mature naïve B cells* express pan–B-cell antigens (CD19, CD20, CD22, CD40, CD79a), HLA class II molecules, complement receptors (CD21, CD35), CD23, CD44, and L-selectin and downregulate CD10 and CD38. Many of the surface antigens expressed by mature B cells are involved in "homing" or adhesion to vascular endothelium, interaction with antigen-presenting cells, and signal transduction. Surface Ig, CD79a, CD19, and CD22 are involved in the BCR signaling; CD40 is involved in interaction with T cells, providing a required costimulatory signal for B-cell activation.[44,45] Resting B cells also express the BCL2 protein, which promotes survival in the resting state.[46] A subset of human naïve B cells expresses CD5 and resembles murine *B1 cells* in several aspects. Whether the human mature CD5-positive B cells are a separate B-cell lineage, as the murine B1 cells, with particular roles in T-cell independent immune responses is unclear.

Morphologically, naïve B cells are small resting lymphocytes. In fetal tissues, they are the predominant lymphoid cell in the spleen; in

children and adults, they circulate in the blood, where they typically encompass 50% to 60% of the B cells and constitute a majority of the B cells in primary lymphoid follicles and follicle mantle zones.[47] Studies of single cells picked from the mantle zones of reactive follicles show that they are clonally diverse and contain unmutated Ig genes, consistent with naïve B cells.[48]

Chronic lymphocytic leukemia (CLL) and mantle cell lymphoma (MCL) were traditionally considered neoplasms of naïve B cells but are now interpreted as derived from CD5-positive B cells that have experienced antigens, possibly having passed through the germinal center or matured through an extrafollicular pathway (**Table 7-2**).[49-51]

Antigen-Dependent B-Cell Differentiation

T-Cell–Independent B-Cell Reaction

Some antigens can trigger a B-cell immune reaction without T-cell cooperation. Large nonprotein antigens interact with the BCRs and toll-like receptors (TLRs), a group of pattern recognition receptors, providing two activating signals to naïve cells. Large antigens with repeat structures may also activate naïve B cells by strong crosslinking of BCR molecules. These activated cells transform into proliferating blast and short-lived plasma cells, producing the IgM antibody of the primary immune response.[52] In general, such immune responses do not give rise to long-lived MBCs. Class-switching can occur in some of the activated B cells in T-cell–independent immune responses. This response is rapid, but the antibodies have a lower affinity for antigens than the antibodies generated in T-cell–dependent immune reactions, as Ig somatic

hypermutation is not induced or occurs at a low level. Cells activated by these T-cell–independent mechanisms may receive accessory signals from myeloid cells, particularly neutrophils and macrophages, mediated by BAFF and APRIL (a proliferation-inducing ligand), which stimulate the nuclear factor-κB (NF-κB) pathway in the activated B cells.[53] These signals likely have an effect similar to CD40L-CD40 interactions in the germinal center.

T-Cell–Dependent Germinal-Center Reaction

Later in the primary response (within 3 to 7 days of antigen challenge in experimental animals) and in secondary responses, the T-cell–dependent germinal-center reaction occurs. The mechanisms triggering this response may depend on the type of antigen and requires simultaneous stimulation of the BCR and cognate activation of the B cells by T_{FH} cells mediated by CD40L, IL-4, IL-21, and further coactivating factors.[54] Each germinal center is formed by a few to dozens of naïve B cells and ultimately contains approximately 10,000 to 15,000 B cells; thus, more than 10 generations are required to form a fully developed germinal center.[48] Proliferating IgM-positive B blasts formed from naïve B cells that have encountered antigens in the T-cell zone (paracortex) migrate into the center of the primary follicle and fill the FDC meshwork about 3 days after antigen stimulation, forming a germinal center.

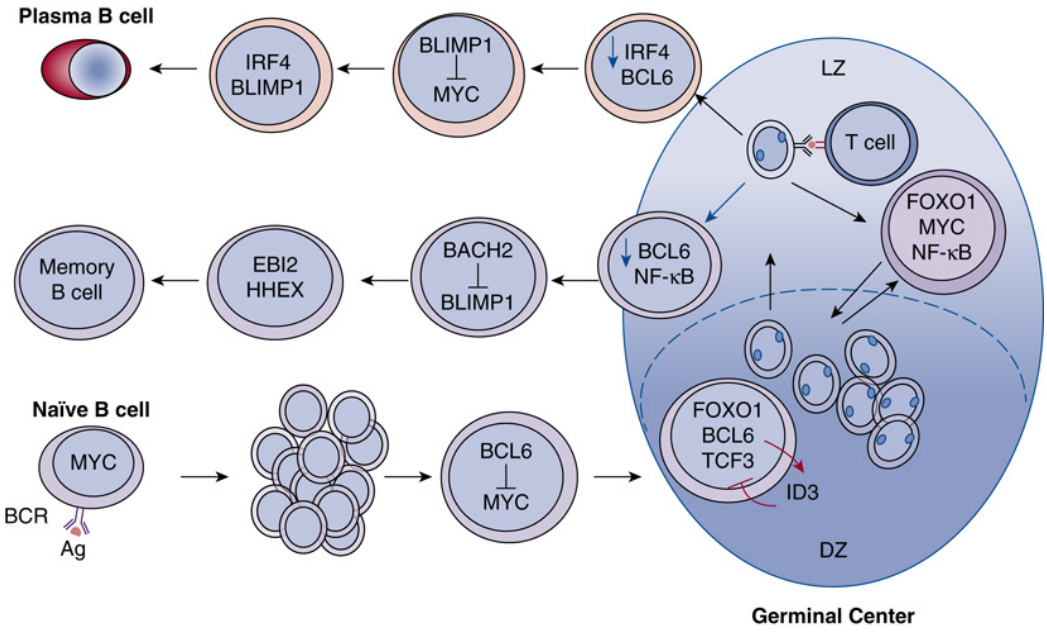

FIGURE 7-9 Interactions between different transcription factors in germinal-center formation and B-cell differentiation.MYC is initially expressed in naïve B cells that have interacted with antigens and T cells.[56] The subsequent BCL6 expression represses MYC and turns on the germinal-center formation. The proliferation program in the dark zone is maintained by activation of the TCF3 program. The inhibitory loop between ID3 and TCF3 attenuates the proliferation and allows the cells to move toward the light zone of the germinal center. Here, depending on the intensity of the T_{FH} activation, the cells will follow different pathways.[53] A weak T-cell signal resulting from low affinity of the B-cell receptor (BCR) will trigger low NF-κB activation, downregulation of BCL6, and expression of BACH2, leading to

memory B-cell differentiation. A moderate T signal will lead to expression of FOXO1 and MYC and re-entry of the centrocytes to the dark zone to follow subsequent rounds of proliferation and somatic mutations of the immunoglobulin genes. If the T signal is very strong because of high affinity of the BCR, the cell will express IRF4 and BLIMP1 and exit the germinal center to differentiate toward a memory or plasma cell.

Movement from the T cell to the follicular area is determined by the upregulation of CXCR5 in the primed B and T cells. This receptor binds to the CXCL13 ligand produced by the FDCs and adjacent stromal cells (**Table 7-1**). The germinal-center reaction is an efficient mechanism to generate expanded B-cell clones with a highly selected antigen receptor and two types of effector cells—MBCs and long-lived plasma cells. This process includes four major steps: proliferation, induction of Ig somatic hypermutation and class switch, selection, and differentiation.[55]

An important event in the early phase of germinal-center formation is the expression of MYC in the naïve B cell, induced by interaction with the antigen and T cells (**Fig. 7-9**).[56] This expression is transient but essential for the germinal-center formation. MYC regulates proliferation through activation of cyclin D2 and D3 and E2F1 that in turn induces the expression of EZH2, further promoting proliferation by suppressing the expression of CDK inhibitors and phosphorylation of RB, among others.[53] In a subsequent step, BCL6 is expressed and represses MYC by binding to its promoter. BCL6 is expressed by centroblasts, centrocytes, and germinal-center T cells,

but not by naïve B cells, MBCs, mantle zone B cells, or plasma cells.[10,11,55] BCL6 upregulation is necessary for germinal-center formation and maintenance, and its transcription program targets a series of genes directly involved in the germinal-center reaction.[55] BCL6 downregulates genes involved in negative cell cycle regulation and the genotoxic response. One of the major targets is *TP53*. Its inhibition in the germinal center leads to the downregulation of the cell cycle inhibitor *CDKN1A* (p21) and consequently facilitates proliferation. In addition, the downregulation of *TP53, ATM,* and *ATR,* genes involved in the cell response to DNA damage, facilitates the germinal-center cells' tolerance to the DNA breaks and rearrangements that occur during the somatic hypermutation and class-switch processes. Finally, BCL6 represses the differentiation of centrocytes to plasma cells and MBCs, particularly by inhibiting the plasma cell differentiation transcription factor BLIMP1, among others. Other transcription factors required for germinal-center formation are FOXO1 and MEF2B.[10,11,55] FOXO1 regulates a program overlapping in part with BCL6. It is essential for the development of the dark zone, promoting proliferation and reducing affinity maturation, and it is downregulated when the cells move to the light zone.[53] MEF2B collaborates with BCL6 in germinal-center formation.[55]

T_{FH} cells are important modulators of germinal-center B-cell responses, mainly mediated by IL-4, IL-21, and CD40L, cooperating with BCR signaling.[57] They participate in the initial steps of B-cell stimulation, class-switch recombination, and selection in light zones. Their function is negatively modulated by TNFRS14 (HVEM), which is expressed in B cells and binds to BTLA in T_{FH} cells. These

interactions prevent uncontrolled expansion of B cells in the germinal center.[58] Frequent inactivation of *TNFRS14* in follicular lymphoma B cells seem to favor lymphomagenesis by disrupting this negative control of T_{FH} cells on B cells.[59]

Proliferation

The antigen-stimulated B blasts differentiate into centroblasts, which appear at about 4 days and accumulate in the dark zone.[10,11,55] These cells are highly proliferative, with inactivation of cell-cycle inhibitors and expression of cell-cycle activators. The proliferation program of these cells seems orchestrated by the transcription factor TCF3 (E2A), which is highly expressed in the cells of the dark zone. TCF3 induces genes required for the proliferation, such as *CCND3* and *E2F2*. It also induces its own inhibitor, ID3, which creates an autoregulatory loop that attenuates the TCF3 proliferative program, allowing the cell to move toward the light zone of the germinal center. The proliferation program of germinal-center cells differs from that of proliferative cells in other tissues. Thus, centroblasts activate telomerase to prevent the shortening of telomeres in each cell cycle, downregulate antiapoptotic genes such as *BCL2* and other members of the family, and upregulate proapoptotic molecules such as CD95 (FAS). The effect of this proapoptotic default program is to facilitate the survival of only those cells that will be rescued by the generation of highly selected receptors to the specific antigen present in the germinal center.[10,11,55]

Somatic Hypermutation and Class Switch

Centroblasts undergo somatic hypermutation of the Ig heavy and light chain V-region genes, which alters the antigen affinity of the

antibody produced by the cell.[10,11,55] This process requires the activity of AID, which is induced in these cells by IL-4 and CD40L. Somatic hypermutation results in marked intraclonal diversity of antibody-combining sites in a population of cells derived from only a few precursors. Studies of single centroblasts picked from the dark zone of germinal centers suggest that, in the early stages, a germinal center may contain about 5 to 10 clones of centroblasts, which show only a moderate amount of Ig V-region gene mutation; later, the number of clones diminishes to as few as three, and the degree of somatic mutation increases.[48] This process introduces somatic mutations in other genes expressed in the germinal center, such as *BCL6,* although at a much lower frequency than is seen in the Ig genes.[60-62] In some types of germinal-center–associated B-cell lymphomas, the targeting of non-Ig genes is further deregulated, causing targeting of more genes, including several proto-oncogenes. This lymphoma-associated extensive targeting of non-Ig genes has been termed *aberrant somatic hypermutation*.

Class-switch recombination is a further AID-mediated process that allows replacement of the heavy chain isotype. This process had been considered to occur in light zone centrocytes. However, evidence from murine studies suggests that this phenomenon mainly occurs very early after the initial antigen activation of B cells, before entering the germinal center and starting somatic hypermutation.[63] This sequence of events may explain the observations, in some lymphomas, of translocations between Ig genes and different oncogenes mediated by AID and aberrant class-switched mechanisms in cells with unmutated Ig (occurring prior to the germinal-center reaction).[64]

Selection

Centroblasts mature to nonproliferating centrocytes, which accumulate in the opposite pole of the germinal center—the light zone. Centrocytes express the somatically mutated Ig genes and now need to be selected for expression of a BCR with improved affinity.[48] Centrocytes whose Ig-gene mutations have resulted in *decreased* affinity for antigens rapidly die by apoptosis; the prominent "starry sky" pattern of phagocytic macrophages seen in germinal centers at this stage is a result of the apoptosis of centrocytes. In contrast, centrocytes whose Ig-gene mutations have resulted in *increased* affinity are able to bind to native, unprocessed antigens trapped in antigen-antibody complexes by the complement and Fc receptors on the processes of FDCs. The centrocytes are able to process the antigen and present processed peptides on MHC class II molecules to T cells in the light zone of the germinal center. The activated T cells express CD40L, which can engage CD40 on the B cell, "rescuing" them from apoptosis.[10,11,55]

Selected cells in the light zone typically undergo several cycles of recirculating backward to the dark zone, allowing additional rounds of proliferation and Ig somatic mutations to create antibodies of higher affinity and further expand clonally. This re-entry to the dark zone requires downregulation of BCL6 that allows the transient re-expression of MYC in a subset of the light-zone cells (**Fig. 7-9**). An important step preparing the cell to re-enter the dark zone is the activation of the mTORC1 pathway in positively selected B cells, increasing the anabolic metabolism necessary for cell growth and subsequent proliferation.[53,65] Once the cell enters the dark zone, it

again upregulates BCL6 and TCF3 and downmodulates MYC and mTORC1.[56]

Differentiation

Termination of the germinal-center program and post–germinal-center differentiation of selected centrocytes into plasma cells or MBCs require inactivation of the master regulator BCL6. The increasing signaling activity from the selected high-affinity BCR induces the ubiquitination of BCL6 and subsequent degradation. Similarly, the CD40-CD40L activation of B cells induces NF-κB activation and expression of the transcription factor IRF4, which in turn represses BCL6.[55] Centrocytes of the light zone may be directed to exit the germinal center and become MBCs or plasma cells. IRF4 and BLIMP1 seem to cooperate as potent inductors of plasma cell differentiation, whereas PAX5, which has maintained the B-cell program from the early stages of B-cell differentiation, needs to be shut off to allow plasma cells to develop. The transcription of BLIMP1 is negatively regulated by BCL6, and this inhibition is released by the downregulation of BCL6 at the end of the germinal-center program. BLIMP1, in turn, represses PAX5, opening the pathway to plasma cell differentiation and MYC, preventing centrocytes from re-entering the dark zone of the germinal center. BLIMP1 also stimulates the transcription of XBP1, which is required to maintain and tolerate the endoplasmic reticulum stress signals that appear during the secretory phenotype of the plasma cells.[53,55,66]

Most B-cell lymphomas originate in cells derived from the germinal center and carry mutations in key genes involved in the

normal development of the cells in this structure (**Table 7-2**).[55,67-70]

Memory B Cells

MBCs have the capacity to survive long term and to rapidly differentiate into antibody-secreting cells upon antigen re-encounter, therefore conferring life-long immunity. T-cell dependent memory cells are generated in the light zone of the germinal center, preferentially in the early phases of the immune response, and typically carry lower levels of somatic mutation and show less affinity maturation relative to plasma cells.[53,54] Cells in the light zone seem to differentiate to memory cells when they receive moderate levels of T-cell activation that prevents the activation of MYC and re-entry to the dark zone. The low levels of IL-4 and IL-21 also reduce the expression of *BCL6* required to exit the germinal center. Downregulation of BCL6 allows the expression of EBI2 and HHEX, two transcription factors that promote MBC differentiation and exit of the germinal center. Expression of the BACH2 transcription factor is also crucial to direct the cell to the memory differentiation, as it downregulates cell cycle elements and prevents the BLIMP1 expression required for plasma cells differentiation (**Fig. 7-9**). MBCs leave the follicle and are detectable in the peripheral blood and different tissue compartments, including the marginal zones. Studies in mice showed that some antigen-activated B cells, after first interaction with T cells in the primary reaction in the T-cell area of lymph nodes, had already differentiated into MBCs without even entering the germinal center and undergoing somatic hypermutation there. The small subset of human MBCs with unmutated IgV genes

may mostly derive from this differentiation pathway, assuming it also exists in humans.

Human MBCs are a heterogeneous population, usually expressing CD27 with variable expression of other markers. Two major subsets have been recognized that express either IgM or IgG/IgA. Upon antigen rechallenge, IgG or IgA memory cells mostly differentiate rapidly into plasmablasts, whereas IgM memory cells preferentially proliferate and generate a new germinal-center reaction.[71] IgM memory cells represent 10% to 20% of all B cells in the peripheral blood of adults, whereas the class-switched cells account for 15% to 25% and the naïve cells for about 50% to 70%. Similar IgM memory cells are present in tissues, particularly in splenic and MALT marginal zones, tonsils, and lymph nodes.

Most of the IgM-positive CD27-positive B cells with mutated IgV genes co-express IgD. These cells are present in the peripheral blood and are the dominant B-cell subset populating the splenic marginal zone. There is still some controversy about the origin and identity of these cells. Some minimally mutated IgM-positive IgD-positive CD27-positive B cells are detectable in patients with hyper-IgM syndrome owing to a CD40-CD40L genetic deficiency in whom classical germinal-center reactions are absent. Because of their resemblance to murine marginal zone B cells, which are typically involved in T-cell–independent immune responses, it is postulated that these are MBCs generated in a similar T-independent pathway, with somatic hypermutation outside of germinal centers. However, other features of these cells argue that they are bona fide germinal-center–derived MBCs.[72-74] They frequently carry mutations in the *BCL6* gene, which should only occur in germinal-center B cells where

BCL6 is transcribed. They often form common clones together with classical class-switched MBCs. Genealogic trees of such clones show an intermingling of IgM-positive IgD-positive and class-switched B cells, strongly indicating an origin from a common mutating germinal-center B-cell clone. They also show a transcriptome more similar to IgG/IgA MBCs than to naïve B cells. Perhaps, early in life, a first subset of IgM-positive IgD-positive CD27-positive B cells with no or very few Ig mutations is generated in a germinal-center–independent pathway, but with increasing age, these cells are replaced by post–germinal-center IgM-positive IgD-positive CD27-positive MBCs.

Nodal, extranodal, and splenic lymphomas carrying IgV mutations consistent with germinal-center exposure and antigen selection resembling normal marginal zone and monocytoid B cells have been described (**Table 7-2**).[75,76] In addition, about 50% of CLLs and 10% of MCLs have mutated Ig V-region genes and appear to derive from a CD5-positive memory-like B-cell subset.[77]

Plasma Cells

Plasma cells are heterogeneous. The precursor of a mature, antibody-secreting plasma cell is a cell that retains proliferating activity, known as a plasmablast. Mature plasma cells are divided into short-lived and long-lived subsets.[66] Plasmablasts express MHC class II but lose mature B-cell markers such as CD20 and PAX5 and the CXCR5 and CCR7 receptors that maintain the lymphoid cells in the B-cell and T-cell compartments in response to CXCL13, CCL19, and CCL21. Plasmablasts acquire CXCR4, which attracts the cells to the CXCL12-secreting tissues in the bone marrow and other plasma cell

niches such as the lymph node medullary cords and splenic red pulp cords.[66]

Short-lived IgM-secreting plasma cells are generated in the T-cell–independent immune response and reside in secondary lymphoid organs, whereas long-lived IgM-positive and class-switched plasma cells are effector cells of the T-cell–dependent immune response. IgG-producing plasma cells accumulate in the lymph node medulla and splenic cords. From there, it appears the predecessors of the bone marrow plasma cell leave the nodes and spleen and migrate to the bone marrow.

Plasma cells lose surface Ig (although IgM and IgA plasma cells retain some surface BCR expression),[78] pan–B-cell antigens, HLA-DR, CD40, and CD45 and accumulate cytoplasmic IgM, IgG, or IgA. Plasma cells also express CD138 (syndecan) and higher levels of CD38 than germinal-center B cells. PAX5 is lost at the plasma cell stage, whereas BLIMP1, XBP1, and IRF4/MUM1 are expressed.

Tumors of bone marrow–homing plasma cells correspond to osseous plasmacytoma and multiple myeloma (**Table 7-2**). Some aggressive lymphomas have the morphology and cell-proliferation activity of centroblasts or immunoblasts but the immunophenotype of plasma cells and may correspond to the malignant counterpart of plasmablasts (**Table 7-2**). These lymphomas include plasmablastic lymphoma, primary effusion lymphoma, and large B-cell lymphomas associated with multicentric Castleman disease.[79]

Mucosa-Associated Lymphoid Tissue

A subset of B cells is programmed for gut-associated rather than nodal lymphoid tissue. In these tissues (Waldeyer's ring, Peyer's

patches, mesenteric nodes), similar responses to antigens occur, but both the intermediate and end-stage B cells that originate in the gut or mesenteric lymph nodes preferentially return there rather than to the peripheral lymph nodes or bone marrow. Thus, the plasma cells generated in gut-associated lymphoid tissue home preferentially to the lamina propria rather than to the bone marrow.[34,35] The mechanisms facilitating this tissue-specific traffic of effector cells include chemokines and their receptors and different adhesion molecules. Many extranodal low-grade B-cell lymphomas are thought to arise from MALT and have somatically mutated V-region genes, consistent with an antigen-selected post–germinal-center B-cell stage (**Table 7-2**).[80-82]

T-Cell Differentiation

Antigen-Independent T-Cell Differentiation

Cortical Thymocytes

The earliest antigen-independent stages of T-cell differentiation occur in the bone marrow; later stages occur in the thymic cortex. The cells entering the thymus are common lymphoid progenitors with potential to differentiate to several lymphoid lineages. They express CD34, CD45RA, CD7, CD44, and CD25.[1,83] The expression of NOTCH1 by the precursor cell and the ligand by thymic cortical epithelial cells determine the commitment to the T-cell lineage.[84] The initial T cells are negative for CD4 and CD8 (double negative). These cells express RAG1, RAG2, and TdT and rearrange the β chain of the TCR expressed in the cytoplasm but not on the surface. CD3 is also expressed in the cytoplasm. Subsequently, they acquire CD1a, CD2, and CD5 and lose CD25 and CD44 expression. At this stage, the

cells express first the CD4 and then the CD8 antigen together (double positive). The α chain of the receptor is rearranged and expressed with the β chain and CD3 on the surface. Cortical thymocytes express CD45RO instead of CD45RA. At this stage, T cells undergo a positive selection if they recognize the HLA molecules. T cells recognizing MHC class I become CD8-positive T cells (single positive), whereas T cells recognizing MHC class II differentiate into CD4-positive T cells (single positive). Subsequently, a negative selection occurs if they recognize self-antigens. The final selected cells express increased levels of surface CD3, acquire CD27, switch their CD45 isotype from RO back to RA, lose CD1a, express BCL2, and become mature naïve T cells.[1,83]

Naïve T Cells

Mature, naïve T cells are small lymphocytes with low proliferation fraction that lack TdT and CD1 and express either CD4 or CD8 in addition to surface CD3, CD5, CD7, CD2, and CD45RA and the costimulatory receptors CD27 and CD28 (**Fig. 7-10**).[1,83] These cells leave the thymus and can be found in the circulation, in the paracortex of lymph nodes, and in the thymic medulla. These are migratory cells with a surveillance function. They arrive at the secondary lymphoid tissues via the bloodstream and exit the circulation through HEVs in the nodes and MALT and through the sinusoids in the spleen. Naïve T cells express CCR7 and CD62L (L-selectin), which are instrumental at these sites by recognizing the CCL21 and vascular addressins, respectively, expressed by the HEVs. Some cases of T-cell prolymphocytic leukemia may correspond to naïve T cells (**Table 7-3**).

Antigen-Dependent T-Cell Activation

A complex interaction of T-cell surface molecules with molecules on the surface of antigen-presenting cells is required for T-cell activation in response to antigens. The complex of CD3, the coreceptor molecules CD8 or CD4, and the T-cell receptor (which may be either γ-δ or α-β and has a combining site that "fits" the specific peptide antigen) binds to the antigen-MHC complex on the antigen-presenting cell. CD4 and CD8 T cells bind to MHC class II or I molecules, respectively. The adhesion molecule LFA-1 on the T cell binds to ICAM-1 on the antigen-presenting cell; the activation-associated molecule CD40L on CD4-positive T cells binds to CD40; CD28 and CTLA-4 on the T cell bind to B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell.[1] The interaction of CD40-CD40L provides an activation stimulus for both the T cell and the antigen-presenting cell, and binding of CD28 to CD80/CD86 provides a crucial second stimulus for the T cell.[85] CTLA-4 also binds to CD80/CD86 but provides an inhibitory signal to the T lymphocyte that limits its activation. CD4-positive T cells primarily interact only with professional antigen presenting cells that express MHC class II (dendritic cells, macrophages, B cells). CD8-positive T cells can principally interact with all nucleated cells, as all cells express MHC class I, an important means to scan the cells in the body, for example, for a viral infection.

T Immunoblasts

On encountering antigens, mature T cells transform into immunoblasts, which are large cells with prominent nucleoli and basophilic cytoplasm that may be morphologically indistinguishable

from B immunoblasts. T immunoblasts, in contrast to T lymphoblasts (thymocytes), are TdT negative and CD1 negative, strongly express pan–T-cell antigens, and continue to express either CD4 or CD8. Activated or proliferating T cells express HLA-DR in addition to CD25 (IL-2 receptor) and both CD71 and CD38. Antigen-dependent T-cell reactions occur in the paracortex of lymph nodes, the periarteriolar lymphoid sheath of the spleen, and at extranodal sites of immunologic reactions.

Effector T Cells

Activated CD4 and CD8 T cells become effector cells with different functions and phenotypes, and a small proportion of them will become memory cells. After clearance of the pathogens, most T cells undergo apoptosis. However, a small subset of memory T cells persists for a long time, often for the life of the host.

Antigen-stimulated T cells switch CD45RA to CD45RO. CD4 effector T cells typically act as helper cells, and CD8 effector T cells are cytotoxic and kill other cells. Activated CD8-positive cells produce interferon-γ and have cytoplasmic cytotoxic granules containing several types of granzymes, perforin, and TIA-1.

Different subsets of specialized CD4-positive effector cells are now recognized.[86] The major subsets are T-helper 1 (Th1), Th2, and Th17 cells and are induced by distinct interleukins and involved in the production of different cytokines. These states display a high degree of plasticity, changing form one to another under specific stimuli. Th1 cells are generated by IL-12 and secrete interferon-γ. They are important activators of macrophages, NK cells, and CD8-positive T cells. Th2 cells are generated by IL-4 and secrete IL-4, IL-5, IL-6, IL-

13, and IL-25. These cells are involved in allergic reactions and mobilize B cells, eosinophils, basophils, mast cells, and alternatively, activated macrophages. Th17 cells produce IL-17 and tumor necrosis factor-α (TNF-α) and regulate acute inflammation. The differentiation of these Th1, Th2, and Th17 cells is mediated by the transcription factors TBX21(T-bet), GATA3, and RORC, respectively. Other subsets have been recognized with the expression of specific cytokines such as Th22 producing IL-22 and Th9 producing IL-9.

CD4 cells involved in the germinal-center B-cell response are a specific subset of T_{FH} cells. BCL6 is the crucial transcription factor required for T_{FH} differentiation. These cells express CXCR5 and are recruited into B-cell follicles by CXCL13 produced in the germinal centers by FDCs. T_{FH} cells also express the costimulatory molecule ICOS, CXCL13, and the receptor PD1, and a subset is CD57 positive. They produce IL-21 and IL-4 and express CD40L, which stimulates B cells.

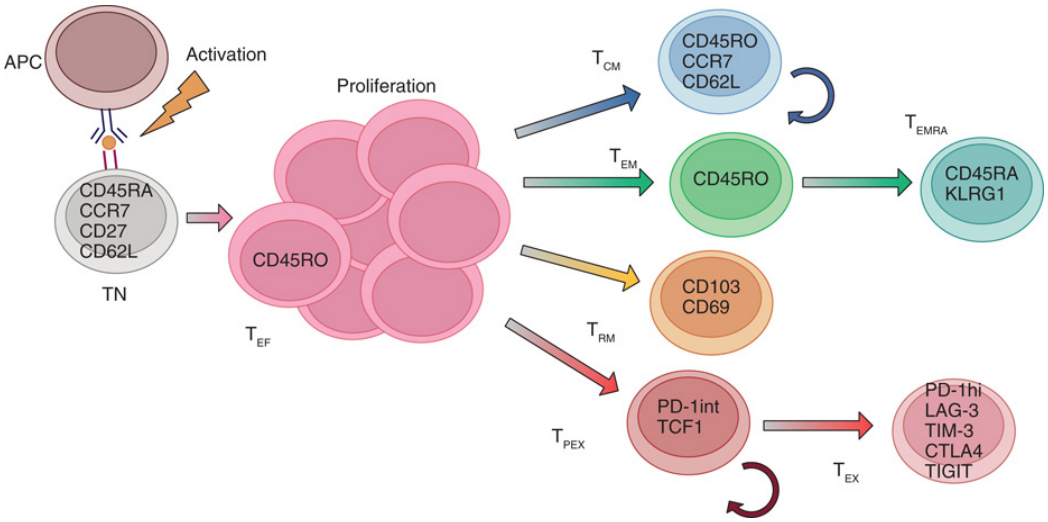

FIGURE 7-10 Upon antigen recognition in antigen presenting cells (APCs), naïve T cells (TN) become activated, proliferate, and differentiate into effector T cells (T_{EF}) to kill target cells.[83] Once the pathogenic agent is cleared, effector T cells undergo apoptosis, and only a small population of cells persists as memory T cells. Central memory T cells (T_{CM}) maintain self-renewal capacities and reside in the secondary lymphoid organs. Effector memory T cells (T_{EM}) provide rapid protection against secondary exposure to the same pathogen and differentiate into terminally differentiated effector memory cells re-expressing CD45RA (T_{EMRA}). Tissue-resident memory T cells (T_{RM}) reside in nonlymphoid tissues. The signals that regulate fate decision, i.e., the acquisition of a given memory phenotype, are largely unknown. Chronic antigen exposure drives an alternative

differentiation program in which precursor exhausted T cells (T_{PEX}) produce an expanded pool of terminally exhausted (T_{EX}) progeny that is unable to clear the established infection or tumor.

CD4-positive Treg cells are an important element in limiting the expansion of immune responses. Treg cells express CD25 and the inhibitory receptor CTLA4, secrete IL-10, and are generated by the activity of the transcription factor FOXP3.

Most cases of peripheral T-cell lymphoma (PTCL) correspond to stages of antigen-dependent T-cell differentiation (**Table 7-3**).[87] Nodal T_{FH} cell lymphoma is the malignant counterpart of T_{FH} cells.[87] However, the relationship between neoplastic and normal T cells is not nearly as well understood as that in the B-cell system.

Memory T Cells, Exhaustion, and Senescence

A subpopulation of T cells differentiates to memory T cells after antigen recognition and activation (see **Fig. 7-10**). These cells are long-lived and can quickly expand after re-exposure to their antigens, again becoming effector T cells. Memory T cells may be either CD4 positive or CD8 positive and maintain CD45RO expression, and most of them lack CD45RA. Depending on the cell surface expression of certain receptors and ligands, these cells may migrate to different tissues. Expression of CD62L (L-selectin) and CCR7 facilitates homing to lymph nodes, whereas selectin P ligand (CLA) guides lymphocytes to the skin and α4β7 integrin and CCR9 lead to the small intestine.[88] Several subpopulations of T memory cells have been recognized with similar phenotypes within the different subsets of CD4-positive and CD8-positive

cells.[86,89] *Central memory T cells* (T_{CM}) express CD62L (L-selectin) and CCR7 and have high proliferative potential, resistance to apoptosis, and self-renewal properties (see **Fig. 7-10**). These cells maintain and supply new generations of memory T cells, although they have a limited immediate effector function. Upon antigen stimulation, they may differentiate to T effector cells (see **Fig. 7-10**). *Effector memory T cells* (T_{EM}) lack expression of CCR7 and CD62L and are found mainly in the peripheral circulation and nonlymphoid tissues. Upon antigen stimulation, they have a rapid effector response with production of cytokines and cytotoxic granules. *Terminally differentiated effector memory cells re-expressing CD45RA* (T_{EMRA}) are a subpopulation of T_{EM} cells that have a potent effector function but decreased proliferative capacity with a tendency toward apoptosis or senescence. Contrary to naïve T cells, this subpopulation lacks CCR7 and CD62L and the costimulatory molecules CD27 and CD28. They tend to be excluded from lymphoid organs but are present in peripheral blood and nonlymphoid tissues. *Tissue-resident memory T cells* (T_{RM}) can be either CD4-positive or CD8-positive lymphocytes, are present in nonlymphoid tissues, and can promptly respond when re-exposed to their antigens, providing protective immunity independently of T cells newly recruited from peripheral blood. This subpopulation seems to have a relevant role in antitumor functions.

After chronic antigen stimulation, memory T cells may become dysfunctional, acquiring an exhausted or senescence state in which the cells lose their proliferative and functional properties.[86] *Exhausted T cells* (T_{EX}) may be recognized by the expression of a constellation of inhibitory receptors that include high

PD-1, TIM-3, CTLA-4, LAG-3, or TIGIT. Exhausted cells express more than one of these markers. Precursor T_{EX} cells still maintain proliferative capacity and may reverse the exhausted state when treated with immunotherapy strategies with monoclonal antibodies targeting some of these receptors (e.g., anti-PD-1, anti-PD-L1, or anti-CTLA-4).[90] Senescent cells are more resistant to apoptosis, and it is a nonreversible state. These cells express KLRG1 and CD57, lose costimulatory receptors such as CD27 and CD28, and lack the migratory signals CD62L and CCR7.

Differentiation of Cells of the Innate Immune Response

The innate immune system is conserved through evolution and constitutes a first line of defense that is based on relatively non-specific germline-encoded receptors.[1] The cells involved in the innate immune response are localized mainly in barriers such as the mucosa and skin and do not require antigen-presenting cells or the association of antigens with MHC. The main lymphoid cells involved in innate immune responses are γ-δ T cells and NK cells. Phagocytes, mast cells, eosinophils, and basophils are also involved in innate responses.

γ-δ T Cells

Mature γ-δ T cells express these two chains of the TCR. The γ-δ TCR binds directly to the antigens and does not require specialized antigen processing and presentation by the HLA system, as α-β T cells do. The γ-δ T cells are mainly present in mucosa, skin, and splenic red pulp but are rare in lymphoid organs. These cells are generated in the thymus, most of them already with effector capacity

and little plasticity in the periphery. They are positive for CD3, CD2, and CD7 but negative for CD4 and CD8, and they express cytotoxic granules in the cytoplasm. These cells participate in rapid innate immune responses and also in tissue repair by expressing epithelial growth factors.[91,92] Hepatosplenic γ-δ T-cell lymphoma and primary cutaneous γ-δ T-cell lymphoma are considered neoplasms derived from these cells (**Table 7-3**).[87]

Natural Killer Cells

NK cells appear to derive from a progenitor common with T cells. They can kill certain targets such as virus-infected self–class I MHC molecules on the surfaces of cells through killer cell Ig-like receptors (KIRs), and they kill cells that lack these antigens.[93] A main function of NK cells is to detect and eliminate virus-infected cells that have been instructed by viral factors to downregulate MHC class I as a viral strategy to evade recognition by cytotoxic CD8-positive T cells. Activated NK cells express the epsilon and zeta chains of CD3 in the cytoplasm, but these cells do not rearrange their TCR genes or express TCRs or surface CD3. They are characterized by certain NK-cell–associated antigens (CD16, CD56, CD57), which can also be expressed on some T cells; they also express some T-cell–associated antigens (CD2, CD5, CD28, CD8). Similar to γ-δ T cells, NK cells have cytotoxic granules that specifically contain granzyme-M. NK cells appear in the peripheral blood as a small proportion of circulating lymphocytes; they are usually slightly larger than most normal T and B cells, with abundant pale cytoplasm containing azurophilic granules—so-called “large granular lymphocytes”. Nasal NK/T-cell lymphoma, aggressive NK-cell leukemia, and possibly NK-

cell large granular lymphocytic leukemia are thought to be neoplasms of NK cells[87] (**Table 7-3**).

We thank Drs. Elaine S. Jaffe and Nancy L. Harris, previous authors of this chapter, for the information provided.

Pearls and Pitfalls

- The immune system has two differentiated arms: the innate and the adaptive systems. The innate system is a first line of defense mediated by cells that express germline-coded receptors, recognize a wide but relatively non-specific number of antigens, and do not generate immunologic memory. The adaptive system reacts specifically against antigens presented to lymphocytes, in most instances associated with MHC. The immune cells of the adaptive immune system express specific receptors encoded by somatically rearranged genes that may recognize a virtually universal spectrum of antigens and generate cells with immunologic memory.
- Lymphoid tissues are highly organized microenvironments in which different cell populations, vascular structures, and stromal components facilitate the selective interactions between lymphocytes and antigens for the initiation and expansion of immune responses.
- The follicular lymphoid germinal center is a complex structure in which cells of the adaptive immune system expand clonally

and the IgV genes are somatically mutated to select high-affinity antigen receptors. The Ig heavy chain gene also undergoes idiotype switch, and the cell commits to an MBC or plasma cell.

- The high proliferation and DNA breaks that occur in germinal-center B cells are mechanisms that facilitate the development of lymphoid neoplasms. Most B-cell lymphomas carry somatically mutated IgV genes, indicating they derive from cells with germinal-center experience.
- Most lymphoid neoplasms are related to a normal cell counterpart of the immune system. Some lymphomas, however, do not correspond to a known normal stage of differentiation, and others display aberrant phenotypes, lineage heterogeneity, or changes in cell lineage that may represent the malignant counterpart or the physiologic plasticity of the immune cells.

Chapter 8: Reactive Lymphadenopathies

Rebecca L. King, and Eric D. Hsi

OUTLINE

FOLLICULAR AND NODULAR PATTERNS

- **Follicular Hyperplasia**
- **Autoimmune Disorders (Rheumatoid Arthritis)**
- **Luetic (Syphilitic) Lymphadenitis**
- **Castleman Disease, Hyaline Vascular Type (Angiofollicular Lymphoid Hyperplasia)**
- **Progressive Transformation of Germinal Centers**
- **Mantle Zone Hyperplasia**
- **Mycobacterial Spindle Cell Pseudotumor**

PREDOMINANTLY SINUS PATTERN

- Sinus Histiocytosis
- Histiocytic Expansion Caused by a Specific Cause (Storage Disease, Lymphangiogram, Prosthesis, Whipple Disease)
- Vascular Transformation of Sinuses
- Hemophagocytic Lymphohistiocytosis

INTERFOLLICULAR OR MIXED PATTERNS

- Paracortical Hyperplasia and Dermatopathic Reaction
- Granulomatous Lymphadenitis
- Immunoglobulin G4–Related Disease
- Kimura Disease

Drug-Associated Lymphadenopathy

The major question that confronts the surgical pathologist when examining a lymph node biopsy is whether the process is benign or malignant.[1] The pathologist must be familiar with the histologic changes of a diverse group of non-neoplastic disorders in order to differentiate them from lymphoma and to render a specific diagnosis or a differential diagnosis on morphologic grounds. A specific diagnosis often requires correlation with the clinical history and the results of additional studies such as immunohistochemistry, stains for microorganisms, cultures, serologic studies, and molecular analysis for microbial genetic material.

We group the reactive lymphadenopathies into four major categories according to their predominant architectural histologic pattern: follicular/nodular, sinus, interfollicular or mixed, and diffuse. Although this approach is convenient, multiple nodal compartments may be involved in a single process, and variation exists from case to case. Furthermore, reactive conditions of the lymph node are dynamic processes, and the predominant pattern may differ, depending on the time during the course of the disease at which the biopsy is performed.

Box 8-1 lists the major reactive conditions that cause lymph node enlargement and that may result in lymph node biopsy. Several benign disorders and borderline lesions such as immune deficiency-

related lymphadenopathy, sinus histiocytosis (SH) with massive lymphadenopathy, and the plasma cell and plasmablastic variants of Castleman disease are covered in other chapters.

FOLLICULAR AND NODULAR PATTERNS

Follicular Hyperplasia

Follicular hyperplasia (FH) is defined as an increase in the number and usually in the size and shape of secondary lymphoid follicles (**Fig. 8-1**). It is among the most common reactive patterns encountered by the surgical pathologist. The antigens responsible are usually not known. Hyperplastic follicles contain germinal centers (GCs) with a mixture of centroblasts (noncleaved cells) and centrocytes (cleaved cells), which vary in proportion depending on the duration of immune response. Tingible body macrophages containing apoptotic cellular debris are common and impart a starry-sky pattern to the GC (**Fig. 8-1A and B**). The prominence of the starry-sky pattern correlates with the proliferative index in the GC. Typically, some follicles show polarization of the GC with the proliferative dark zone, composed mostly of centroblasts, located toward the medullary side of the GC and an apical light zone, containing a predominance of centrocytes, located on the capsular side of the follicle (**Figs. 8-1C** and **8-2A**). Proliferation and somatic hypermutation of GC B cells occurs in the dark zone while affinity maturation occurs in the light zone.[2] Early in a hyperplastic reaction, GCs may consist almost exclusively of centroblasts (**Fig. 8-3**). The high proliferative index is highlighted by staining with MIB-1 (Ki-67) (**Fig. 8-1D** and **Fig. 8-3B**). Centrocytes, plasma cells, varying

numbers of follicular helper T cells (TFH) (CD4-positive, CD57-positive, PD1-positive, ICOS-positive), and follicular dendritic cells (FDC) are present in the light zone.[3] FDC have intermediate-sized, pale nuclei, which contain a small central nucleolus; many are binucleated, with apposing nuclear membranes appearing flattened (**Fig. 8-2B**). A variably prominent mantle zone composed of small lymphocytes surrounds the GC. In a polarized GC, the mantle zone is expanded around the light zone (**Fig. 8-1C**). Other features of FH include large, irregular GCs with oddly shaped geographic outlines (**Fig. 8-1B**) and, occasionally, follicular lysis (**Fig. 8-4**). The latter is characterized by disrupted GCs because of infiltration by mantle zone lymphocytes. The interfollicular area may show variable expansion with scattered transformed cells, small lymphocytes, plasma cells, and high endothelial venules.

Box 8-1 The Reactive Lymphadenopathies

I. Follicular and Nodular Patterns

- Follicular hyperplasia
- Autoimmune disorders (rheumatoid arthritis)
  - Luetic lymphadenitis
  - Castleman disease, hyaline vascular type
  - Progressive transformation of germinal centers
  - Mantle zone hyperplasia

- Cytomegalovirus infection
- Herpes simplex lymphadenitis

Dilantin lymphadenopathy

GCs are composed predominantly of CD20+ B cells, with varying numbers of CD4+/CD57+/PD1+/ICOS+ TFH. These PD1-positive T cells tend to be present at the periphery of the GC.[4] BCL2 is not expressed by reactive GC B cells, whereas BCL6 and CD10 are expressed in both benign and neoplastic GC B cells. Other GC B-cell markers such as GCET1, HGAL, and LMO2 are also expressed in reactive and neoplastic GC B cells.[5,6]

Differential Diagnosis

The main differential diagnosis in FH is follicular lymphoma. Features that favor a benign process include polarization, tingible body macrophages with a starry-sky pattern, the presence of plasma cells within follicles, and a well-defined mantle zone. Immunostains show a lack of BCL2 protein in B cells.[7,8] Because T cells express BCL2, this stain should always be interpreted in conjunction with B-cell and T-cell markers so that relative percentages of each type of cell can be determined, allowing appropriate interpretation of the BCL2 stain. Although the t(14;18)(q32;q21) translocation, characteristic of follicular lymphoma, may be detected in hyperplastic lymph nodes by polymerase chain reaction (PCR),[9] this finding does not appear to be a significant problem with assays that have sensitivity of one in 10^4 or less.[10] An uncommon incidental finding in the setting of FH is strong CD10-positive/BCL2-positive co-expression of follicular B cells that represents in situ follicular neoplasia. This finding is characterized by lack of architectural distortion with involvement (often partial) in only a minority of follicles.[11] This occurs in approximately 2% of reactive lymph nodes

and is likely associated with a low risk for development of overt follicular lymphoma.[12]

Pediatric-type follicular lymphoma (PTFL), a variant of follicular lymphoma, may also rarely enter the differential diagnosis. PTFL occurs predominantly in young males with localized disease and histologically demonstrates effacement of the lymph node by large ill-defined follicles with a starry-sky pattern. They are composed of sheets of large centroblasts. Although monoclonal, BCL2 protein is not expressed and *BCL2* translocation is absent. Prognosis is excellent even with conservative management.[13,14]

Lack of surface immunoglobulin light chain on a B-cell population by flow cytometry is considered an abnormal finding and seen in more than 5% of cases of small lymphocytic leukemia/chronic lymphocytic leukemia, follicular lymphoma, and diffuse large B-cell lymphoma. However, it can rarely be seen in reactive lymph nodes, particularly in the setting of HIV.[15,16] By immunostaining, kappa- or lambda-restricted plasmacytic cells can be seen in scattered reactive GCs and likely reflects local clonal dominance as a result of affinity maturation and selection, rather than emerging lymphoma. The cells represent plasma cells and centrocytes/centroblasts with plasmacytic differentiation. There is always a mixture of polytypic and monotypic GCs with the latter in the minority or isolated.[17] Clinical correlation is important; when in doubt, observation and repeat biopsy of persistently enlarge lymph nodes may be a reasonable approach (particularly in the context of a needle biopsy).

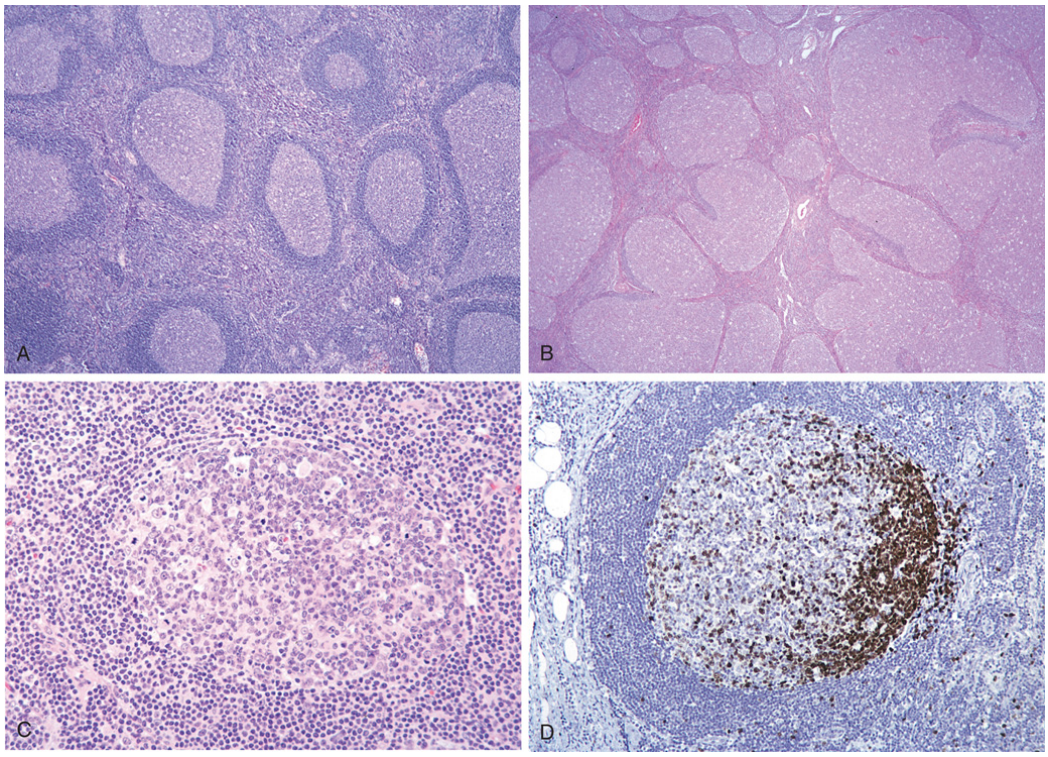

FIGURE 8-1 Follicular hyperplasia.**A,** Increased numbers of follicles with large irregular germinal centers (GCs), preserved mantle zones, and ample interfollicular areas (hematoxylin and eosin [H&E], ×35). **B,** GCs may be large and form irregular large, bizarre structures (H&E, ×90). **C,** Polarization of GC with a dark zone composed of centroblasts and tingible body macrophages and a light zone with a predominance of centrocytes (H&E, ×330). **D,** MIB-1 stain showing that almost all cells in the dark zone are positive. The mantle zone is expanded adjacent to the light zone (MIB-1, ×70).

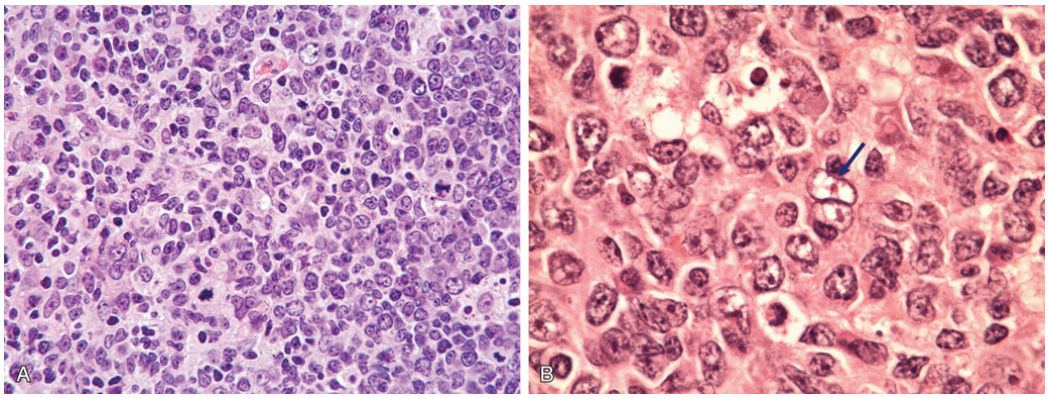

FIGURE 8-2 **A,** Higher magnification of a GC. The light zone *(left)* shows a predominance of centrocytes, while the dark zone *(right)* contains mostly centroblasts interspersed by tingible body macrophages (H&E, ×500). **B,** A follicular dendritic cell is shown *(arrow)*. These cells have clear chromatin with a small central nucleolus and often appear bilobed with flattening of opposing nuclear membranes (H&E, ×500).

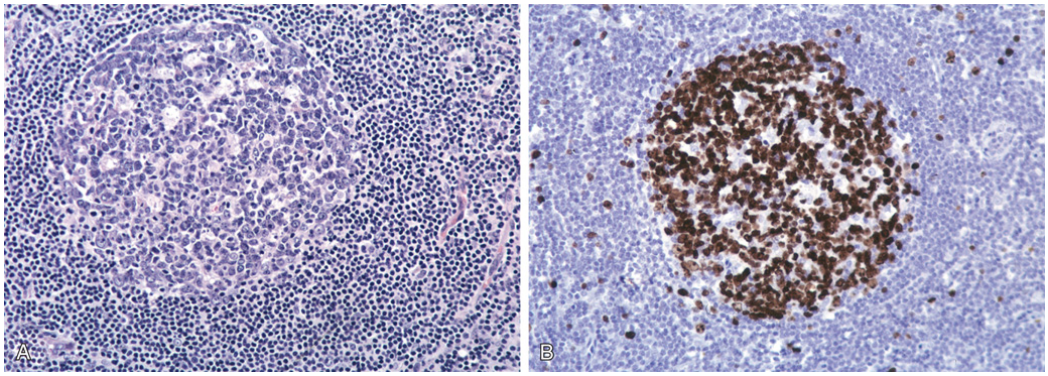

FIGURE 8-3 **A,** GC consisting almost exclusively of centroblasts. Tingible body macrophages are scattered throughout (H&E, ×330). **B,** MIB-1 staining of the GC in **A** showing positivity in all centroblasts, indicating that these cells are proliferating (MIB-1, ×400).

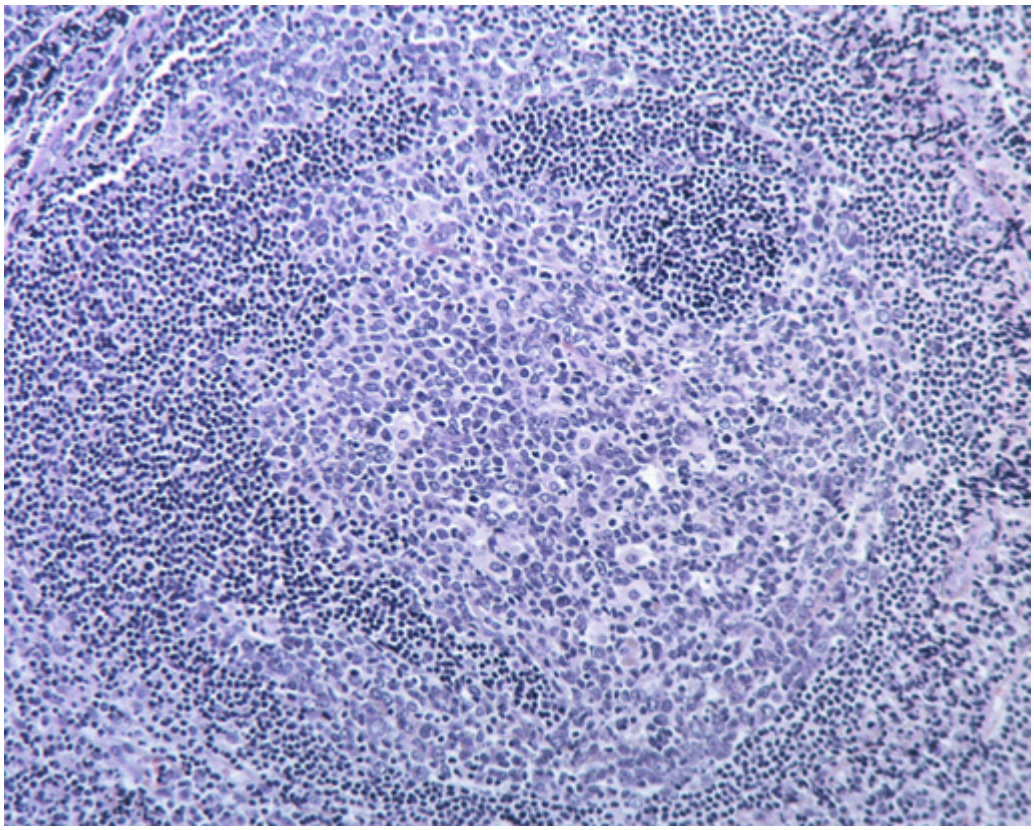

FIGURE 8-4 Follicular lysis of a germinal center.Mantle cell lymphocytes infiltrating into and disrupting the GC (H&E, ×100).

Monocytoid B-Cell Proliferation

FH may be associated with proliferation of monocytoid B cells in and around cortical sinuses, around venules, or in a parafollicular location.[18-20] Although this proliferation may be associated with non-specific FH (**Fig. 8-5**), it is characteristic of toxoplasmic lymphadenitis, HIV-associated lymphadenopathy, cytomegalovirus (CMV) lymphadenitis, and disorders associated with suppurative granulomas, especially cat scratch disease (CSD).[21] Monocytoid B cells are medium-sized cells with abundant pale to clear cytoplasm and round to slightly indented nuclei with moderately dispersed

chromatin. Neutrophils and immunoblasts are usually scattered among the monocytoid cells (**Fig. 8-5**). The differential diagnosis when the monocytoid B-cell proliferation is prominent includes marginal zone lymphoma. Although this differentiation may be difficult in some cases, evidence of clonality supports a diagnosis of lymphoma and can be established by demonstrating light chain restriction in paraffin sections or by immunoglobulin gene rearrangement molecular studies. Morphologic features favoring lymphoma include partial effacement of the architecture by the monocytoid B-cell proliferation and increased numbers of large cells with an increased mitotic index. BCL2 expression has been suggested to be useful in distinguishing marginal zone lymphoma (positive) from marginal zone hyperplasia (negative), but hyperplastic processes in the spleen, abdominal lymph nodes, and ileum have been shown to express BCL2. Thus it is considered a soft criterion.[22,23] Molecular genetic analysis for immunoglobulin gene rearrangement by PCR may be helpful if other features are not diagnostic. Follicular lymphoma with marginal zone differentiation may also be considered. In this situation, there are increased numbers of follicles composed of monotonous centrocytes surrounded by a rim of monocytoid B cells several layers thick. Demonstration of BCL2-expressing GC B cells, monoclonality, or presence of a *BCL2*::*IGH* translocation support this diagnosis.

Autoimmune Disorders (Rheumatoid Arthritis)

Patients with autoimmune disorders such as rheumatoid arthritis (RA), juvenile RA, and Sjögren syndrome often develop lymphadenopathy, which is characterized by FH.[24-27] Although

biopsies are not ordinarily performed in these patients, they may be done if there is a clinical suspicion of lymphoma. The features of RA-associated lymphadenopathy are well characterized. We will focus primarily on RA.

The lymph node histologic changes seen in RA are FH, interfollicular and intrafollicular plasmacytosis, and neutrophils within sinuses (**Fig. 8-6**).[24,27] The lymph node capsule may be thickened but is not infiltrated by plasma cells. Expansion of the lymphoid reaction into perinodal tissue may occur and does not necessarily connote malignancy. Compared with non-specific FH, the reactive GCs of RA were found to be smaller and more regularly spaced, with a predominance of centrocytes exhibiting less mitotic activity.[27] Sarcoidal granulomas and focal deposition of PAS-positive hyaline material in the interfollicular areas, which may become calcified, can be seen.[28] Immunohistochemical studies have shown CD4-positive T cells to predominate in the interfollicular areas with CD8-positive T cells within GCs.[24,27] Increased numbers of polytypic CD5-positive B cells, which can be expanded in autoimmune disorders, may also be seen.[24] These features may also be seen in other disorders such as Sjögren syndrome; however, monocytoid B-cell hyperplasia is more frequent in the latter.

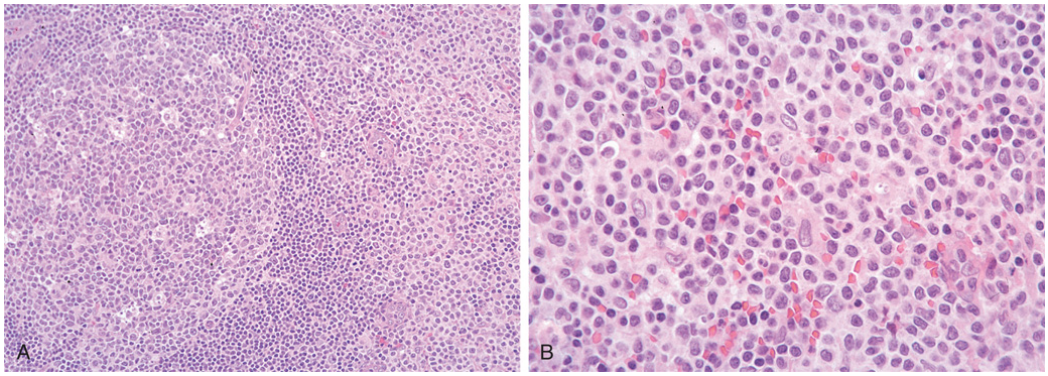

FIGURE 8-5 **A,** Reactive follicle with adjacent monocytoid B-cell proliferation (H&E, ×100). **B,** The monocytoid cells are medium sized with slightly indented nuclei and ample cytoplasm. Neutrophils are scattered among the monocytoid cells (H&E, ×400).

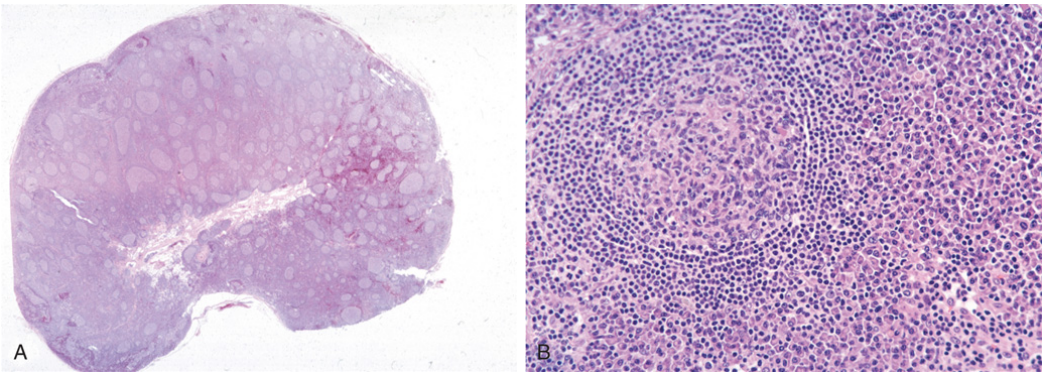

FIGURE 8-6 Follicular hyperplasia in a lymph node from a patient with rheumatoid arthritis.**A,** Follicles with enlarged GCs varying in size and shape are present throughout cortex and medulla (H&E, ×5). **B,** Follicle surrounded by sheets of plasma cells (H&E, ×250). From Schnitzer, B, Pathology of lymphoid tissue in rheumatoid arthritis and allied diseases. In Glynn LE, and Schlumberger HD, eds: Bayer Symposium VI, Experimental Models of Chronic Inflammatory Diseases. New York, Springer-Verlag, 1977, pp. 331-348; and from Schnitzer, B: Reactive lymphoid hyperplasia. In Jaffe ES, ed: Surgical Pathology of the Lymph Nodes and Related Organs. Philadelphia, W.B. Saunders Company, 1985, pp. 22-56.

In some RA patients, an atypical proliferation that is unlike the typical FH with plasmacytosis can occur. It has been divided into three types. The first resembles multicentric Castleman disease with hyaline vascular lymphoid follicles, interfollicular polytypic plasmacytosis, and vascular proliferation. The second is a

paracortical hyperplasia and has well-formed lymphoid follicles with GCs. The paracortex is expanded by polyclonal CD4-positive T cells with varying degrees of atypia, plasma cells, immunoblasts, and histocytes. Epstein-Barr virus (EBV) is absent in the few cases reported. The third type is an atypical lymphoplasmacytic, immunoblastic proliferation, and occasional Hodgkin-like cells.[29] This latter type may be akin to the atypical, usually EBV-driven, proliferations seen in the setting of methotrexate or other immune modulatory drugs.

Still disease is an acute febrile form of juvenile RA characterized by high-spiking fever, skin rash, arthralgia, arthritis, polyserositis, hepatosplenomegaly, lymphadenopathy, leukocytosis, elevated erythrocyte sedimentation rate (ESR), polyclonal hypergammaglobulinemia, and absence of autoantibodies. Adult-onset Still disease (AOSD) occurs and represents 5% of fevers of unknown origin. Lymph node findings overlap with that describe for RA. Small series describe four features, the most common of which is paracortical hyperplasia with vascular proliferation, admixed B and T immunoblasts, and infiltration by reactive lymphocytes and inflammatory cells. Paracortical hyperplasia, lack of follicles, SH, and S100-positive histocyte aggregates are uncommonly seen. A third pattern consisting of an exuberant but patchy paracortical T-immunoblastic reaction (polyclonal) should be differentiated from lymphoma (monoclonal). CD30 may be expressed in a subset of immunoblasts. The fourth pattern consists of FH. Few scattered EBV-positive small lymphocytes may be seen, and are not associated with a specific pattern. Cases with dermatopathic features or resembling histiocytic necrotizing lymphadenitis have been reported,

and increased expression of chemokines CXCL10 and CXCR3 by immunohistochemistry has been suggested to be helpful in distinguishing AOSD from mimics such as PTCL and histiocytic necrotizing lymphadenitis.[30]

The differential diagnosis of FH associated with RA also includes FH due to other causes. Appropriate clinical history and laboratory findings should help confirm the diagnosis of RA-associated lymphadenopathy.

Syphilis may show histologic features similar to those in RA. However, in contrast to RA, the capsule is often thickened and infiltrated by plasma cells and lymphocytes, especially around small vessels. In addition, epithelioid granulomas may be present in interfollicular areas. Also, endarteritis and venulitis are typically found. Special stains for spirochetes may be diagnostic. HIV infection, particularly early in its course, may show histologic changes similar to those in RA. Follicular lymphoma might also be considered in the differential diagnosis. Demonstration of BCL2 protein positive GC B cells or the presence of the t(14;18)(q32;q21) translocation would confirm the diagnosis of follicular lymphoma, although its absence does not negate such a diagnosis.[31]

In FH associated with Sjögren syndrome, marginal zone lymphoma should be excluded. Features suggesting lymphoma include large confluent areas of monocytoid B cells. Demonstration of monoclonality may be necessary to confirm the diagnosis in cases of FH with extensive monocytoid B-cell proliferation.[32]

Luetic (Syphilitic) Lymphadenitis

Although lymph node biopsy does not play a significant role in the diagnosis of syphilis, the localized or generalized lymphadenopathy of primary and secondary syphilis may be clinically suspicious for lymphoma, and, therefore, biopsies may be performed.[33] The typical histologic picture is FH with interfollicular plasmacytosis, similar to that seen in RA-associated lymphadenopathy.[33,34] Features that point to luetic lymphadenitis include capsular and trabecular fibrosis with infiltration by plasma cells and lymphocytes, especially around capillaries (**Fig. 8-7**). Sarcoidal-type or, rarely, suppurative granulomas in the paracortex, clusters of epithelioid histiocytes, and endarteritis or venulitis with clusters of neutrophils around small vessels may be present.[35] Rarely, a suppurative form of syphilitic lymphadenitis produces a necrotizing lymphadenitis. Stains such as Warthin-Starry or Steiner stains may demonstrate spirochetes anywhere in the lymph node but most consistently within the walls of blood vessels and epithelioid histiocytes.[33] Spirochetes may be difficult to identify, but serologic studies should be positive.[36] Immunohistochemistry is extremely helpful in detection of the organisms.[37]

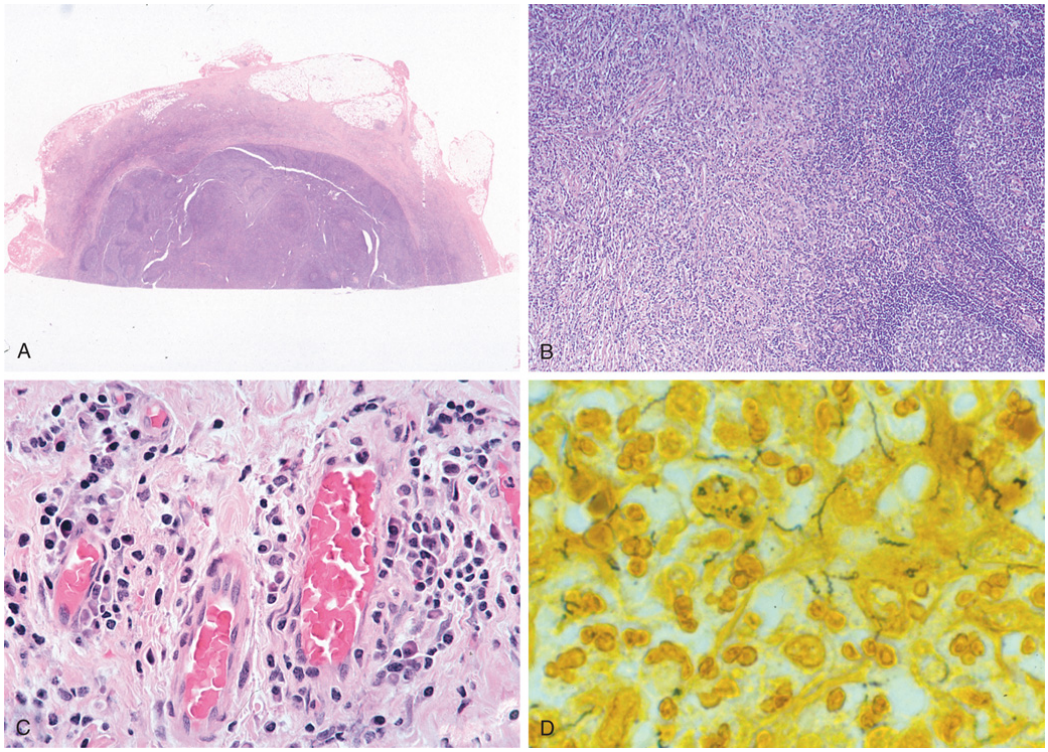

FIGURE 8-7 Syphilitic lymphadenitis.**A,** The thickened, fibrotic capsule is infiltrated by chronic inflammatory cells. Follicular hyperplasia (FH) and interfollicular plasmacytosis are present (H&E, ×5). **B,** Higher magnification of heavily inflamed fibrotic capsule and two large reactive follicles (H&E, ×45). **C,** The vessels in the capsule are surrounded by plasma cells along with lymphocytes (H&E, ×500). **D,** Steiner stain shows numerous spirochetes in a case of necrotizing syphilitic lymphadenitis. D, Courtesy Dr. Judith A. Ferry, Pathology, Massachusetts General Hospital.

Another described manifestation of syphilitic disease in lymph nodes is luetic inflammatory pseudotumor (IP) of lymph node,[38]

described later in this chapter.

The differential diagnosis includes other causes of FH, and because of the increased number of plasma cells, autoimmune disorders such as RA.

Castleman Disease, Hyaline Vascular Type (Angiofollicular Lymphoid Hyperplasia)

Castleman disease may be either localized (unicentric) or one of the multicentric types. Unicentric Castleman disease is typically the hyaline vascular Castleman disease (HVCD), but the plasma cell variant may also be localized. HVCD is typically a disease of young adults, although it can affect patients of any age. Clinically it presents as a localized mass, with the mediastinal and cervical lymph nodes being the most common sites involved. Patients with HVCD are usually asymptomatic, unlike those who have the plasma cell type, and are not infected with HIV.[39] In general, localized CD can be successfully treated with surgical resection, whereas multicentric forms require systemic therapy.[40]

Often considered a hyperplastic or reactive process, reports of stromal tumors arising in patients with HVCD as well as karyotypic abnormalities have led to the hypothesis that HVCD is a monoclonal proliferation. A study examining cases of HVCD in female patients using human androgen receptor assays have detected monoclonality in a high proportion of cases and correlation with size of the tumor. While no immune receptor gene rearrangements were seen, cytogenetic abnormalities in stromal cells were seen, suggesting that HVCD may be a neoplasm of lymph node stromal cells.[41] This is supported by a whole exome sequencing study that identified a

recurrent activating *PDGFRB* mutation in 17% of cases of UCD cases, localizing the mutation to CD45-negative stromal cells.[42]

Histology

The histologic features of HVCD include numerous small, regressively transformed GCs surrounded by expanded mantle zones, and a hypervascular interfollicular region (**Fig. 8-8A** and B).[43] The cells within the regressively transformed GCs are predominantly FDC and endothelial cells. Relatively few follicle center B cells remain. The mantle cells tend to form concentric rings lined up along FDC processes, imparting an onion-skin pattern. Blood vessels from the interfollicular area may penetrate at right angles into the GC to form a lollipop follicle (**Fig. 8-8C**). The interfollicular area contains increased numbers of high endothelial venules and varying numbers of small lymphocytes. A useful diagnostic feature is the presence of more than one GC within a single mantle (twinning) (**Fig. 8-8D**). Occasional clusters of plasmacytoid dendritic cells are found. The relative numbers of follicular and interfollicular components may vary from case to case. Sclerosis in the form of perinodal fibrosis and fibrous bands, often perivascular, within the lesion is common.

A stroma-rich variant of HVCD has been described, with stromal cells consisting of an angiomyoid component expressing actins. This variant is also clinically benign.[44,45] In some cases, there may be atypical FDCs with enlarged, irregular nuclei, which some investigators regard as dysplastic.[46] Clonal karyotypic abnormalities in these dendritic cell proliferations have also been seen.[47] Although the exact relationship is not known, these cells may be precursors to

FDC tumors and sarcomas that have been reported in patients with HVCD.[44,48,49] Plasma cell Castleman disease (PC-CD) may be localized (approximately 10% of localized Castleman disease). It may be associated with constitutional symptoms that may resolve with resection. The predominant features of PC-CD are FH with dense interfollicular plasmacytosis. The plasma cells are not cytologically atypical. A mixed or transitional type of Castleman disease may be diagnosed when occasional hyaline vascular-type follicles are present.

Immunophenotype

The immunophenotype of the follicles in HVCD is like that of reactive follicles. Expanded, concentric meshworks of FDCs stain with antibodies to CD21 or CD23; multiple GCs may be found within a single expanded FDC meshwork.[50] The expanded mantle zone B cells express CD20 and may express CD5 in approximately one-third of cases when sensitive staining protocols are used.[51] Terminal deoxynucleotidyl transferase (TdT)-positive T-lymphoblastic populations of cells can be seen in most cases (75%) of HVCD as rare individual cells or, less commonly, in patchy clusters in interfollicular areas.[52] Flow cytometric studies show these cells may be double positive or double negative for CD4 and CD8 and rarely may be CD4-negative/CD8-positive.[53] Patches of plasmacytoid dendritic cells are highlighted by stains for CD123, CD68, and CD43.[54] Staining for human herpesvirus 8 (HHV-8) is typically negative in HVCD. Plasma cells in localized PC-CD are generally polytypic plasma cells; however, as with multicentric PC-CD, monotypic plasma cells may be present.

Differential Diagnosis

The morphologic features of HVCD are not entirely specific, and the differential diagnosis includes late-stage HIV-associated lymphadenopathy, early stages of follicular T-cell lymphoma (TFH) of angioimmunoblastic type (AITL), follicular or mantle cell lymphomas, and non-specific reactive lymphadenopathy. Clinical history and serologic testing can exclude HIV infection. AITL is typically a diffuse process containing expanded meshworks of FDCs outside of B-cell follicles, highlighted by CD21 or CD23 staining. However, atrophic GCs may occasionally be present. In early stages, the atypical infiltrate of AITL may be interfollicular, and the proliferation of high endothelial venules may resemble the hypervascular interfollicular region of HVCD. Atypia of the lymphoid cells, including characteristic clear cells, is usually seen, and CD10+/PD1+/BCL6+/ICOS+/CXCL13+ T cells outside of GCs are characteristic of the follicular T-helper cell origin of AITL.[55,56] In-situ hybridization for EBV-EBV encoded RNA (EBER) may reveal EBV-positive B immunoblasts in the interfollicular region in early AITL; however, these cells should not be present in HVCD.

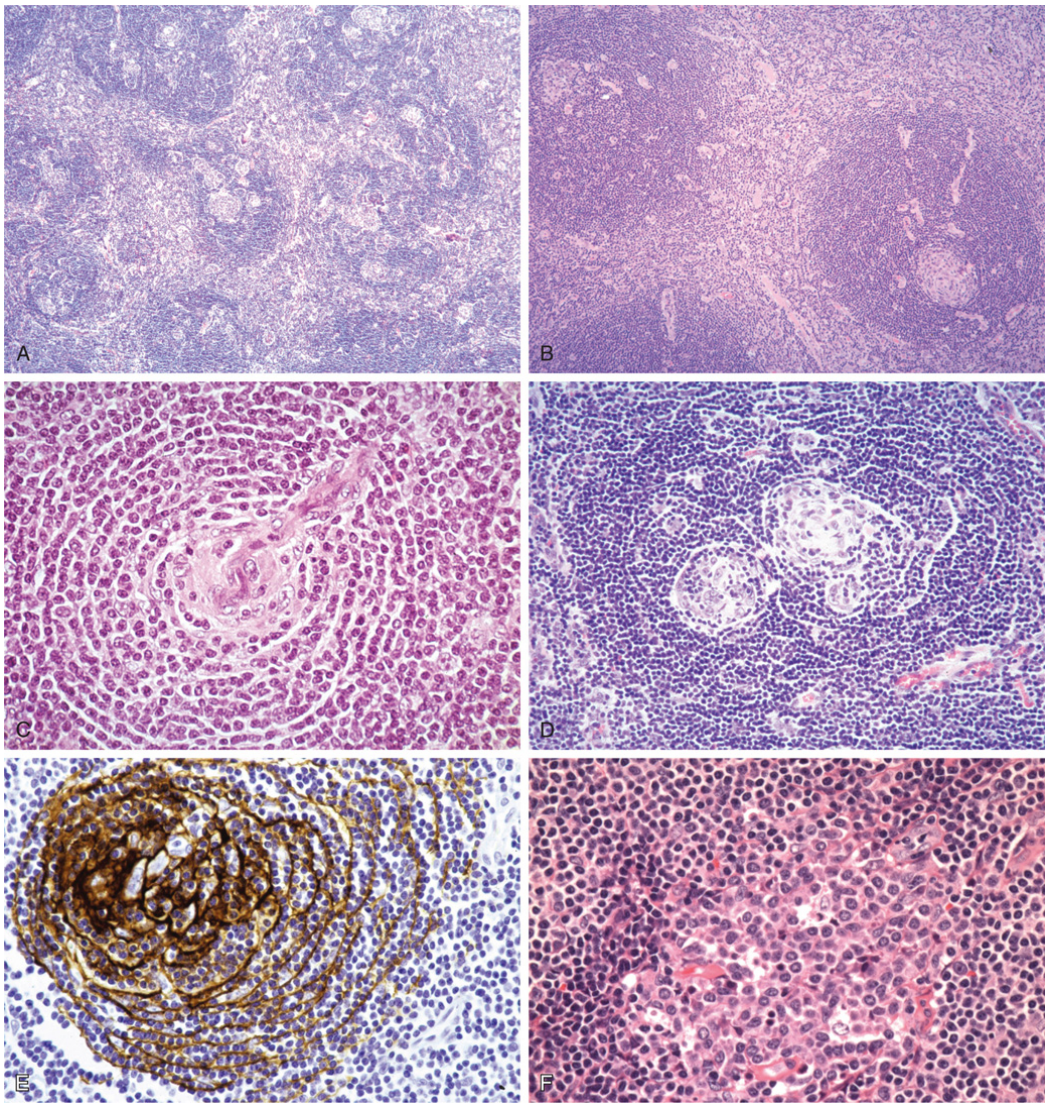

FIGURE 8-8 Hyaline vascular Castleman disease.**A,** Follicles with expanded mantle zones containing regressively transformed GCs. Interfollicular vascular proliferation is prominent (H&E, ×25). **B,** Higher magnification of expanded mantle zones penetrated by vessels from the interfollicular areas and atrophic GCs (H&E, ×90). **C,** Residual GC penetrated at right angle by hyalinized vessel rendering a lollipop appearance to the follicle. Small lymphocytes

palisade around the GCs (onion-skin appearance) (H&E, ×330). **D,** Two atrophic GCs within a single mantle zone (H&E, ×180). **E,** CD21 staining shows the tight follicular dendritic meshwork within the atrophic GC extending in a loosely arranged pattern into the mantle zone. (CD21 immunostain, ×20). **F,** A cluster of plasmacytoid dendritic cells that is characteristically seen in hyaline vascular Castleman disease (HVCD) (H&E ×180).

The mantle zone pattern of MCL may mimic HVCD. However, the lymphoid component in MCL is atypical, monotypic, and expresses cyclin D1. The characteristic interfollicular vascularity of HVCD is absent. Small follicles of FL can be mistaken for the regressively transformed GCs of HVCD. However, immunostains demonstrate the typical phenotype of FL (CD20-positive, CD10-positive, BCL2-positive). Exclusion of autoimmune processes such as RA or HIV infection is important when considering a diagnosis of PC-CD.

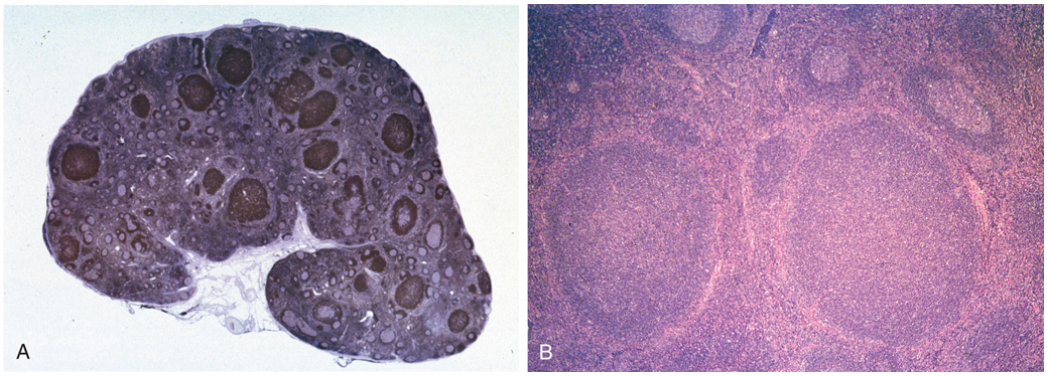

FIGURE 8-9 Progressive transformation of germinal centers.**A,** FH characterized by increased numbers of reactive follicles among progressively transformed GCs that are recognized by their large size (CD20, ×5). **B,** Reactive follicles and two large progressively transformed GCs that are composed predominantly of small lymphocytes (H&E, ×10).

Progressive Transformation of Germinal Centers

Progressive transformation of GCs (PTGC) is a pattern of reactive lymphadenopathy that often presents as a single enlarged lymph node in asymptomatic young adults (peak incidence in the second decade and predominantly in males), although it is also seen in children. Cervical and axillary lymph nodes are most commonly involved.[57-59] The few cases studied by FDG-PET have shown increased uptake. PTGC has been shown to be associated with autoimmune phenomena in a pediatric population.[60]

PTGC occurs as macronodules scattered in the background of typical FH (**Fig. 8-9**). The nodules are usually at least twice as large as, and often much larger than, the hyperplastic follicles and are

composed predominantly of small lymphocytes with scattered follicle center cells present singly or in small clusters. Five patterns of PTGC have been described that range from nodules resembling FH, to those that resemble large primary follicles. Pattern 1 shows scalloped mantle zones with budding of the GCs into mantle zones. Pattern 2 shows incomplete septum-like protrusion of mantle zone cells into the residual GCs, while pattern 3 is completely dissected by variably thick septae of expanding mantle zone cells. Patterns 4 and 5 show few or no remnants of residual GC cells. In practice, these patterns are not generally reported, but help in understanding the spectrum of PTGC.[61] In most cases, a single or a few PTGCs are present in a lymph node. However, florid PTGC, in which numerous progressively transformed GCs are present, may occur, especially in young males.[62] Even in these cases, typical reactive follicles are always present between PTGC. Epithelioid histiocytes may occasionally be seen surrounding the follicles. Immunophenotypically, the small cells are predominantly IgM-positive, IgD-positive, mantle zone B cells.[63] Concentric, smooth meshworks of CD21-positive, CD23-positive FDCs outline the follicles. PD1-expressing T cells are increased both within the nodules and in extrafollicular areas.[3,4]

Differential Diagnosis

The main differential diagnostic consideration is nodular lymphocyte predominant B-cell (Hodgkin) lymphoma (NLPBL). NLPBL and PTGC resemble one another, and both may occur in the same lymph node. NLPBL may be present focally in cases of florid PTGC; in such cases, it is imperative that the entire lymph node be submitted for

histologic examination. Like PTGC, NLPBL contains macronodules, but in contrast to those in PTGC, they efface the nodal architecture and lack interspersed reactive follicles. As in PTGC, the nodules also consist predominantly of small B cells with scattered large cells. However, the large cells in NLPBL are Reed-Sternberg cell variants also known as popcorn cells or LP cells. The LP cells, unlike the centroblasts in nodules of PTGC, have large, lobulated nuclei and variably sized nucleoli. T cells and CD57-positive/PD1-positive (CD279) TFH are often present in small clusters in NLPBL, whereas they are more uniformly scattered in PTGC. A feature useful in the differential diagnosis is the rosetting of CD3 and PD1-positive TFH around the neoplastic CD20-positive LP cells in NLPBL,[64] a finding typically absent in PTGC. Popcorn cells are EMA-positive in some cases of NLPBL, whereas residual centroblasts in PTGC are negative. In addition, the nodules in PTGC usually have sharply defined borders, while in NLPBL the nodules have ragged, “moth-eaten” edges.[65] These features are accentuated in sections stained with CD20 or CD79a. Epithelioid histiocytes are also commonly seen, not only around but also within the nodules in NLPBL. The presence of epithelioid histiocytes within nodules should raise suspicion for NLPBL rather than PTGC. To rule out NLPBL, morphologic and immunophenotypic features should be carefully evaluated in areas in which the nodules are closely packed.

A PTGC-like pattern of immunoglobulin G4 (IgG4)–related lymphadenopathy has been described.[66] Thus, in patients with known extranodal IgG4-related disease or with the clinical signs/symptoms of IgG4-related disease (particularly in elderly males), such as generalized lymphadenopathy and the common

laboratory abnormalities associated with IgG4-related disease (elevated ESR, hypergammaglobulinemia, increased serum IgG4, IgG, and IgE, but not IgA or IgM), and circulating autoantibodies, immunostaining for IgG and IgG4 may be indicated.

Although surgical excision is often curative, PTGC may recur in the same site. Indeed, repeat biopsies after a diagnosis of PTGC were done in 11/29 patients in one report. It showed many recurring instances of PTGC.[60] Some investigators suggest a histogenetic relationship between PTGC and NLPBL, since PTGC can be seen preceding, simultaneously present with, or after a diagnosis of NLPBL.[58,60,67] Most studies show that the risk of development of NLPBL in a patient with PTGC is low, but the magnitude of risk is not known.[62] Thus, patients with florid or recurrent PTGC, particularly in the context of prior NLPBL, should be followed closely and suspicious lymph nodes should be biopsied to rule out development of NLPBL.[57,68]

Mantle Zone Hyperplasia

Mantle zone hyperplasia (MZH) rarely causes lymph node enlargement.[69] Mantle zones may be expanded around either hyperplastic or atrophic GCs. MZH may arouse suspicion for HVCD, mantle cell, or marginal zone lymphomas. The interfollicular vascularity seen in Castleman disease is lacking. Mantle cell lymphoma (mantle zone pattern) usually involves a majority of the lymph node, whereas MZH is most often limited to the cortex or involves only selected follicles (**Fig. 8-10**). Fusion of adjacent mantle zones may be present in MCL. Stains for CD5, CD43, cyclin D1, and immunoglobulin light chains may be useful in excluding

mantle cell or marginal zone lymphoma; rarely, gene rearrangement analysis may be required to exclude lymphoma.[69] Mantle cell lymphoma in situ is recognized by cyclin D1-positive mantle zone B cells limited to mantles and is generally not part of the differential diagnosis of MZH, since the architecture of the lymph node is not altered and the mantle zone is generally not expanded.

Mycobacterial Spindle Cell Pseudotumor

Mycobacterial spindle cell pseudotumor (MP) is a spindle cell lesion sometimes occurring in HIV-positive patients.[70] These rare tumors usually involve lymph nodes but can be seen in other sites such as skin. Histologically, they appear as nodules within the lymph node, which may replace the normal architecture. The nodules are composed of bland spindle cells that form fascicles or take on a storiform pattern. These cells are histiocytes expressing CD68 and contain mycobacterial organisms that can be demonstrated with acid-fast stains.[70,71] The differential diagnosis, particularly in the clinical setting of HIV infection, is Kaposi sarcoma (KS). KS cells may also form spindle cell tumors but can be distinguished from MP by their immunohistochemical profile (CD34-positive/CD31-positive). KS cells also contain HHV-8.

PREDOMINANTLY SINUS PATTERN

Sinus Histiocytosis

SH is a common, non-specific reaction that is characterized by expansion of sinuses by histiocytes. It is often seen in lymph nodes draining a tumor. Its prognostic significance (a marker of immune response) in this setting has been debated in older literature, with

some studies suggesting a better survival when SH was present. SH may also be a reaction to recent surgery for a malignancy such as breast cancer.[72]

SH is a non-specific and benign finding in a clinically enlarged lymph node.[73-77] The degree of histiocytic reaction is variable. Cytologically, the histiocytes are bland (**Fig. 8-11**), without mitoses, which is a key distinguishing feature between this entity and sinusoidal involvement by malignancies such as melanoma, mesothelioma, and anaplastic large cell lymphoma. These malignancies may preferentially involve the sinuses with an infiltrate of noncohesive cells. In contrast to SH, they are composed of cytologically atypical cells. Uncommonly, SH may take on a signet ring appearance and mimic metastatic adenocarcinoma.[77] Immunohistochemistry for markers specific for these tumors and for histiocytes (CD68) can be used to sort out rare problematic cases.

Histiocytic Expansion Caused by a Specific Cause (Storage Disease, Lymphangiogram, Prosthesis, Whipple Disease)

Histiocytic reactions involving lymph nodes, although they may not primarily manifest as sinusoidal histiocytosis, may sometimes be attributed to specific causes, which are briefly described here.

Lymphangiogram, performed in the past for staging of lymphomas, produced large vacuoles formed by lipid-rich contrast material, resulting in the formation of lipogranulomas and foamy histiocytes in sinuses and foreign body giant cells (**Fig. 8-12**).[78]

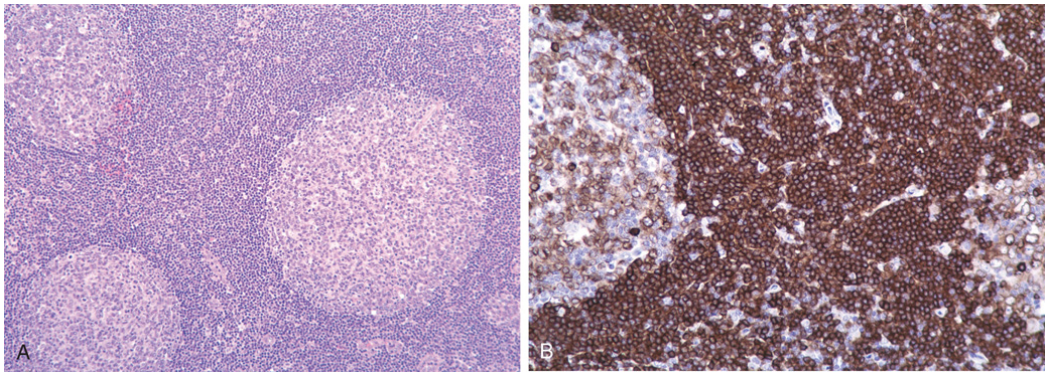

FIGURE 8-10 Mantle zone hyperplasia.**A,** Three follicles with expanded mantle zones that have virtually replaced the interfollicular area (H&E, ×70). **B,** CD79a stain shows positive mantle zone B cells with absence of interfollicular areas and parts of two GCs (CD79a, ×90).

Histiocytic reactions may result from release of foreign material from deteriorating joint or silicone prostheses and also can cause regional lymphadenopathy.[79-83] Foreign material may be present in the regional lymph node in sinuses with extension into the paracortex and granuloma formation. Metal fragments and refractile prosthetic material can be demonstrated in the histiocytes. Silastic prostheses have been reported to produce granulomas with multinucleated giant cells containing yellow refractile, nonbirefringent silicone.[84] Breast implants may also result in lymphadenopathy with diffuse infiltrates of vacuolated and foamy histiocytes along with large cystic spaces containing silicone.[83] Polarized light examination may be helpful in demonstrating certain types of material such as polyethylene.[85]

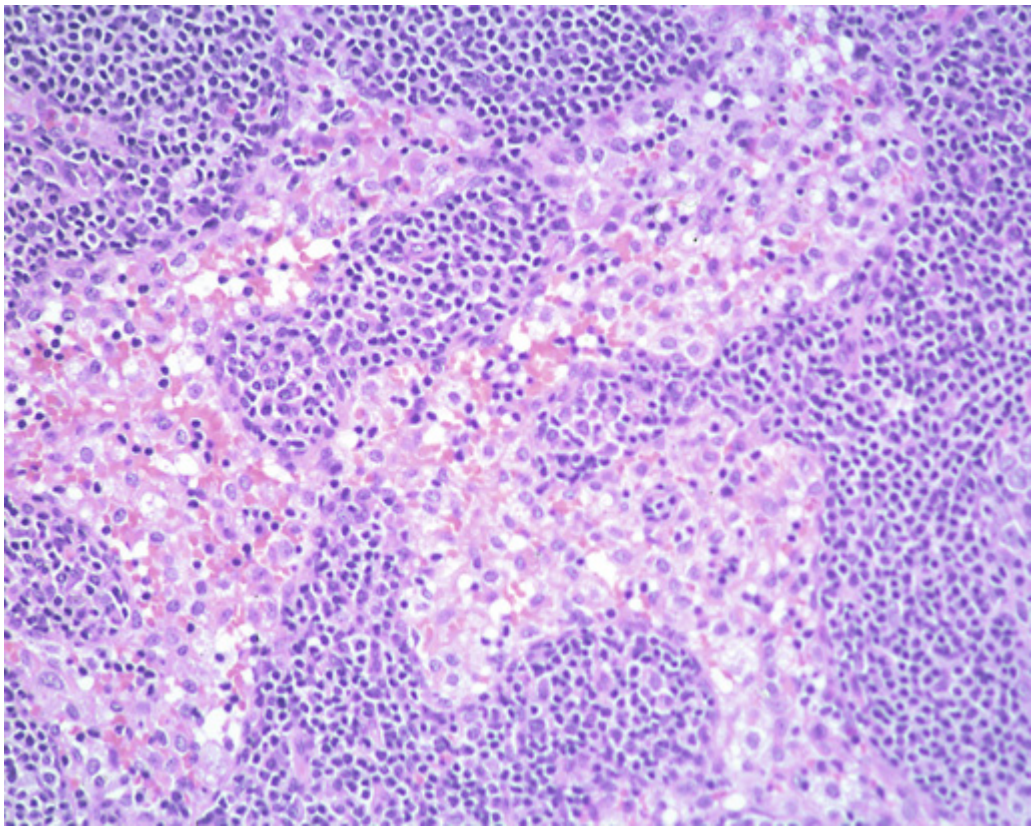

FIGURE 8-11 Sinus histiocytosis.The sinus is distended with histiocytes that have ample cytoplasm and bland-appearing nuclei without nucleoli (H&E, ×200).

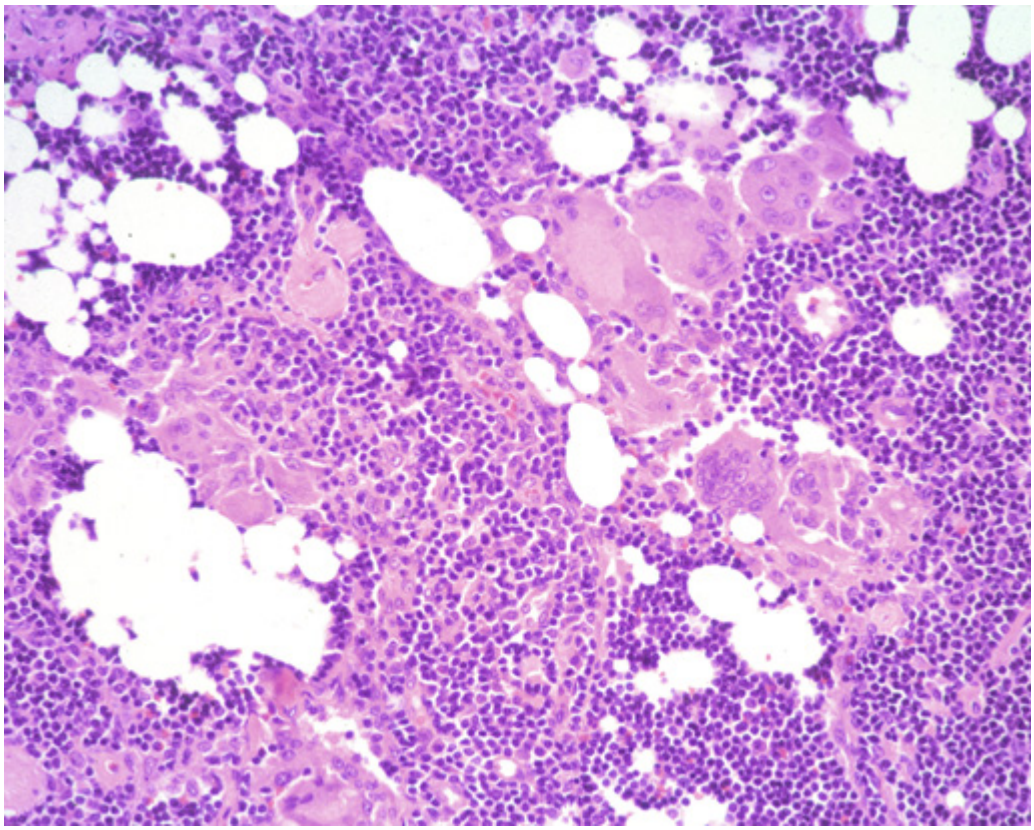

FIGURE 8-12 Abdominal lymph node from a patient who had a lymphangiogram.The sinuses are distended by large vacuoles surrounded by sinus histiocytes and foreign body-type giant cells (H&E, ×350).

Hereditary storage diseases such as Gaucher and Niemann-Pick diseases may also be associated with nodal infiltrates of storage-product-laden macrophages. The histiocytes retain the characteristics of the particular disease seen in other sites (e.g., tissue-paper appearance in Gaucher disease).[59,86]

Whipple Disease

Whipple disease, first described by George Whipple in 1907,[87] is an infection caused by the bacterium *Tropheryma whipplei* (formerly *T.*

whippelii).[88,89] It occurs most commonly in middle-aged males with symptoms of weight loss, diarrhea, abdominal pain, and often arthralgia. Abdominal lymphadenopathy is usually present, with peripheral or mediastinal lymphadenopathy in about 50% of cases. Although Whipple disease is often diagnosed by small bowel biopsy, a lymph node may be the first tissue biopsied, especially in patients without abdominal complaints.

Lymph node sinuses contain large, pale-staining, finely vacuolated histiocytes that harbor diastase-resistant, PAS-positive sickle-form structures and large cystic vacuoles (**Fig. 8-13**). Electron microscopy confirms the presence of bacteria.[87,90,91] Not all cases have the characteristic findings; some cases have nonnecrotizing granulomas resembling sarcoidosis.[92,93] The PAS stain may be only focally positive when few organisms are present.[88] A high degree of suspicion is required in order not to miss this diagnosis.

The differential diagnosis of Whipple disease includes lymphangiogram effect, mycobacterial infection such as *Mycobacterium avium-intracellulare* (MAI), sarcoidosis, and leprosy.[94] The latter can show diffuse infiltrates of histiocytes with abundant vacuolated cytoplasm. Cystic spaces, however, are absent. In MAI, the organisms are both PAS and acid-fast positive, whereas in leprosy the organisms are acid-fast positive but PAS negative.[95] The presence of *T. whipplei* in fixed tissues can be confirmed by PCR.[87] Immunostaining has also been used to detect the organism in tissue section.[96]

Vascular Transformation of Sinuses

Vascular transformation of sinuses (VTS) (stasis lymphadenopathy, nodal angiomatosis, or hemangiomatoid plexiform vascularization) is an uncommon vasoproliferative lesion that occurs in patients of all ages; it is usually an incidental finding in a lymph node removed for other reasons. Histologically, subcapsular sinuses and, less frequently, other sinuses are expanded by thin-walled blood vessels lined by flat endothelial cells. The vascular spaces are more cellular in the intermediate sinuses and become ectatic and less cellular in the subcapsular sinuses (**Fig. 8-14**).[97] Arborizing slitlike spaces may also be formed. The histologic appearance varies, some cases having a more solid appearance because of plump endothelial cells and smaller vascular spaces. A plexiform variant consists of dilated and anastomosing spaces with flat lining cells. Extensive VTS may form spindle cell nodules.[97-100] Immunophenotypic analysis shows some loss of the lymphatic marker D2-40 in cells lining these spaces.[101]

The pathogenesis of VTS is thought to be lymphatic or vascular obstruction.[98-100,102] The differential diagnosis includes KS, hemangioma, and bacillary angiomatosis (BA).KS involves subcapsular sinuses in its early stages and is composed of slitlike vascular spaces. The nodal capsule, which is often involved in KS, is never infiltrated in VTS. Sclerosis is minimal in KS, and there are long spindle cell fascicles, whereas BA, as discussed, forms nodules, and contains granular eosinophilic material and neutrophilic debris not seen in VTS. Hemangiomas have well-developed vascular spaces and form nodules.[103,104]

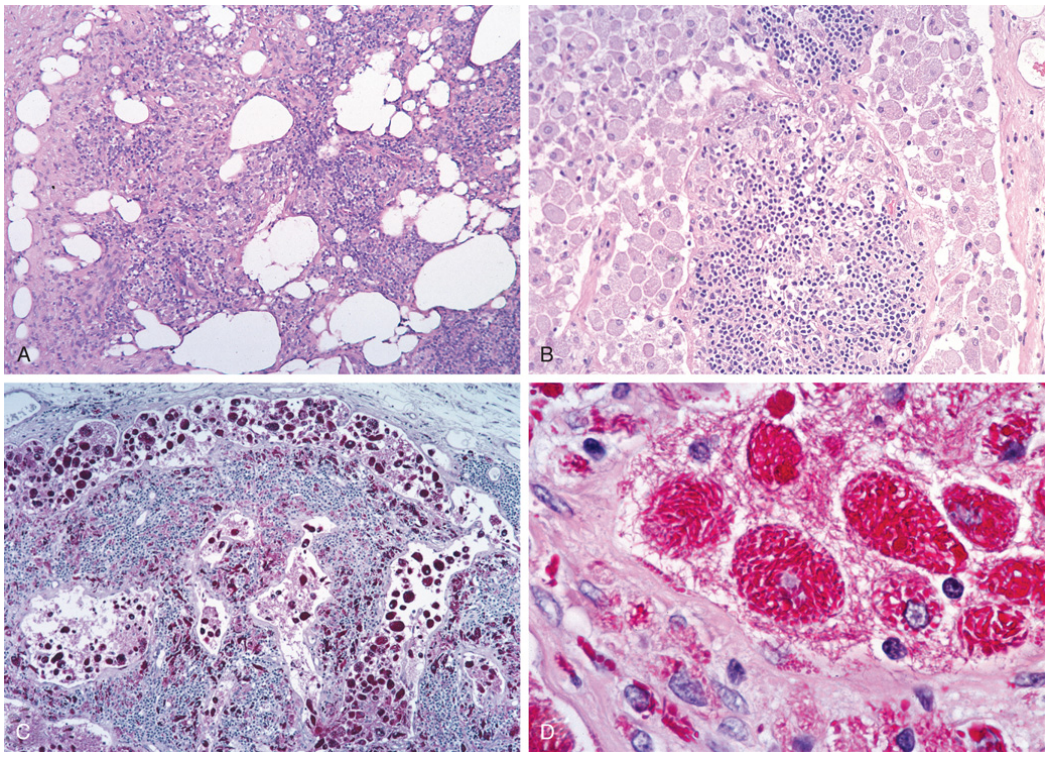

FIGURE 8-13 Whipple disease involving a lymph node.**A,** Sinuses contain varying-sized vacuoles and few histiocytes (H&E, ×25). **B,** Sinuses filled with large, pale-staining histiocytes (H&E, ×140). **C,** PAS-positive histiocytes fill sinuses (PAS, ×25). **D,** High magnification of histiocytes filled with PAS-positive sickle-form particles (PAS, ×700).

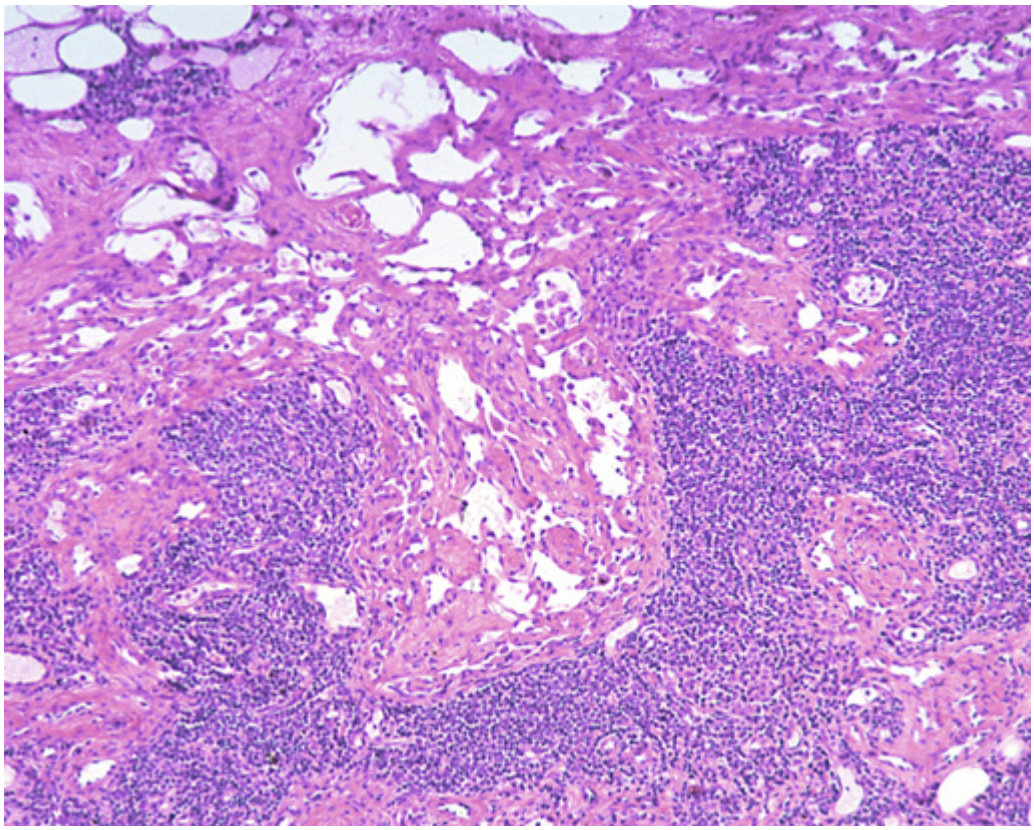

FIGURE 8-14 Vascular transformation of sinuses.The subcapsular and intermediate sinuses are replaced by vascular structures ranging from slitlike spaces, especially in the intermediate sinus, to ectatic vessels in the subcapsular sinus and associated fibrosis (H&E, ×25).

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a potentially fatal disorder of immune regulation characterized by abnormal activation of macrophages and lymphocytes, production of proinflammatory cytokines, and tissue infiltration of histiocytes that demonstrates hemophagocytosis. It can be classified into primary and secondary

forms. Primary (genetic) forms of HLH are often associated with familial HLH (*PRF1, UNC13D, STS11,* and *STXP2* mutations), albinism syndromes (*RAB27A, LYST,* and *AP3B1*), or immune deficiencies (*SH2DIA, XIAP, ITK, MAGT1,* and *CD27* defects). Secondary causes include infections (often viral), autoimmune disorders (often termed *macrophage activation syndrome* in this setting), immunosuppression, malignancy, and rare metabolic disorders.[105] Lymphomas, especially T- and NK-cell lymphomas, may be complicated by HLH, a combination associated with a very poor prognosis. Primary cutaneous gamma/delta T-cell lymphoma is particularly associated with HLH.[105-108] Patients are constitutionally ill, usually with organomegaly, fever, and skin rash. Common laboratory findings include hyperlipidemia, cytopenias, and elevated ferritin. More detailed information on the classification, pathogenesis, and clinicopathologic characteristics of HLH are covered in **Chapter 28** and **52**.

Bone marrow aspiration and biopsy are the most performed procedures to document the presence of hemophagocytosis and to exclude leukemia as a cause for the HLH. Lymph node or tissue biopsy is usually avoided, except to exclude other malignancies. Of note, by revised diagnostic criteria for HLH diagnosis, demonstration of hemophagocytosis by bone marrow, spleen, or lymph node biopsy is not absolutely required if other criteria are met.[109]

Regarding lymph node pathology, there is a proliferation of benign histiocytes present in sinuses. There may be an immunoblastic proliferation or, alternatively, the lymph node may be depleted of lymphocytes. The histiocytes may be stuffed with erythrocytes, but

other hematopoietic cells may also be phagocytized (**Fig. 8-15**). This latter feature may be seen especially clearly in smears of bone marrow aspirates.[110,111] In lymphoma-associated HLH, there may or may not be involvement of the lymph node by neoplasia. Lack of evidence of malignancy in the lymph node does not exclude the possibility of a lymphoma-associated HLH.[112,113]

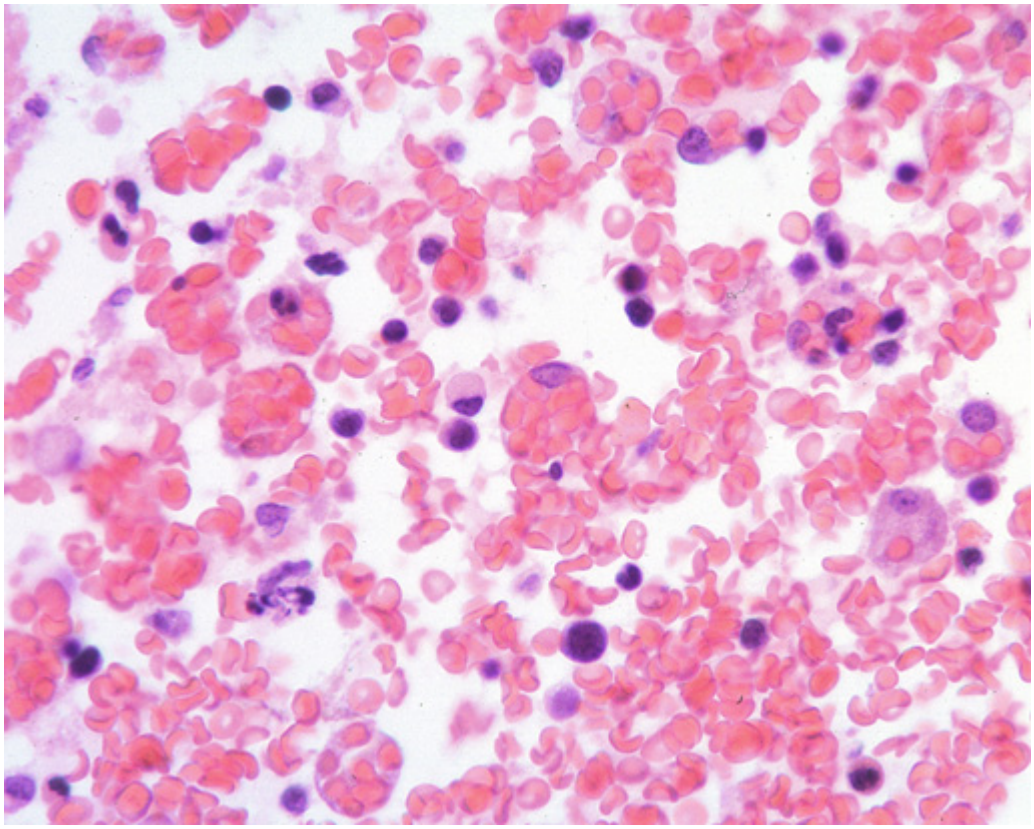

FIGURE 8-15 Lymph node from a patient with hemophagocytic lymphohistiocytosis.The distended sinus contains histiocytes engorged with phagocytized red blood cells (H&E, ×625).

The differential diagnosis includes SH with massive lymphadenopathy (Rosai-Dorfman disease). This disorder is

characterized by a sinusoidal infiltrate of large histiocytic cells with prominent nucleoli demonstrating emperipolesis of lymphocytes and occasionally plasma cells, rather than true cytophagocytosis.[114] The histiocytes are strongly S100 positive, while the histiocytes in HPS or SH are S100 negative or variably and weakly positive (see **Chapter 52** for more detailed information).

Cells of Langerhans cell histiocytosis (LCH) also involve sinuses, but are CD1a and langerin positive, in addition to being S100 positive. Furthermore, the nuclei of the LCH cells have a characteristic nuclear groove/crease and are accompanied by an inflammatory infiltrate that often includes eosinophils (see **Chapter 52** for more detailed information).

INTERFOLLICULAR OR MIXED PATTERNS

Paracortical Hyperplasia and Dermatopathic Reaction

Paracortical hyperplasia, or expansion of the paracortical (T-zone) region of the lymph node, may be a cause of lymphadenopathy. Causes include response to viral infection, reaction to a nearby malignancy, and autoimmune disease, although frequently the pathologist is not able to identify a specific etiology.[115-117] Histologically, there is a mixed population of small lymphocytes with variable numbers of immunoblasts and plasma cells. There may be admixed histiocytes, prominent vascularity (high endothelial venules), and interdigitating dendritic cells.[118-120]

Dermatopathic lymphadenitis is a specific type of paracortical hyperplasia that typically manifests in lymph nodes draining areas of

chronic skin irritation. Histologically, there are vague paracortical lymphoid nodules that are composed of small lymphocytes admixed with increased numbers of interdigitating dendritic cells, Langerhans cells, and histiocytes containing melanin, or, less commonly, iron (**Fig. 8-16**). The various populations of histiocytes and dendritic cells have a mottled appearance at low magnification. Both interdigitating dendritic cells and Langerhans cells are positive for S100 protein, and Langerhans cells also express CD1a and langerin. The histiocytes are positive for CD68. Studies have shown that dermatopathic changes can often occur in the absence of dermatitis.[121] The lymphocytes present within the nodules are predominantly T cells, which lack significant cytologic atypia. In most instances, there is no need for extensive immunophenotypic evaluation of lymph nodes with dermatopathic change. One pitfall is that these nodules should not be confused for involvement by LCH. The paracortical pattern (rather than sinusoidal as in LCH) and lack of eosinophilic infiltration can provide clues to the dermatopathic nature of the infiltrate.

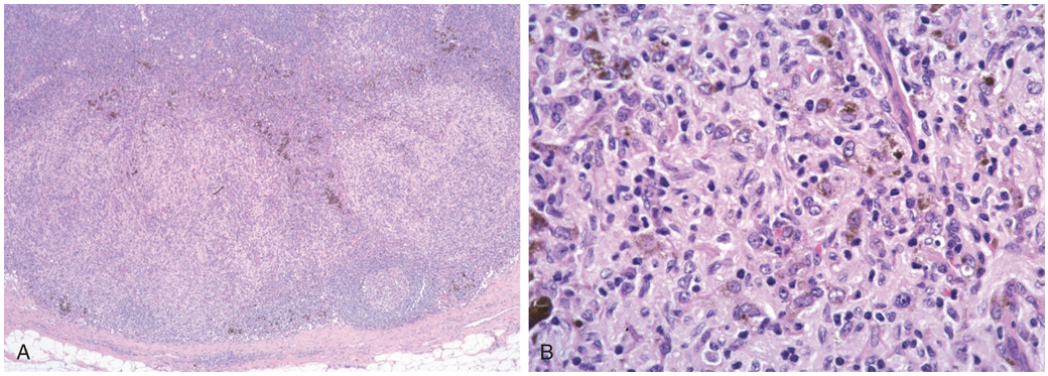

FIGURE 8-16 Dermatopathic lymphadenitis.**A,** Two pale-staining nodules in the expanded paracortex composed of Langerhans cells and histiocytes, some containing melanin. A follicle is compressed adjacent to the capsule (H&E, ×25). **B,** Higher magnification showing mixtures of pigment containing macrophages and Langerhans cells (H&E, ×400).

The major differential diagnosis is with lymph node involvement by mycosis fungoides (MF), in which dermatopathic change is common. Lymph node involvement by MF may take several forms, ranging from the presence of atypical cells in clusters without obvious effacement of the lymph node architecture to diffuse involvement by lymphoma that may even resemble classic Hodgkin lymphoma (CHL).[122] Scoring systems to grade this involvement and predict behavior have been suggested,[123] but multivariate survival analysis calls into question their utility.[124] If there is a clinical history of MF, more extensive phenotyping of the T cells and careful morphologic evaluation should be performed. Gene rearrangement studies may be helpful in evaluating histologically equivocal cases and predicting outcome.[125,126]

Granulomatous Lymphadenitis

Granulomatous lymphadenitis can be divided into nonnecrotizing, necrotizing, and suppurative forms. Although a specific cause often cannot be determined, specific causes of granuloma formation in lymph nodes are presented here.

Nonnecrotizing Granulomas

Nonnecrotizing epithelioid granulomas are often seen as non-specific reactions to malignancy such as lymphoma or carcinoma. The lymph node may or may not be involved with the malignancy.[86,127,128] Types of lymphoma particularly associated with granulomas include CHL, nodular lymphocyte predominant B-cell lymphoma, lymphoplasmacytic lymphoma, and some peripheral T-cell lymphomas (Lennert lymphoma), although clusters of histiocytes smaller than granulomas are more characteristic of the latter. Metastatic nasopharyngeal carcinoma may be associated with a florid granulomatous reaction that obscures the tumor.

Sarcoidosis involving the lymph node results in discrete, well-formed epithelioid granulomas with or without multinucleated giant cells and scattered lymphocytes. The granulomas first involve the paracortical regions but often become confluent and can eventually replace the entire lymph node (**Fig. 8-17**). Schaumann, asteroid, and Hamazaki-Wesenberg bodies may be seen but are not specific for sarcoidosis.[129-132] PAS-positive and acid-fast Hamazaki-Wesenberg bodies (1–15 μm ovoid to spindle-shaped intracellular and extracellular structures) should not be mistaken for microorganisms.[132] The granulomas may be surrounded and replaced by fibrous tissue. Immunophenotyping shows a

predominance of CD4-positive T cells.[133] Although almost any tissue can be involved, lung and mediastinal lymph nodes are most commonly affected. Cultures and special stains for microorganism should be done to exclude infectious etiologies, particularly looking for fungi and acid-fast organisms.[134]

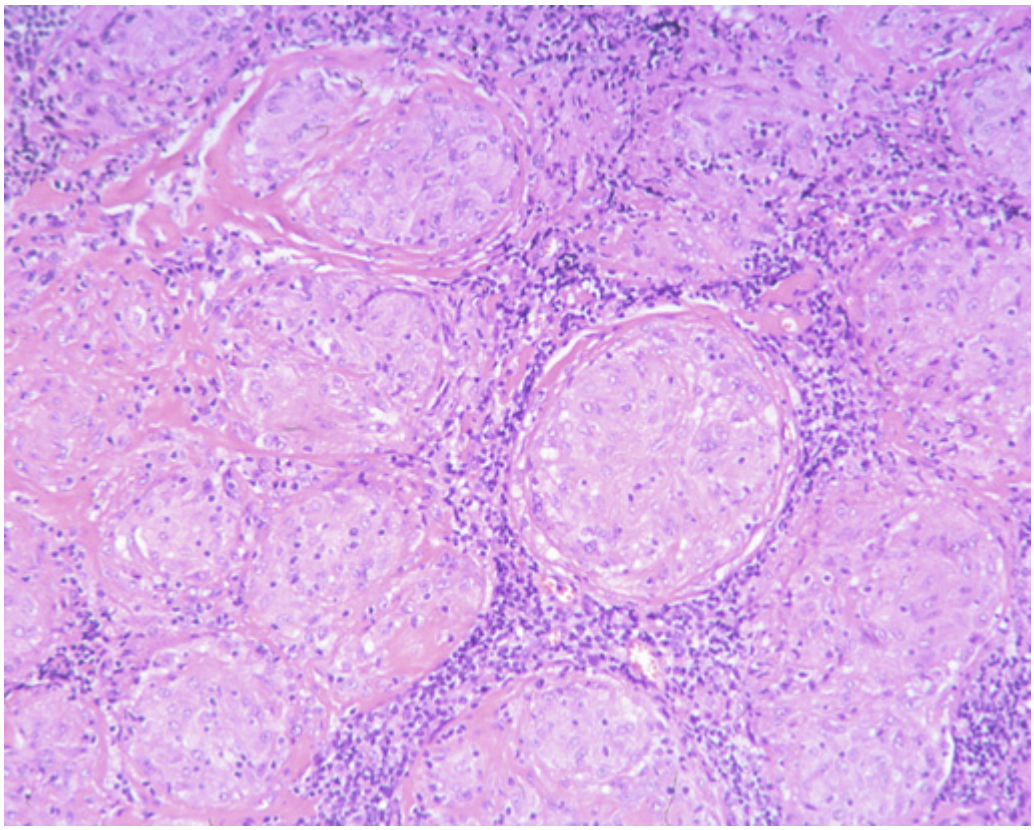

FIGURE 8-17 Sarcoidosis in a lymph node characterized by epithelioid granulomas, some surrounded by delicate fibrous bands (H&E, ×140).

Necrotizing Granulomas (Tuberculosis, Fungal Infections, Cat Scratch Disease)

Necrotizing granulomas are caused by a variety of infectious organisms including mycobacteria, fungi, and bacteria. Some show characteristic histologic features.

Tuberculosis

Mycobacterial infections, particularly *Mycobacterium tuberculosis*, are common throughout the world.[135] After increasing incidence in the 1980s and 1990s, the numbers in the United States have stabilized at 6.8/100,000 per year.[135,136] In tuberculosis patients who present with peripheral lymphadenopathy, cervical lymph nodes are most commonly involved.[137] Cervical lymphadenopathy may also be the presenting feature in atypical mycobacterial infection with organisms such as *Mycobacterium scrofulaceum,* particularly in children.[138,139] Epitrochlear, axillary lymph, or inguinal nodes may be infected with *Mycobacterium marinum* from cutaneous lesions (swimming pool granulomas).

Histologically, lymph nodes infected by mycobacteria of any kind contain multiple well-formed granulomas consisting of epithelioid histiocytes and multinucleated giant cells. Caseating necrosis is often seen. In immunocompromised patients, the granulomas may not be well formed and may contain neutrophils. Mycobacterial organisms may be demonstrated in the granulomas with acid-fast stains. Culture is usually required to definitively identify species, although PCR has also been used.[140,141] Brucellosis (infection by the *Brucella* species bacteria) may cause a granulomatous lymphadenitis similar to that seen in tuberculosis; organisms are difficult to demonstrate in tissue sections.

Fungal Infection

Fungal infections of lymph nodes typically cause granulomatous lymphadenitis that may be necrotizing and indistinguishable from mycobacterial infection. Fibrosis and calcification may occur in older lesions. In general, the lymphadenitis occurs as part of pulmonary-based disease or a disseminated infection. Disseminated infections usually occur in immunocompromised patients, either in the setting of HIV infection, malignancy, or in iatrogenically immunosuppressed patients.[135,142,143] In immunocompromised patients, the granulomas may not be well formed. In a large series of cases, *Histoplasma capsulatum* was the most common fungal infection in immunocompetent patients.[134] Gomori methenamine silver (GMS) or PAS stains will aid in identification of the organisms, although organisms are often absent in older lesions. The differential diagnosis includes necrotizing granulomas caused by an infectious cause such as mycobacteria.

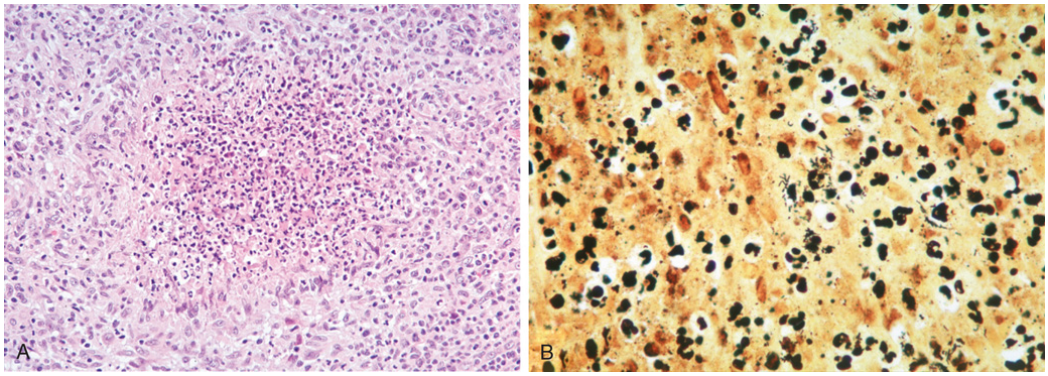

FIGURE 8-18 Lymph node from a patient with cat scratch disease.**A,** Suppurative granuloma with central area composed predominantly of neutrophils surrounded by palisading histiocytes and fibroblasts (H&E, ×250). **B,** Warthin-Starry stain showing the causative *Bartonella henselae* organisms (Warthin-Starry, ×700).

Cat Scratch Disease

CSD, caused by *Bartonella henselae,* is histologically characterized by suppurative granulomas.[144,145] It is likely underrecognized and may be one of the more common causes of chronic lymph node enlargement in children.[146] Patients usually present with axillary or cervical lymphadenopathy and mild fever of 1 to 2 weeks' duration.[146,147] As cats are the reservoir of the causative organism, there is often, but not always, a history of exposure to cats, particularly kittens, which have higher levels of bacteremia and are more likely to scratch than adult cats.[146] The disease usually resolves spontaneously in several months.

The histologic features of CSD are characteristic but not entirely specific. Well-developed lesions are characterized by FH,

monocytoid B-cell reaction, and suppurative granulomas (**Fig. 8-18**). Suppurative granulomas consist of a central necrotic focus containing abundant neutrophils and neutrophilic debris surrounded by palisaded macrophages forming the classic stellate microabscess.[144] Various stages in the development of the characteristic suppurative lesion are often seen in the same node. Early lesions show small foci of necrosis within clusters of monocytoid B cells, containing small clusters of neutrophils. Later lesions are surrounded by histiocytes. Very old lesions may contain central areas of caseation, similar to that seen in mycobacterial infection. Although the stellate microabscess (suppurative granuloma) is characteristic, over 40% of cases may not have these characteristic features, and instead may show features mimicking other reactive patterns including those of fungal/mycobacterial disease, Kikuchi disease, and toxoplasma.[148]

The bacilli in CSD can be identified within the granulomas or walls of vessels with a Warthin-Starry stain, although these stains are challenging to interpret.[145] They are most readily seen in early lesions, where they tend to cluster in the walls of blood vessels (**Fig. 8-18**). Cultures are rarely definitive, but PCR tests in fixed tissue have been successful in detecting the organism.[148,149] Confirmation of the diagnosis by acute and convalescent serologic testing is recommended.

The differential diagnosis of suppurative granulomas includes other infectious agents such as *Chlamydia trachomatis* (lymphogranuloma venereum), *Francisella tularensis* (tularemia), *Yersinia pseudotuberculosis* (mesenteric lymphadenitis), *Listeria monocytogenes* (listeriosis), *Burkholderia mallei* (glanders), and

Burkholderia pseudomallei (melioidosis). Many of these disorders are rare but have a specific clinical picture or a history of exposure to animals to aid in the clinical diagnosis, when combined with appropriate microbiological studies.[150-154] Potential uses of some of these agents in bioterrorism have raised awareness of their virulence and manifestations.[155,156]

Immunoglobulin G4–Related Disease

IgG4-related disease is a fibro-inflammatory disorder consisting of tumefactive lesions in multiple sites and a dense[157] plasmacytic infiltrate containing numerous IgG4-positive plasma cells, eosinophils, obliterative phlebitis, and storiform fibrosis (**Fig. 8-19**).[158,159] Serum IgG4 levels are often, but not always, increased. IgG4-related disease can involve virtually any organ, but is frequently seen in the pancreas and salivary and lacrimal glands. In addition, lymph nodes are frequently involved, although the features are less specific than those seen in extranodal sites with storiform fibrosis and obliterative phlebitis being rarely seen.[157] Axillary, mediastinal, and intraabdominal nodes are most commonly affected. There are five different, but sometimes overlapping, histologic patterns in lymph nodes: type I, multicentric Castleman-like disease; type II, FH; type III, interfollicular expansion; type IV, PTGC; and type V, IP-like. Only type V is specific for IgG4-related disease, and is the least common pattern.[66,160] Overlapping patterns may be seen in types I and II, I and III, and between II and IV. All five of these types show an increase in IgG4 plasma cells (often >100 per high power field) and IgG4/IgG ratio (>40%).[66,158,161-163] However, these features are not specific for IgG4-related lymphadenopathy.

Guidelines from the American College of Rheumatology recommend against the use of a lymph node to fulfill the histologic criteria for a diagnosis of IgG4-related disease.[157]

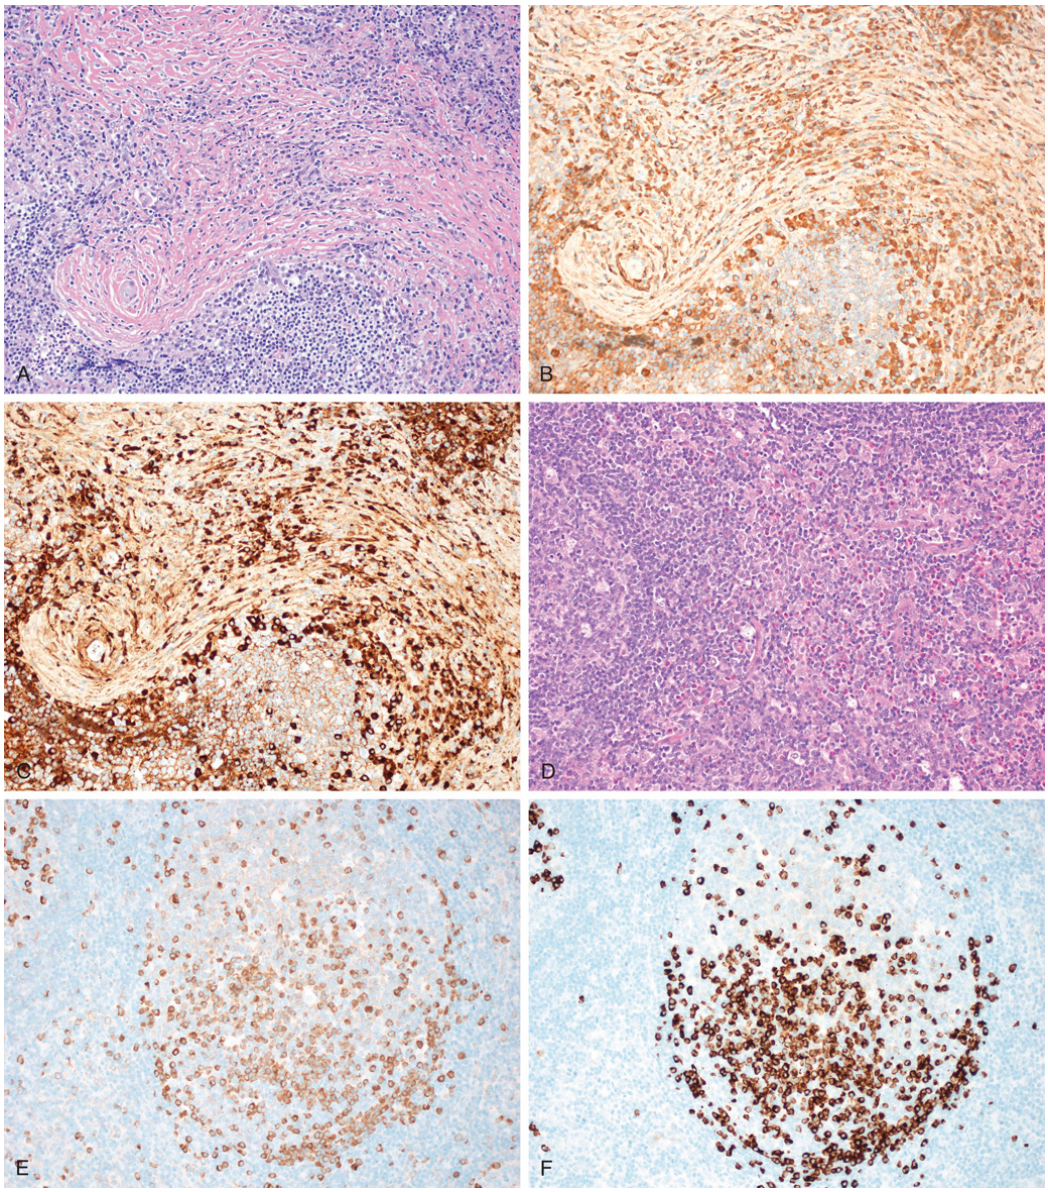

FIGURE 8-19 Features of immunoglobulin G4–related disease involving lymph nodes.**A,** Storiform fibrosis with increased plasma cells (H&E, ×200). **B,** Immunoglobulin G (IgG) stain highlighting plasma cells within fibrosis (×200). **C,** IgG4 stain showing IgG4/IgG ratio of close to 100% (×200). **D,** Follicular and paracortical hyperplasia with increased paracortical

eosinophils and plasma cells is a common finding in lymph nodes from patients with IgG4-related disease but is non-specific (H&E, ×100). **E,** IgG stain showing increased intrafollicular plasma cells (×200). **F,** IgG4 stain showing elevated IgG4/IgG ratio (×200).

Type I pattern resembles multicentric Castleman disease or autoimmune-associated lymphadenopathy. The lymph node architecture is retained, and hyperplastic follicles and regressed follicles are present. Some of the follicles are radially penetrated by high endothelial venules (lollipop appearance) that are abundant in the interfollicular regions, together with numerous mature plasma cells and scattered eosinophils.

Type II pattern shows FH, interfollicular plasmacytosis, and plasma cells in GCs, with occasional eosinophils. Similar findings are seen in rheumatoid lymphadenopathy and other autoimmune disorders.

Type III pattern shows a prominent expansion of the interfollicular zones. Some follicles may be penetrated by high endothelial venules from the interfollicular areas (lollipop appearance), which, in addition, contain mature plasma cells, plasmablasts, immunoblasts, and eosinophils. The latter pattern may resemble TFH AITL. However, in contrast to AITL, there is no cellular atypia, no foci of clear cells, no aberrant immunophenotype, and no increased CD21-positive follicular dendritic meshworks around blood vessels. Increased numbers of EBV-infected cells that are seen in AITL have also been reported in IgG4-related lymphadenopathy, mostly in the PTGC type.[164] In addition, there are

increased IgG4-positive cells and an increased IgG4/IgG ratio, both of which are absent in AITL.

Type IV pattern shows a preservation of architecture with reactive-appearing follicles and large PTGCs (3 to 4 times the size of reactive GCs) in various stages of transformation characterized by infiltration of mantle cells from a thickened mantle zone into the GCs, disrupting and eventually replacing them. Some of the reactive follicles and the PTGCs may be infiltrated by plasma cells and eosinophils.

Type V pattern is the rarest.[157] It is characterized by a storiform pattern of collagen fibers that are infiltrated by plasma cells and lymphocytes. It is similar to the process found in extranodal sites.

Although the numbers of IgG4-positive plasma cells and the IgG4/IgG ratio are increased, they are insufficient for a definitive diagnosis because other conditions, such as RA, Kimura disease, multicentric Castleman disease, Rosai-Dorfman disease, and other conditions may show the same findings. Therefore it is of utmost importance that both clinical correlations be applied when evaluating a lymph node specimen for IgG4-related disease.[157]

Kimura Disease

Kimura disease is a chronic inflammatory condition of unknown cause that affects young to middle-aged patients, most often males of Asian descent.[165] Patients usually present with a mass in the head and neck region with involvement of subcutaneous tissue, soft tissue, salivary glands, and single or multiple regional lymph nodes. Peripheral blood examination shows an eosinophilia and increased

serum IgE levels. The disease is self-limited, although recurrences can occur over a period of years.[165]

Key histologic features include florid FH that may contain a proteinaceous precipitate (IgE in a follicular dendritic network pattern) and vascularization of the GCs (**Fig. 8-20**). The interfollicular areas show prominent high endothelial venules with a mixture of lymphocytes, plasma cells, eosinophils, and mast cells. Follicle lysis is often present, and eosinophilic abscesses are characteristic within GCs and in the paracortex. Polykaryocytes are usually seen in GCs and paracortex. A varying degree of fibrosis is seen.

Immunohistochemistry is of minimal utility in this disease, but may help in excluding other disorders. Because of similar Th2 T-cell responses that promote eosinophil proliferation and class switching of plasma cells to IgE and IgG4, lymph nodes in Kimura disease may have increased IgG4-positive plasma cells and patients may have increased serum IgG4.[166,167] Staining for IgE to identify proteinaceous deposits in GCs has been proposed as a useful diagnostic tool for Kimura disease, but is not specific for this entity.[168]

In lymph nodes, the differential diagnosis includes other entities associated with eosinophilia including allergic/hypersensitivity reactions and parasitic infestation, as well as IgG4-related disease. These disorders less frequently will show eosinophilic abscesses of follicles and paracortex.

The entity most likely to be confused with Kimura disease is angiolymphoid hyperplasia with eosinophilia (ALHE), which also involves the head and neck region. Long thought to be synonymous

with Kimura disease, ALHE is a vascular neoplasm characterized by the proliferation of blood vessels lined by plump endothelial cells with abundant eosinophilic cytoplasm, imparting a hobnail appearance. This lesion is part of the spectrum of what have been called *histiocytoid* or *epithelioid hemangiomas*, and is a low-grade vascular tumor. There is a dense, mixed inflammatory cell infiltrate consisting of lymphocytes, plasma cells, and eosinophils. The prominent histiocytoid endothelial cells seen in ALHE are not seen in Kimura disease, and the presence of this feature is the most reliable distinction between these two entities.[165,169-171]

Toxoplasma Lymphadenitis

Infection by *Toxoplasma gondii* in the immunocompetent patient results most commonly in solitary cervical lymphadenopathy. The organism has a worldwide distribution, with 30% to 40% of adults in the United States having been exposed to it.[172] Patients with an acute infection may be asymptomatic, or, less frequently, they may have non-specific symptoms such as malaise, sore throat, and fever, a constellation of symptoms similar to those found in infectious mononucleosis (IM). In addition, reactive lymphocytes may be found in peripheral blood smears, thus clinically resembling the features of IM.[172-174] The disease is self-limited, but immunodeficient patients may develop severe complications such as encephalitis. Infection during pregnancy may result in birth defect or fetal loss.

Histologically, lymph nodes show prominent FH with expansion of monocytoid B cells in a sinusoidal and perisinusoidal pattern. Small clusters of epithelioid histiocytes in the paracortex encroach upon and are present within GCs (**Fig. 8-21**). The GCs have ragged,

“moth-eaten” margins, and contain numerous tingible body macrophages. Granulomas and multinucleated giant cells are absent. Parasitic cysts are seen only rarely, and earlier attempts to detect the organisms by PCR were mostly unsuccessful.[175,176] Serology is the primary means for confirmation of the diagnosis.[174] However, a study showed a PCR detection rate of 83% in cases with the histologic triad of florid reactive FH, clusters of epithelioid histiocytes, and focal sinusoidal distention by monocytoid B cells.[177]

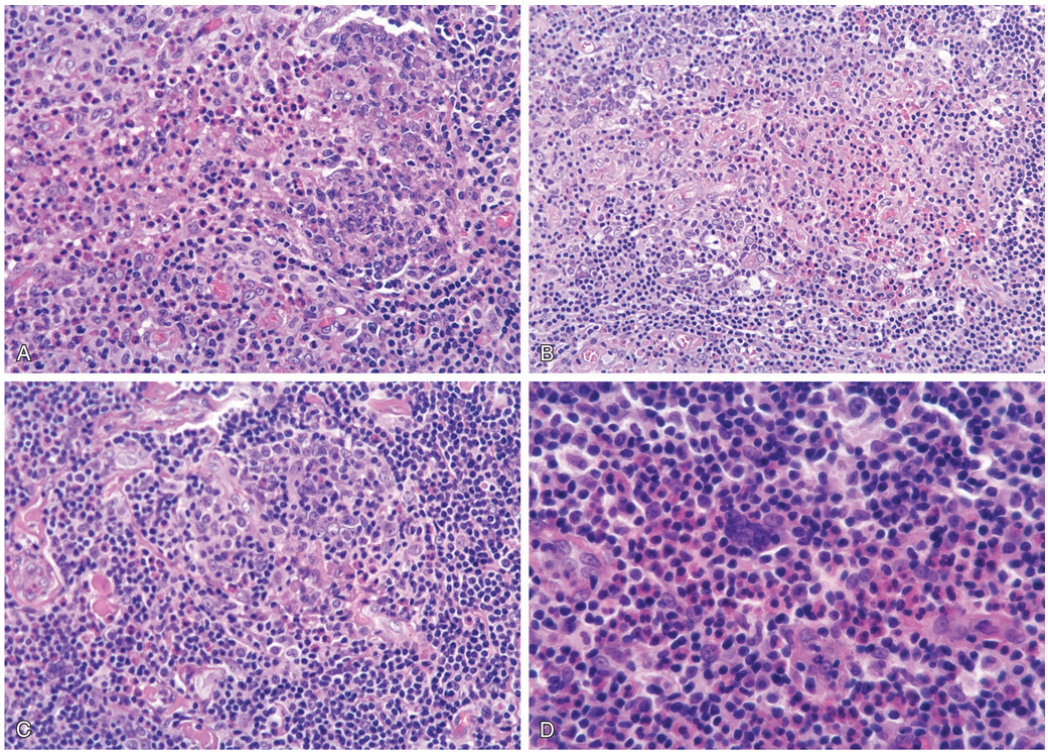

FIGURE 8-20 Kimura disease in a lymph node biopsy from a young man with a mass in the parotid gland region.**A,** Follicular lysis with eosinophils in a hyperplastic GC (H&E, ×330). **B,** Eosinophilic abscess in a GC. Residual clusters of large GC cells are present (H&E, ×330). **C,** Vascularization of a GC and high endothelial venules in the paracortex (H&E, ×330). **D,** Numerous eosinophils in the paracortex along with a polykaryocyte (H&E, ×500).

Although the histologic features are characteristic of toxoplasma lymphadenitis, the differential diagnosis includes leishmanial lymphadenitis, which can result in a histologic picture similar to toxoplasmosis. In leishmaniasis, organisms may be seen in the granulomas. Ultrastructurally, leishmaniasis can be distinguished

from toxoplasma by the presence of kinetoplasts and basal bodies in the former.[178] Early stages of CSD, IM, and CMV lymphadenitis may also have morphologic features similar to that of toxoplasma lymphadenitis.

Systemic Lupus Erythematosus

Patients who have systemic lupus erythematosus (SLE) are at increased risk for development of lymphoma, and lymphadenopathy is present in up to 60% of the patients, most commonly involving cervical and mesenteric nodes.[179,180] The histologic features of lymph nodes in SLE include nonspecific FH, with or without an interfollicular expansion of lymphocytes and immunoblasts, often with numerous plasma cells both within GCs and in the medullary cords. A characteristic feature of lupus lymphadenitis is coagulative necrosis, often involving large areas of the lymph node (**Fig. 8-22**).[179,181-183] The necrotic areas contain ghosts of lymphoid cells, often abundant karyorrhectic debris, and histiocytes; segmented neutrophils are scant, but may be present, in contrast to Kikuchi lymphadenitis. The presence of hematoxylin bodies, extracellular amorphous hematoxyphilic structures probably composed of degenerated nuclei that have reacted with antinuclear antibodies, is specific for SLE. The hematoxylin bodies are found in areas of necrosis and in sinuses. Hematoxylin bodies are absent in Kikuchi disease.

Kikuchi Lymphadenitis (Kikuchi-Fujimoto Lymphadenitis, Histiocytic Necrotizing Lymphadenitis)

Histiocytic necrotizing lymphadenitis, also known as Kikuchi or Kikuchi-Fujimoto lymphadenitis, was described in Japan in 1972.[184,185] It has a worldwide distribution and predominantly affects young adults, especially young women of Asian descent. The disease in most instances resolves spontaneously within several months. Patients most often present with cervical lymphadenopathy, sometimes associated with fever and leukopenia. Three histologic subtypes, probably representing various stages in the evolution of the disease, have been described: proliferative stage, necrotizing stage, and xanthomatous stage.[186]

The earliest proliferative stage is characterized by the presence of numerous immunoblasts with prominent nucleoli and basophilic cytoplasm in the paracortex, raising the differential diagnosis of large-cell lymphoma. The immunoblasts are admixed with large mononuclear cells including histiocytes, some with curved nuclei (crescentic histiocytes) and some with twisted nuclei, and aggregates of plasmacytoid dendritic cells may be prominent. The latter cells are intermediate-sized with round-to-oval nuclei and granular chromatin, placed eccentrically within an amphophilic cytoplasm. They are often difficult to identify within the mixture of cells. Karyorrhectic bodies are often interspersed among the plasmacytoid dendritic cells, and the necrosis seen in Kikuchi disease often appears to begin in nests of these cells.

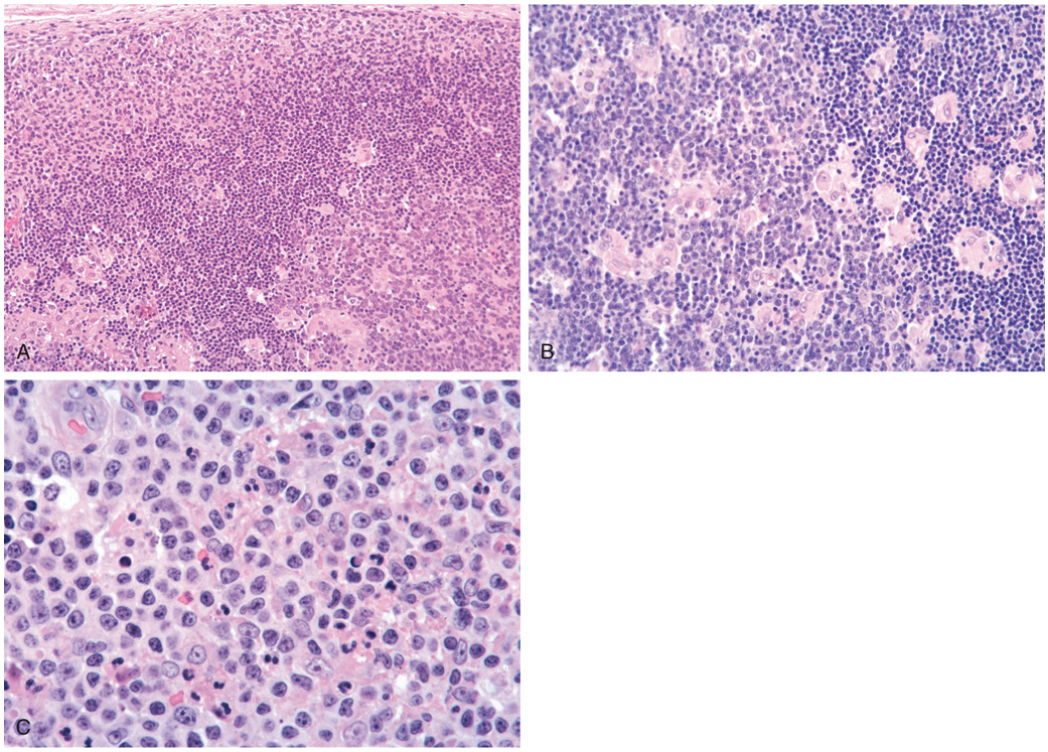

FIGURE 8-21 *Toxoplasma* lymphadenitis.**A,** Reactive follicle with epithelioid histiocytes, some in clusters, in paracortex, encroaching upon and within the GC. The subcapsular sinus is dilated and filled with monocytoid B cells (H&E, ×70). **B,** Higher magnification showing histiocytes close to and within the GC (H&E, ×250). **C,** Higher magnification of the monocytoid B cells, which have ample cytoplasm, indented nuclei, and slightly condensed chromatin. Intermingled neutrophils are present (H&E, ×250).

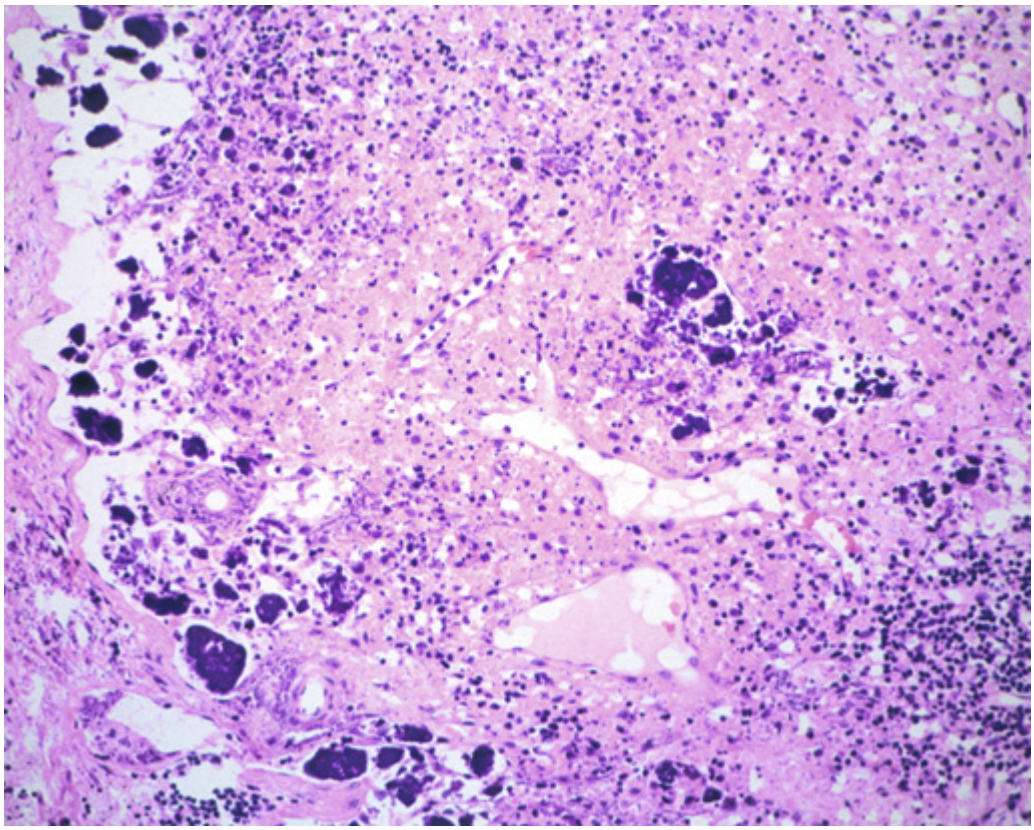

FIGURE 8-22 Lymph node from a patient with systemic lupus erythematosus.Extensive necrosis with apoptotic debris and hematoxylin bodies found predominantly within sinuses. Neutrophils are absent (H&E, ×100).

The necrotizing stage, which is seen in most cases, is characterized by patchy areas of necrosis within the paracortex (**Fig. 8-23**). The necrosis contains no neutrophils, has abundant karyorrhectic nuclear debris, and is surrounded by a mixture of mononuclear cells identical to those found in the proliferative type. The karyorrhectic debris is both extracellular and phagocytized by histiocytes.

The xanthomatous stage is the least common and most likely represents the healing phase of this entity. It contains many foamy

histiocytes and fewer immunoblasts than the other stages. Necrosis may or may not be present in the xanthomatous type.

Minimum criteria for the diagnosis of Kikuchi lymphadenitis include paracortical clusters of plasmacytoid dendritic cells admixed with karyorrhectic bodies and crescentic histiocytes.[187] The noninvolved parts of the node show a mottled appearance caused by the presence of immunoblasts scattered among small lymphocytes. Reactive lymphoid follicles may be seen. There is also a proliferation of high endothelial venules.[187] This histologic picture resembles that seen in viral-associated lymphadenopathy.

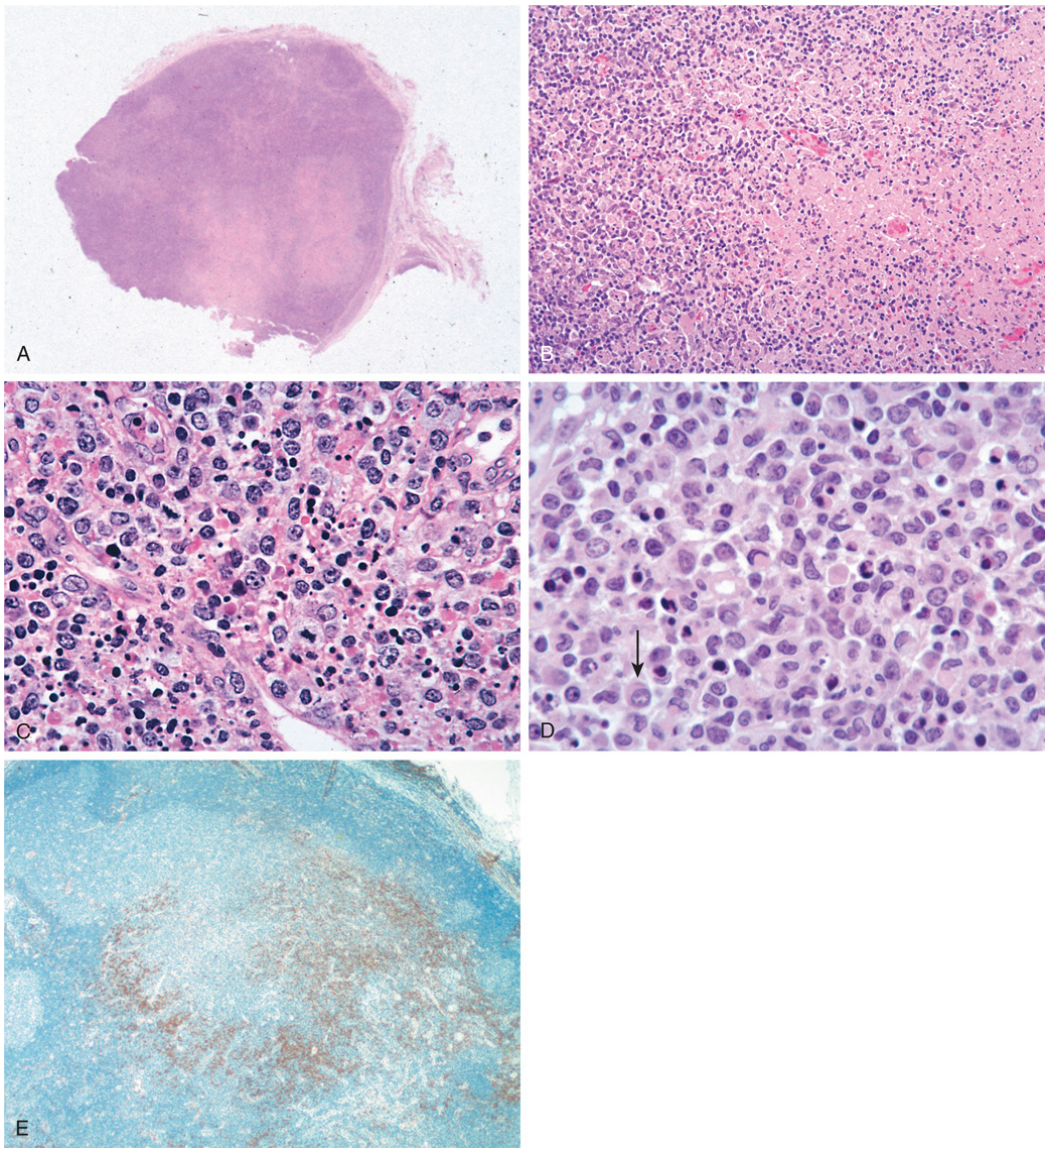

FIGURE 8-23 Lymph node from a young woman with Kikuchi disease.**A,** Confluent foci of necrosis in the paracortex surrounded by large mononuclear cells (H&E, ×5). **B,** Higher magnification showing necrosis with karyorrhectic debris, histiocytes, and immunoblasts. **C,** Predominance of immunoblasts, histiocytes, necrosis, and apoptotic debris (H&E, ×330). **D,** Mononuclear

cells, most of which are histiocytes, some with crescentic nuclei, and plasmacytoid dendritic cells *(arrow)* and immunoblasts (H&E, ×330). **E,** CD123 staining shows plasmacytoid dendritic cells surrounding an area of necrosis (×40).

The immunoblasts are typically CD8-positive T cells but may be a mixture of T and B cells. This is a pitfall that can lead to misdiagnosis as an aggressive lymphoma if the characteristic constellation of findings for Kikuchi is not recognized. Plasmacytoid dendritic cells can be best recognized by staining for CD123, but also express CD68, CD4, and CD43 (**Fig. 8-23E**). CD68 and CD163 stain histiocytes. Myeloperoxidase-positive histiocytes are frequently present but lack specificity.[188] Typically, there is not a prominent B-cell infiltrate.

The differential diagnosis includes lupus lymphadenitis and non-Hodgkin lymphoma. The findings in Kikuchi lymphadenitis may be indistinguishable from those of lupus, and some investigators have raised the possibility of a relationship between the two; however, cases reported as Kikuchi lymphadenitis in association with SLE are almost certainly lupus lymphadenitis misdiagnosed as Kikuchi lymphadenitis.[181,189] Extensive necrosis, the presence of hematoxylin bodies, and plasma cells or occasional neutrophils favor SLE.[181] Most patients with Kikuchi lymphadenitis lack antinuclear antibodies.[187] Because of the difficulty in distinguishing histologically between the two, whenever a diagnosis of Kikuchi lymphadenitis is made, serologic testing for SLE is advisable; if tests are positive, the diagnosis is lupus lymphadenitis.

Cases with abundant immunoblasts may be mistaken for lymphoma. Patchy involvement of the lymph node, abundant

karyorrhectic debris, a mixed cell population including the crescentic histiocytes, the absence of B-cell markers on the immunoblasts, and lack of a B- or T-cell receptor gene rearrangement favor Kikuchi lymphadenitis.[181]

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease is an acute exanthematous childhood disease of unknown etiology,[190] a male-to-female ratio of 1.5:1 and a peak age of 3 to 4 years.[191,192] Diagnosis rests on the presence of five of the six following features not attributable to other causes: fever unresponsive to antibiotics, bilateral conjunctivitis, oral mucositis, distal extremity cutaneous lesions, polymorphous skin exanthems, and cervical lymphadenopathy.[193] The disease appears to be a systemic vasculitis, and the term *juvenile polyarteritis nodosa* has been proposed. Although most children recover, patients are at high risk for coronary artery aneurysm. Sudden death occurs in approximately 1% of patients.[194,195] Histologically, the lymph nodes show nongranulomatous foci of necrosis, with or without neutrophils, associated with vasculitis and thrombosis of small vessels. Scattered lymphocytes, plasma cells, and immunoblasts are seen in the background. The overall nodal architecture is often effaced. The differential diagnosis is extensive and includes other entities with necrosis such as SLE and Kikuchi lymphadenitis.[181,196] Observation of fibrin thrombi in nodal vessels with the appropriate clinical history would strongly favor Kawasaki lymphadenitis.

Inflammatory Pseudotumor

IP is an idiopathic reactive condition of lymph nodes affecting young adults (median age 33) without gender predilection.[197] Patients have constitutional symptoms and often laboratory abnormalities such as hypergammaglobulinemia, elevated ESR, and anemia. Single peripheral or central, or multiple lymph node groups, and the spleen may be involved.[198,199] IP can spontaneously resolve; surgical excision or antiinflammatory agents can relieve symptoms.[199]

The key histologic feature is a fibro-inflammatory reaction of the connective tissue framework of the lymph node with extension into the perinodal soft tissue. The capsule, trabeculae, and hilum are involved by a proliferation of small vessels, histiocytes, and myofibroblastic cells with admixed lymphocytes, plasma cells, eosinophils, and neutrophils. The myofibroblastic cells are spindly to polygonal with bland nuclei and abundant cytoplasm. They can form ill-defined fascicles or appear in a storiform pattern. Fibrinoid vascular necrosis, karyorrhexis, and focal parenchymal infarction may be seen. Invasion and destruction of medium-sized vessels may be present. Lymphoid follicles are uncommon.[197,198,200,201] Immunophenotyping shows that the lymphoid cells are predominantly T cells. CD68-positive histiocytes and vimentin-positive/actin-positive spindle cells are present, supporting the fibrohistiocytic nature of the proliferation.[198,200,201] As the lesions age, the node becomes replaced by fibrotic tissue with a scant inflammatory infiltrate.[198]

The differential diagnosis includes KS, FDC tumors, hypocellular anaplastic large-cell lymphoma, and syphilis infection. Early involvement by KS shows capsular, subcapsular, and trabecular spindle cell areas that may suggest the connective tissue framework

pattern of IP. Vascular structures are poorly formed in KS, in contrast to their appearance in IP. The PAS-positive hyaline globules of KS are not present. The bland cytologic features of IP, the lack of a mass-forming nodule, and the absence of FDC markers such as CD21 and CD35 aid in making the distinction from FDC tumors.[202,203] Hypocellular anaplastic large-cell lymphoma has an edematous fibromyxoid background with scattered myofibroblastic cells that may form fascicles, mimicking IP. CD30 and ALK expression in atypical cells that tend to cluster around vessels confirm lymphoma and exclude IP.[204] Syphilis infection can also result in an IP-like lesion. Thus all IPs should be investigated for spirochetes using *Treponema* immunohistochemistry. Features that might suggest syphilis include pronounced FH and capsular fibrosis with plasma cell infiltrate and neutrophilic infiltrates around small vessels.[38]

Bacillary Angiomatosis

BA caused by infection with *B. henselae* or, less commonly, *Bartonella quintana*[205-207] may cause lymphadenopathy in immunocompromised patients, particularly those infected with HIV. Patients present with skin lesions, lymphadenopathy, and occasionally hepatosplenomegaly.

The lymph nodes demonstrate single or confluent nodules composed of small blood vessels lined by plump endothelial cells, interstitial granular eosinophilic material, and varying numbers of neutrophils with leukocytoclasis. Warthin-Starry staining demonstrates tangles of bacilli in the eosinophilic material,[208,209] and organisms may be detected by *Treponema* immunohistochemistry and PCR (**Fig. 8-24**).[210,211]

The differential diagnosis includes other vasoproliferative disorders.[103] In immunocompromised patients, KS must be considered. In KS, the vascular structures are less well formed, and the fascicular pattern and hyaline globules of KS are not seen in BA. The endothelial cells of BA are positive for *Ulex europaeus* and factor VIIIRA, whereas they are negative in KS. Detection of bacteria in BA and HHV-8 in KS is helpful.

DIFFUSE PATTERN

Diffuse paracortical proliferations are the most difficult benign lymphadenopathies to differentiate from lymphomas because there is often subtotal effacement of the nodal architecture. There are prominent immunoblasts with atypical cytologic features, occasionally mimicking large cell or Hodgkin lymphomas. Clinical history, results of laboratory studies, immunophenotyping, and molecular analysis are crucial in distinguishing benign from malignant proliferations.

Infectious Mononucleosis

IM caused by EBV infection commonly produces lymphadenopathy and enlargement of tonsils in adolescents and young adults, although older adults may also be affected. Clinical features including pharyngitis, fever, cervical lymphadenopathy of short duration, splenomegaly, and laboratory features such as reactive peripheral blood lymphocytes and the presence of heterophile antibody usually lead to a diagnosis without a lymph node biopsy. However, lymph nodes may be biopsied to exclude the diagnosis of lymphoma, and tonsils may be removed for relief of airway obstruction.

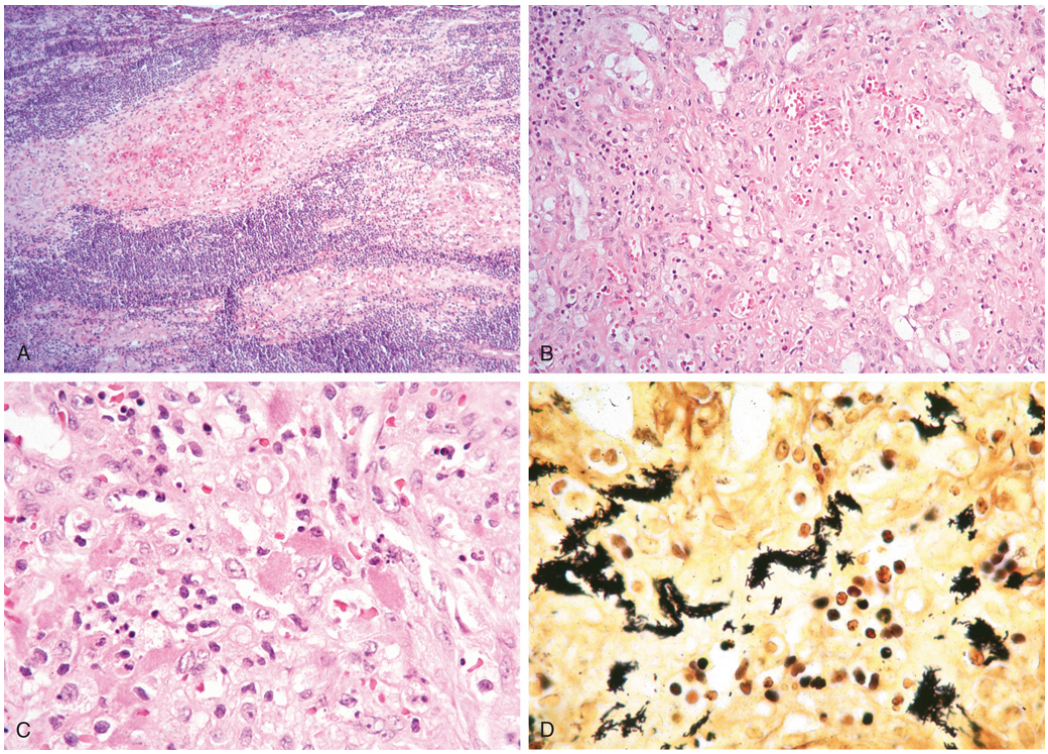

FIGURE 8-24 Bacillary angiomatosis involving a lymph node.**A,** Multiple coalescent nodules of proliferated blood vessels (H&E, ×5). **B,** Blood vessels, some barely canalized, lined by plump endothelial cells with pale cytoplasm (H&E, ×140). **C,** Amphophilic material representing tangles of bacteria among endothelial cells (H&E, ×250). **D,** Tangles of *Bartonella henselae* (Warthin-Starry, ×250).

The histologic features vary during the course of the disease.[19,120,212-214] Early in the disorder, there is FH often with monocytoid B-cell aggregates and epithelioid histiocytes, resembling toxoplasmic lymphadenitis. Later, expansion of the paracortex predominates. Although the architecture of the lymph node or tonsil may be distorted, it is not totally effaced. There is a polymorphous

paracortical infiltrate with a mottled pattern caused by the presence of large immunoblasts in a background of medium-sized and small lymphocytes and plasma cells (**Fig. 8-25**). There may be atypical immunoblastic cells that are occasionally binucleate and resemble classic Reed-Sternberg cells. In areas, there may be a diffuse proliferation of immunoblasts resembling a large cell lymphoma. However, in contrast to large cell lymphoma, intermediate-sized lymphocytes, plasma cells, and plasmacytoid cells are present among the immunoblasts, high endothelial venules are often prominent, and single-cell necrosis is common. The sinuses are often distended and filled with monocytoid B cells, small lymphocytes, and immunoblasts.

Immunophenotyping shows both T- and B-cell immunoblasts, with B-cell immunoblasts usually predominating.[215] The immunoblasts, including Reed-Sternberg–like cells, often express CD30, but they are usually CD15 negative (**Fig. 8-25**).[216] CD8-positive T cells typically outnumber CD4-positive T cells. In situ hybridization for EBER shows numerous positive immunoblasts, plasma cells, and B cells in the paracortex. Monocytoid B cells may also contain EBER.[217,218] LMP-1 protein is also expressed and may be related to p53 accumulation within the cells, because the two proteins appear to colocalize.[219,220] In addition, in acute IM EBNA2 is positive and shows the typical EBV latency III of the acute episode. CD21 staining may reveal an underlying distorted but retained FDC network not readily apparent on hematoxylin and eosin staining.

The most important differential diagnoses are diffuse large B-cell lymphoma, peripheral T-cell lymphoma, and CHL. Morphologic features favoring a benign process include incomplete architectural

effacement, a mixed cellular infiltrate, patent lymph node sinuses, and the presence of high endothelial venules among the large cells. The presence of geographic necrosis in the polymorphous infiltrate is another clue to the diagnosis of IM. Immunohistochemical features include the presence of both B- and T-cell immunoblasts, and a predominance of CD8-positive T cells. The presence of classic Reed-Sternberg–like cells may suggest CHL, but these cells lack expression of CD15, mark with either B- or T-cell antibodies, and are usually CD45 positive. In addition, they are not in the cellular environment of one of the subtypes of CHL. Another difference between CHL and IM is that EBV-positive cells are almost exclusively limited to the RS cells in CHL, whereas they are found in numerous large, activated immunoblasts and in small lymphocytes and plasma cells in IM. Tonsillar location and young patient age should prompt a conservative approach and testing for EBV.

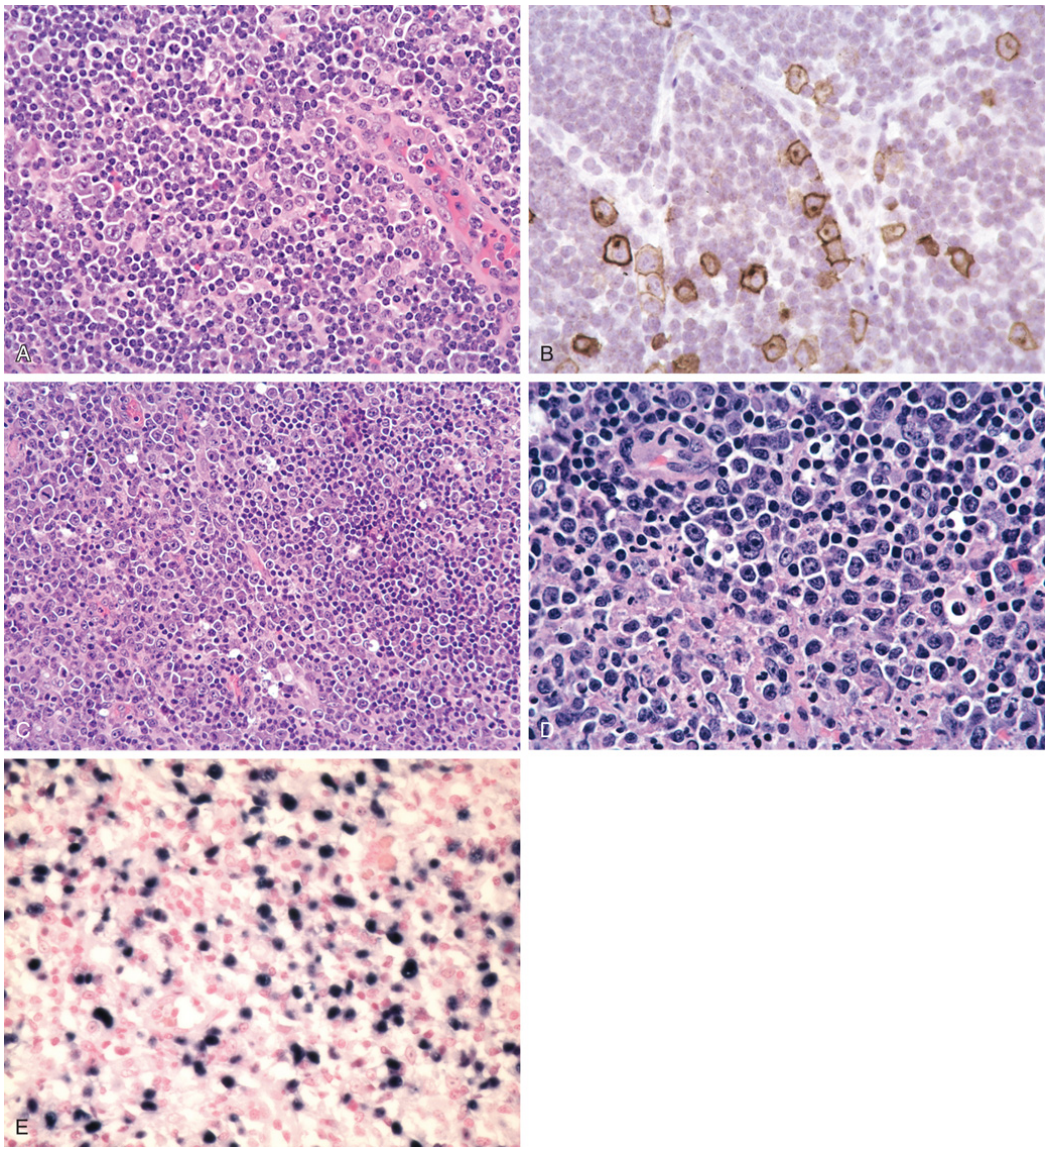

FIGURE 8-25 Infectious mononucleosis.**A,** Paracortex showing a mottled appearance caused by the presence of immunoblasts among small lymphocytes. A high endothelial venule is present (H&E, ×250). **B,** CD30-positive immunoblasts among the small lymphocytes. High endothelial venules are present (H&E, ×140). **C,** Area showing a mottled appearance transitioning to a more solid area of immunoblasts (H&E, ×250).

D, Solid focus of immunoblasts with necrosis. A Reed-Sternberg–like cell is present (H&E, ×300). **E,** Epstein-Barr encoded RNA in situ hybridization showing numerous Epstein-Barr virus–infected cells.

Other viral infections such as CMV and herpes simplex may resemble IM. The presence of characteristic viral inclusions or the demonstration of viral proteins by immunohistochemistry aids in distinction from IM.

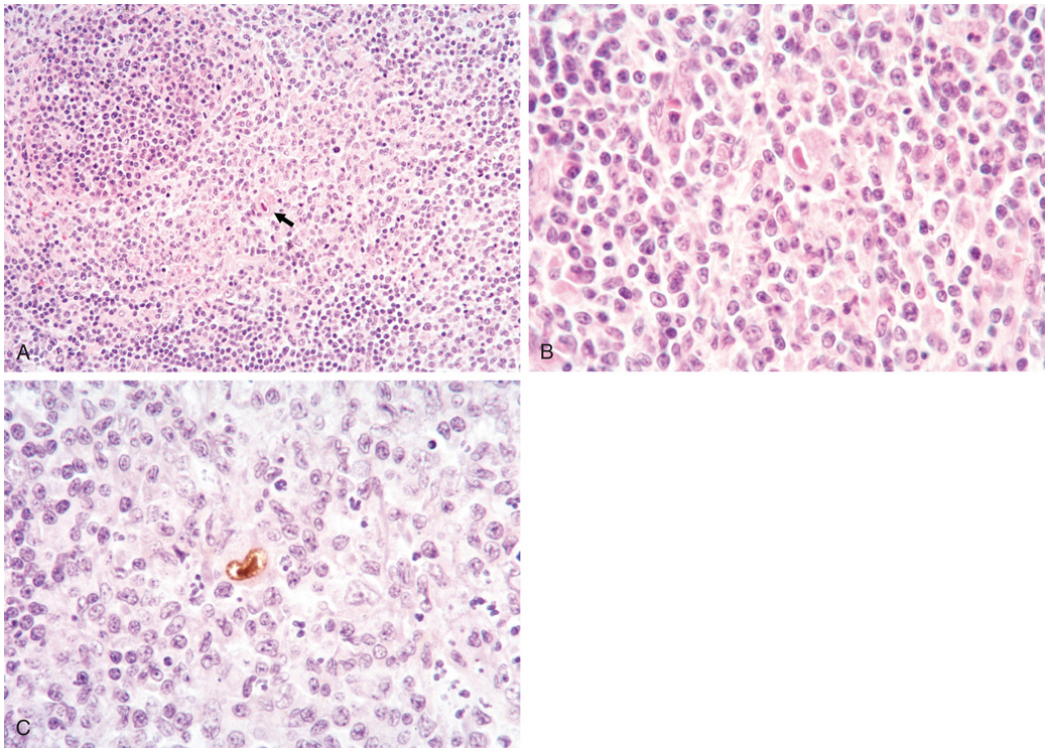

FIGURE 8-26 Lymph node from an immunocompetent patient with cytomegalovirus (CMV) infection.**A,** Among the parafollicular monocytoid B cells is a large cell *(arrow)* with a prominent intranuclear inclusion (H&E, ×70). **B,** Higher magnification of the intranuclear inclusion (H&E, ×180). **C,** Anti-CMV antibody-positive intranuclear inclusion (immunoperoxidase [anti-CMV], ×500).

Cytomegalovirus Infection

CMV infection may resemble the clinical picture of IM, but the heterophile antibody test is negative.[221] The infection affects both immunosuppressed and immunocompetent individuals. Lymph nodes show follicular or paracortical hyperplasia with scattered

immunoblasts, which may resemble RS cells.[222] A hallmark feature is monocytoid B-cell hyperplasia along sinuses (**Fig. 8-26**). CMV-infected cells are usually found among the monocytoid B cells. The infected cells contain large acidophilic and intranuclear viral inclusions and multiple small cytoplasmic inclusions. Less frequently, viral inclusions are seen in endothelial cells. In immunocompetent individuals, the inclusions may be sparse, but if present are in T cells (both CD4- and CD8-positive) but not in B cells.[223] They should be diligently searched for in a lymph node biopsy with an unexplained prominent monocytoid B-cell proliferation.

CMV-infected cells may express CD15 in their cytoplasm, but not on their membranes. This phenotype and the presence of large inclusion-bearing cells may cause confusion with CHL.[224] In contrast to CMV-infected cells, classical RS cells express membrane CD15 and cytoplasmic positivity. In addition, the absence of the typical background of CHL favors CMV lymphadenitis. CMV antigens may be confirmed by immunohistochemistry or by in situ hybridization, both of which are useful, especially in cases without well-developed inclusions.[225]

Herpes Simplex Lymphadenitis

Herpes simplex (Type I or II) produces a lymphadenitis that is most often localized to inguinal lymph nodes but may also be disseminated, and seen predominantly, but not exclusively, in immunocompromised hosts, including patients with chronic lymphocytic leukemia (CLL).[226] When an area of necrosis is found in

a lymph node involved by CLL, herpes simplex infection should be ruled out.

The histologic picture varies. There may be FH with expansion of the paracortex by a proliferation of immunoblasts, resembling other viral infections. Monocytoid B cells may be prominent and mimic marginal zone lymphoma.[227] Usually, foci of necrosis are present containing neutrophils and varying numbers of large cells with margination of nuclear chromatin and prominent nuclear inclusions resulting in a ground-glass appearance (**Fig. 8-27**). Intranuclear eosinophilic inclusions with clear halos have also been reported. Histiocytes often surround necrotic foci, but granulomas are absent.[227] The diagnosis can be confirmed by immunostaining, serology, or in situ hybridization.[228,229]

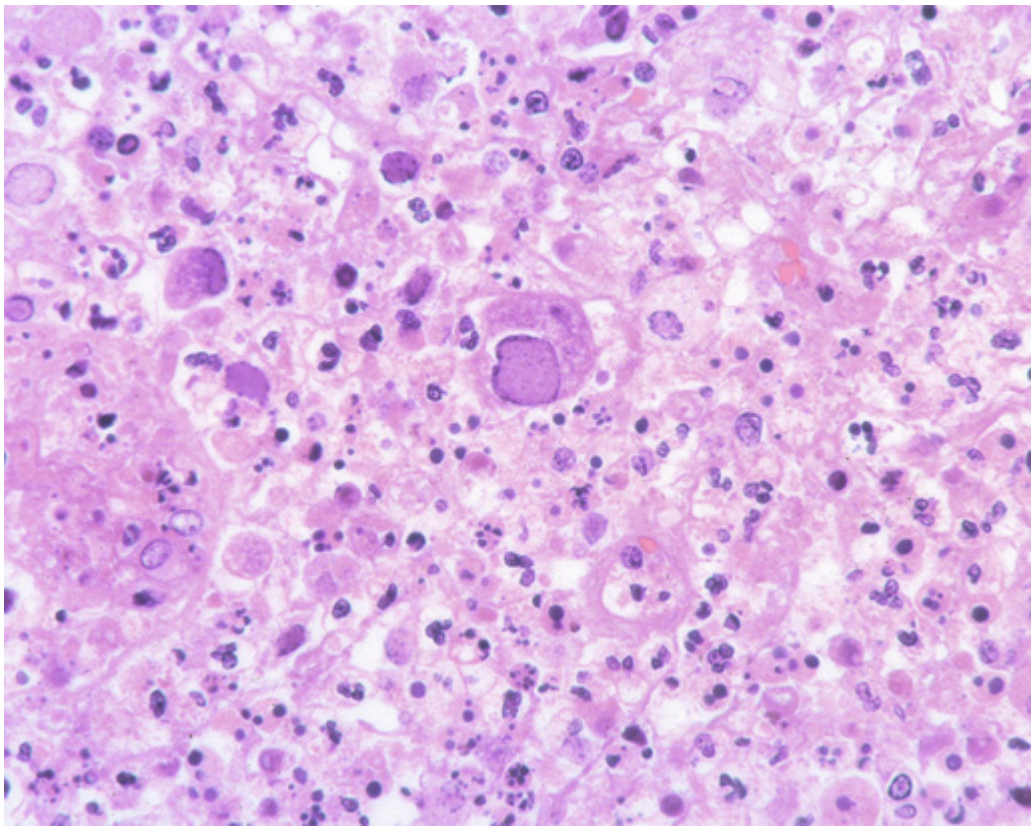

FIGURE 8-27 Lymph node from a patient with chronic lymphocytic leukemia shows a focus of necrosis containing large cells with margination of nuclear chromatin and a ground-glass nucleus characteristic of herpes simplex infection (H&E, ×625).

Drug-Associated Lymphadenopathy

Lymphadenopathy associated with anticonvulsant therapy (diphenylhydantoin most commonly, less often carbamazepine)[230,231] has been the subject of numerous individual case reports and a few larger series. Since its description a similar pattern has been seen in association with other drugs, including various antibiotics. Rarely, cases of lymphoma have developed in

patients using diphenylhydantoin,[232] but a causal role of diphenylhydantoin in the development of lymphoma has not been demonstrated.[233] The syndrome associated with this reaction has been termed drug-induced hypersensitivity syndrome (DIHS) and drug reaction with eosinophilia and systemic symptoms (DRESS). Most patients with suspected DRESS have been on therapy for a prolonged period (median of 2 years), although some have been treated for less than 6 months. Common symptoms include fever, rash, weight loss, fatigue, organomegaly, and eosinophilia. Lymphadenopathy may be localized or generalized.[233]

The histologic appearance is variable. The most common feature is paracortical expansion by a polymorphous population of immunoblasts, plasma cells, histiocytes, and eosinophils, together with high endothelial venules; Reed-Sternberg–like cells may be found (**Fig. 8-28**).[35,59] There is variable FH, and some cases show regressed GCs.[233] Immunophenotyping usually shows an intact immunoarchitecture, and many of the immunoblasts are B cells.

The differential diagnosis includes both CHL and non-Hodgkin lymphomas, and viral and autoimmune lymphadenitis. Although the immunoblasts, including Reed-Sternberg–like cells, may express CD30, they are CD15 negative and CD45 positive, which helps exclude a diagnosis of CHL. When immunoblasts predominate, gene rearrangement studies can be useful to assess clonality[234,235]; however, rare cases of anticonvulsant-related lymphadenopathy can be monoclonal. The bone marrow may also be involved, making the diagnosis of a benign condition even more problematic. Viral-induced lymphadenopathy usually lacks eosinophils in the nodal infiltrate and there is no peripheral blood eosinophilia. The clinical

history is essential to making this diagnosis. Cessation of the drug should result in resolution of the lymphadenopathy within several weeks.[62,236]

Pearls and Pitfalls

- Knowledge of the spectrum of reactive changes that occur in lymph nodes is essential for accurate diagnosis of both benign and malignant entities.
- A pattern-based approach to reactive lymphadenopathy provides a framework for establishing a differential diagnosis, ancillary study selection, and guiding clinical management.
- Clonality studies and immunohistochemical stains should be used with caution and interpreted in the context of morphologic findings to avoid overdiagnosis of malignancy.

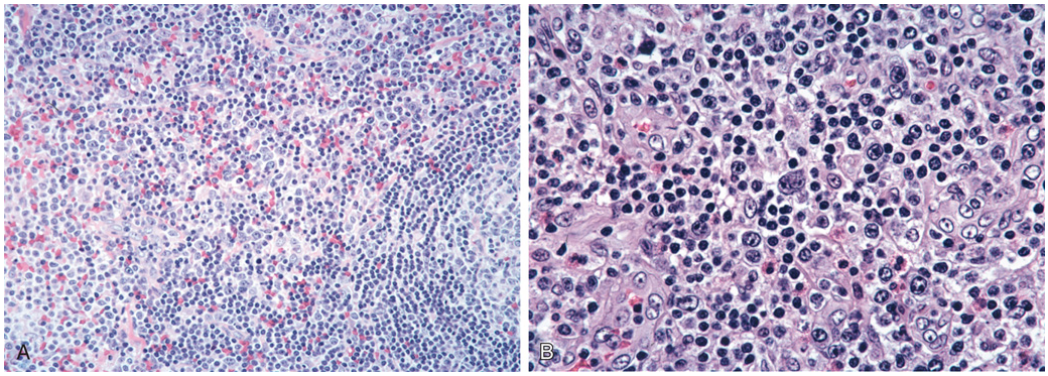

FIGURE 8-28 Lymph node from a patient taking Dilantin for epilepsy.**A,** The interfollicular area is expanded by a polymorphous infiltrate. A portion of a follicle is present on the right (H&E, ×40). **B,** Interfollicular area containing lymphocytes, immunoblasts, histiocytes, eosinophils, and high endothelial venules. A Reed-Sternberg–like cell is present (H&E, ×330).

Chapter 9: The Normal Bone Marrow

Sonam Prakash, Anjanaa Vijayanarayanan, and Laura E. Brown

OUTLINE

INTRODUCTION

MEDICAL INDICATIONS FOR BONE MARROW EXAMINATION

COMPONENTS OF A BONE MARROW EVALUATION

COLLECTION OF BONE MARROW ASPIRATE AND CORE BIOPSY

- **Anatomic Sites**
- **Collection Procedures**
- **General Approach**
- **Bone Marrow Trephine Biopsy Procedure and Touch Imprints**
- **Bone Marrow Aspiration Procedure**

PROCESSING OF MARROW TREPHINE BIOPSY AND ASPIRATE

- Trephine Biopsy
- Bone Marrow Aspirate
- Staining of Bone Marrow Aspirate Smears

BONE MARROW EVALUATION

- Hematopoiesis
- Erythropoiesis
- Granulopoiesis
- Megakaryopoiesis
- Other Myeloid Cells
- Bone Marrow Lymphoid Cells
- Other Cells Present in Normal Bone Marrow

CYTOCHEMISTRY AND HISTOCHEMISTRY

- Cytochemistry
- Histochemistry
- Immunophenotyping Including Immunohistochemistry

BONE MARROW EXAMINATION AND REPORTING

CONCLUSION

INTRODUCTION

Meaningful examination and interpretation of a bone marrow specimen requires an adequate and well-prepared sample and knowledge of normal hematopoiesis as well as normal bone marrow composition and architecture. The definition of "adequacy" depends on the clinical indication for the examination. For example, for staging metastatic disease or lymphoma, a bilateral bone marrow core biopsy is superior to a unilateral biopsy[1-3]; thus for this purpose, a bilateral biopsy defines adequacy. In contrast, for the diagnosis of acute leukemia, a unilateral bone marrow aspiration and core biopsy are usually sufficient, in conjunction with appropriate immunophenotyping and genetic studies. This chapter outlines how to collect and process an adequate bone marrow specimen and describes the features of normal bone marrow and hematopoiesis.

MEDICAL INDICATIONS FOR BONE MARROW EXAMINATION

In general, a bone marrow examination is called for when there are hematologic abnormalities that cannot be explained by available clinical and laboratory data. A peripheral blood smear should always be evaluated before deciding whether a bone marrow examination is necessary. Aside from the diagnostic purposes outlined in **Table 9-1**, staging for metastatic disease and monitoring therapy for antineoplastic effects and/or hematologic toxicity constitute the other two broad indications for bone marrow evaluation.

If the peripheral blood has a sufficient quantity of blasts to meet the diagnostic criteria for acute leukemia and allow other ancillary studies, it has been suggested that a bone marrow examination is superfluous. This approach may save time and money and it is attractive to spare the patient from the discomfort of an invasive procedure. However, subsequent evaluation of postchemotherapy marrow requires knowledge of the preinduction bone marrow landscape and blast proportion.

Comorbid conditions such as coagulopathy, infection close to the proposed biopsy site, or prior radiation to the biopsy site should be carefully assessed before performing a bone marrow biopsy. However, such factors are not necessarily contraindications to biopsy, and the procedure can often be modified to accommodate these circumstances. For example, factor replacement or reversal of anticoagulant therapy may be implemented in the case of severe coagulopathy. The sternum may be selected as the marrow aspiration site if infection or radiation to the pelvis is a concern. Of note, thrombocytopenia is a common indication for bone marrow examination and is not usually in itself a contraindication to bone marrow aspiration as long as pressure is meticulously applied for hemostasis afterward. Thus, when bone marrow examination is truly justified, the aspiration and biopsy can usually be accomplished safely.

Table 9-1

COMPONENTS OF A BONE MARROW EVALUATION

A thorough bone marrow examination includes both marrow aspiration and trephine biopsy. A bone marrow aspirate is required for accurate blast enumeration, differential count, and evaluation of dysplasia, as well as for ancillary studies including flow cytometric immunophenotyping and cytogenetic/molecular genetic studies. A trephine biopsy is required for the assessment of cellularity, architecture of the marrow, fibrosis, and stromal changes, as well as for immunohistochemical studies. For focal processes involving the marrow, such as metastatic tumors, both aspirate smears and trephine biopsies should be evaluated. In a study of more than 4000 diagnostic bone marrow specimens over a 10-year period, approximately 30% of carcinomas would have been missed if only the aspirate had been examined. Conversely, in 9% of bone marrow specimens positive for metastatic carcinoma, the diagnosis was made on the aspirate alone.[1] The benefit of examining both the marrow aspirate and core biopsy also applies to the diagnosis of less focal processes, particularly during follow-up. For example, Barekman and colleagues[1] reported positive findings in the biopsy but not in the aspirate in 20 of 576 marrow specimens obtained as follow-up for acute leukemia. Occasionally, despite a marrow “packed” with leukemic blasts at diagnosis, the aspirate may be sparsely cellular and diagnosis and phenotypic characterization rest on the trephine biopsy. Taken together, these data justify the collection of both marrow aspiration and core biopsy. In general, a bilateral biopsy is recommended to detect marrow involvement by lymphoma, metastatic tumor, or other focal infiltrative processes. Bilateral aspiration may also be considered, especially for staging small cell tumors of childhood.

In addition to obtaining aspirate and trephine biopsy samples for morphologic examination, consideration should be given to procuring sufficient samples for ancillary studies necessary for accurate diagnosis or prognosis. Diagnosing hematopoietic disorders requires a multiparametric approach that includes morphology, immunophenotype, genetic features, and clinical features.[4,5] In general, if the differential diagnosis includes a malignancy, aspirate samples should be obtained for flow cytometric immunophenotyping, cytogenetic, and molecular genetic analyses. Samples for bacterial, mycobacterial, fungal, or viral cultures should be collected if an infectious process is suspected. Consideration should be given to selecting the anticoagulant that is best suited to performance of these various studies.

COLLECTION OF BONE MARROW ASPIRATE AND CORE BIOPSY

Anatomic Sites

In both adults and children, the posterior superior iliac crest is preferred because of its relative distance from other vital structures and its relatively large surface area, which allows the maneuvering of biopsy and aspiration needles. An alternative site in adults is the sternum, but only marrow aspiration can be performed at this location; core biopsies cannot be performed at the sternum. Sites within previous fields of radiation should be avoided as radiation-induced hypocellularity may persist for years.

Collection Procedures

Whether trephine biopsy or aspirate should be performed first is a matter of debate; however, each sample should be obtained through a separate bone puncture 0.5 to 1 cm away from each other and with a separate and appropriate needle to minimize morphologic distortion from hemorrhage.[6,7] Detailed instructions on how to perform the bone marrow core biopsy and aspiration are beyond the scope of this chapter. Importantly, informed patient consent must be obtained after a careful discussion of the risks and benefits. The following discussion focuses on aspects of the procedure that are relevant to the handling of specimens.

General Approach

Because sterile techniques minimize infectious complications, it is helpful to work with a trained medical technician or technologist who can assist with the handling. Once the procedure begins, it is important to proceed quickly and efficiently to minimize patient discomfort and the clotting of specimens. It is important to plan for the number of core biopsies needed, aspirate volumes, and types of anticoagulants necessary for all required laboratory testing, and, because each successive aspirate becomes more hemodiluted, the sequence in which the various aspirate samples are to be obtained. It is generally recommended that the first aspirate be reserved for morphology.[8] Samples obtained for morphology should ideally be collected without anticoagulant, but if smears for examination cannot be prepared immediately, the aspirated marrow can be placed in ethylenediaminetetraacetic acid (EDTA), with the caution that prolonged exposure to EDTA beyond 2 hours can cause morphologic distortion.[7] Heparin should be avoided, as it may also induce

morphologic abnormalities. Specimens for flow cytometric immunophenotyping may be collected in EDTA, or alternatively in sodium heparin or acid citrate dextrose. DNA- and RNA-based molecular assays typically require collection in EDTA, while preservative-free heparin is preferred for cytogenetic studies (karyotype and fluorescence in situ hybridization [FISH]). It is important that the individual performing the aspiration and core biopsy procedure be familiar with the specimen requirements of each specialty laboratory so that the correct anticoagulants are used.

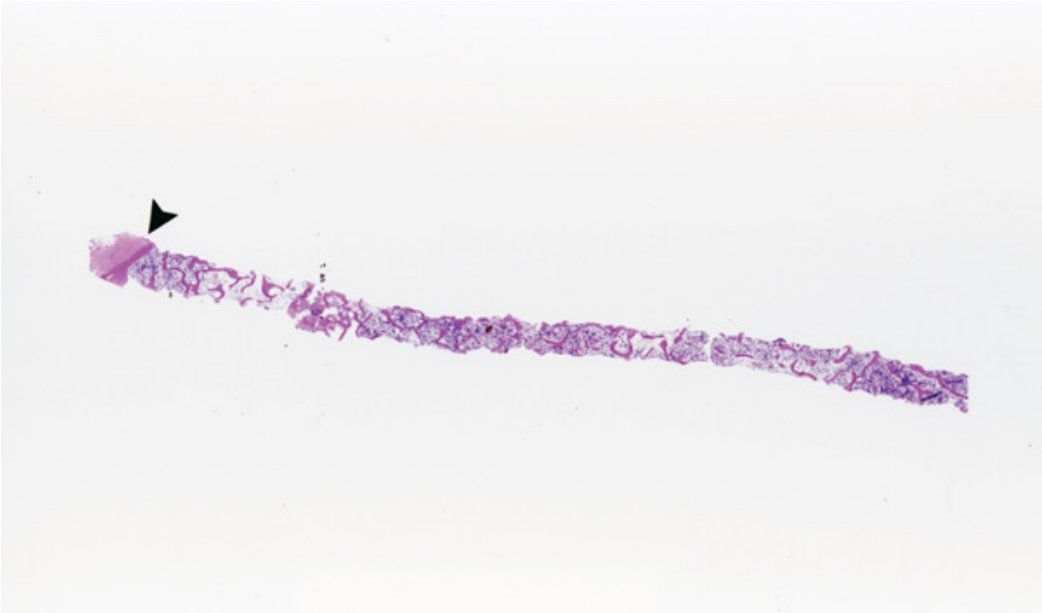

FIGURE 9-1 An example of an excellent core biopsy (>1 cm long) consisting of mostly marrow, with very little cortical bone or periosteal soft tissue *(arrowhead)*, and with minimal crush artifact or hemorrhage.

Bone Marrow Trephine Biopsy Procedure and Touch Imprints

Several versions of the Jamshidi biopsy needle are available for procuring the core biopsy. Most adult patients require a 4-inch, 11-gauge needle. When patients are osteopenic, a larger bore needle (8-gauge) allows the collection of an intact core biopsy while minimizing crush artifact. For pediatric patients, a 2- or 4-inch 13-gauge biopsy needle is sufficient. Sola and associates[9] described a bone marrow biopsy technique for neonates in which a 1/2-inch, 19-gauge Osgood needle is used, but in practice, neonatal bone marrow collection is limited to aspiration in some centers. Various powered devices for accessing the bone marrow and procuring core biopsies have become increasingly popular because of a reduction in patient-perceived pain, longer core biopsies, and decreased procedure time.[10]

With the exception of young pediatric patients, an adequate core biopsy prior to fixation should be at least 1.6 cm to 2.0 cm long exclusive of cortical bone, periosteum, and cartilage, and should be free of crush artifact or fragmentation (**Fig. 9-1**).[5] Some studies have suggested that the number of intertrabecular 40× areas of evaluable marrow might be a better predictor of adequacy than core biopsy length.[11] In a study of 470 core biopsies, O'Neill et al. demonstrated that cores with ≥5.5 intertrabecular areas were contributory to diagnosis.[11] Grossly, cores of marrow have a finely mottled, deep red color and a gritty texture. When the marrow is severely hypoplastic the core may appear pale yellow but should still have a gritty surface. Marrow completely replaced by leukemia, lymphoma, or other neoplasms may appear white. Cortical bone, in contrast, often has an

ivory color with a hard, smooth surface, and cartilage is gray-white and glistening, characteristics that should prompt the operator to make another attempt. If an adequate aspirate cannot be obtained, collection of multiple core biopsies may be considered to increase the amount of material available for ancillary studies, particularly in cases of suspected hematopoietic neoplasm that do not significantly involve the peripheral blood.

Touch preparations are a valuable adjunct to morphologic examination of the bone marrow aspirate and are particularly valuable if an adequate bone marrow aspirate cannot be obtained. There are several ways to prepare touch imprints. First, the core can be gently blotted to remove adherent blood. Several clean glass slides are then touched gently to the marrow core. One can also touch the cores to the glass slides. Alternatively, the core is gently rolled between two glass slides, which may yield more cells but carries a higher risk of fragmentation of the core and crush artifact. Once touch imprints have been prepared, the core biopsy should be immediately placed in fixative.

Bone Marrow Aspiration Procedure

For collection of the bone marrow aspirate, although the needle is advanced through the same skin incision used for the biopsy, the site of bone puncture should be separate from the site of the trephine biopsy, preferably 0.5 to 1.0 cm away. This minimizes the risk of obtaining an aspirate composed only of clotted blood, as well as the risk of core biopsy distortion by hemorrhage. Because each successive aspiration becomes more hemodiluted, a rapid and forceful aspiration of 0.5 to 1.0 mL should be obtained first for

morphologic examination. Additional aspirations can be obtained, in sequence, for flow cytometry followed by cytogenetics, molecular diagnostic evaluation, and culture, as applicable. The needle used to collect the samples for morphologic examination should be free of anticoagulant, whereas the syringes used for other studies should be coated in the appropriate anticoagulant. Undiluted bone marrow aspirate is deep red in color and slightly thicker than blood, and flecks of marrow spicules may be visible.

PROCESSING OF MARROW TREPHINE BIOPSY AND ASPIRATE

Trephine Biopsy

The following discussion applies to paraffin embedding only.

Fixation

Accurate microscopic evaluation of the bone marrow core biopsy can direct the appropriate selection of ancillary immunohistochemistry and other special studies or may even obviate their need (**Fig. 9-2**). It is important to recognize the essential role of the core biopsy for immunophenotypic characterization of myeloid and lymphoid neoplasms when the aspiration yields a dry tap, or the aspirate is hemodiluted. Optimal fixation of the core biopsy for preservation of morphologic detail and preservation of tissue for subsequent immunohistochemical studies is essential.

Mercury-based fixatives such as Zenker's and B5 solutions were previously used as they provided excellent cytologic detail. However, they are now unavailable in many countries because of their mercuric chloride content.[12] In laboratories where bone marrow

trephine biopsies are processed along with other surgical specimens, neutral buffered formalin is often used. Excellent morphologic detail can be achieved with this fixative,[13] but care should be taken to ensure adequate fixation time relative to the diameter of the biopsy. Zinc acid formalin also provides excellent morphologic detail and has a somewhat shorter fixation time. Core biopsies should be placed in 10 to 20 mL of fixative. The recommended fixation time for neutral buffered formalin is 8 to 72 hours[12] and for zinc formalin, at least 2 hours but ideally overnight to 72 hours.[12]

Decalcification

After fixation, the core biopsy is removed from the fixative, rinsed with several changes of water, and then decalcified. Several types of decalcification solutions exist, which vary in their decalcification times and degree of preservation of antigenic epitopes and nucleic acids. While hydrochloric-acid based decalcification solutions offer the most rapid decalcification, they are also the least likely to preserve nucleic acids, although antigenic epitopes for immunohistochemistry are generally retrievable. EDTA-based formulas offer the best preservation of nucleic acids for molecular studies and FISH, but the long decalcification time required may result in longer turnaround times for core biopsies. Formic acid–based solutions occupy a middle ground, offering both a moderate degree of nucleic acid preservation as well as a reasonably short decalcification time.[12,14] Some laboratories may prefer to use rapid decalcification for most routine cases in which sufficient fresh aspirate is available for ancillary testing, reserving the use of solutions with longer turnaround time for those specimens with

limited alternative material for special studies (e.g., dry tap). Following decalcification, the biopsy should again be washed in several changes of water before being placed in neutral buffered formalin for processing in an automated tissue processor.

Sectioning

Ideally, the paraffin-embedded core biopsies should be sectioned in thicknesses of 3 µm and preferably no more than 4 µm. The importance of adequate sampling cannot be overemphasized, especially if marrow involvement by a focal process such as metastatic disease is a consideration. Statistical modeling has shown that false-negative rates for the detection of metastatic tumor in bone marrow biopsies is inversely proportional to the number of sections examined.[15] While the appropriate number of sections to be prepared also depends on several factors, including laboratory resources and the types of diseases likely to be encountered, at a minimum, several step sections should be mounted for microscopic examination.

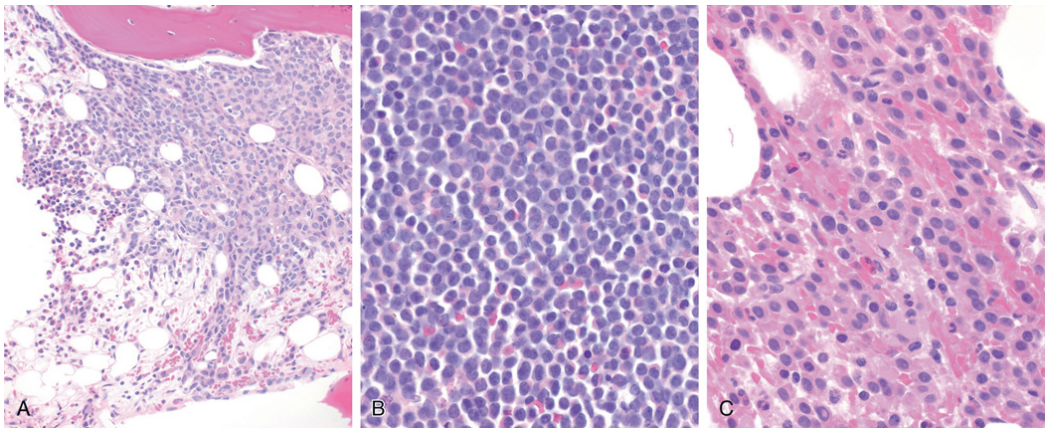

FIGURE 9-2 Hematoxylin-eosin–stained trephine sections of bone marrow specimens.**A,** Metastatic carcinoma involving bone marrow. **B,** Acute myeloid leukemia. **C,** Marrow infiltration by plasma cells in a patient with a plasma cell neoplasm.

Staining

If the core biopsy has been well-fixed, decalcified, processed, and sectioned, routine hematoxylin-eosin staining provides excellent histologic detail. Depending on the individual laboratory and patient population, other stains may be routinely performed. Periodic acid–Schiff (PAS) stains provide a means of evaluating morphology and simultaneously visualizing fungal organisms and may be helpful in institutions with large populations of immunocompromised patients. In cases of myeloproliferative neoplasms, assessment of marrow fibrosis is best done with a silver impregnation stain for reticulin; the normal presence of reticulin fibers around arterioles serves as an internal positive control (**Fig. 9-3**). Collagenous fibrosis is uncommon in the bone marrow and should be looked for on a case-

by-case basis. Giemsa stain can be helpful in highlighting mast cells and plasma cells and in distinguishing myeloblasts from proerythroblasts. There is a high false-negative rate with iron stains of decalcified core biopsy sections, caused by chelation of iron during decalcification[16]; therefore routine iron staining of the core biopsy is not recommended.

Bone Marrow Aspirate

From the 0.5 to 1.0 mL of fluid marrow aspirate obtained for morphologic examination, several preparations can be made that allow the maximal use of all components of the sample: direct smears, particle crush preparations, and particle clot sections. Buffy coat smears are labor intensive and may not add much to the morphologic evaluation; therefore they are not commonly performed.[17]

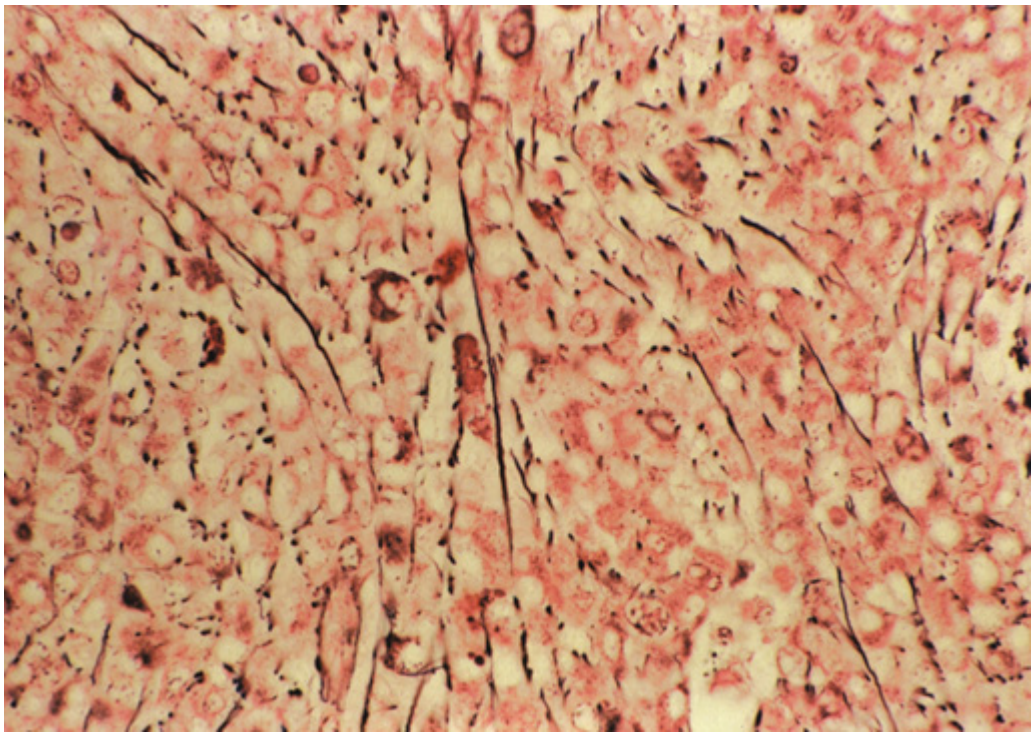

FIGURE 9-3 Reticulin stain of the bone marrow core section of a patient with chronic myeloid leukemia showing increased reticulin fibers *(brown-black lines)* within the marrow interstitium, away from the expected normal perivascular location *(Wilder reticulin stain)*.

Direct Smears

As soon as possible, after the 0.5 to 1.0 mL of the first non-anticoagulated fluid marrow is aspirated, most of it is transferred to an EDTA-containing tube. The tube should be inverted several times to ensure adequate mixing. This anticoagulated tube can be used for preparation of additional aspirate smears for morphology and other studies such as iron stains and cytochemistry; if applicable it can also be used to prepare buffy coat smears.

From the remaining non-anticoagulated fluid, individual drops of marrow are quickly placed directly on 6 to 10 glass slides, and a spreader device is used to create aspirate smears. These smears are dried quickly for the preservation of cytologic detail.

Particle Crush Preparation

For particle crush preparation, contents of the EDTA-anticoagulated tubes are placed in a clean Petri dish. Marrow spicules should be picked up, placed on three to four clean glass slides, and gently squashed by placing another glass slide on top and pulling the two slides apart in opposite but parallel directions.

Particle Clot Sections

Any marrow spicules that remain in the Petri dish are rinsed with 0.015 M calcium chloride and pushed close together to form a clot. These particle clots are processed similarly to the core biopsy, but without decalcification. Alternatively, all remaining marrow spicules and fluid can be mixed and dispersed in formalin, filtered, and embedded as a cytoblock. Since marrow clots or cytoblocks are not decalcified, in addition to providing morphologic information, they are also suitable for FISH or molecular studies and can serve as archival material for such studies.

Relative Utility of Different Marrow Aspirate Preparations

Not all these aspirate preparations are necessary for every case, and their contribution to the bone marrow examination sometimes overlaps. On one hand, the direct smears provide excellent cytologic detail with minimal distortion by anticoagulation or centrifugation. On the other hand, examination of a hypocellular specimen can be

tedious, and the cell distribution may be uneven. The particle crush preparation bears the closest resemblance to marrow tissue in vivo and allows an approximation of cells' spatial relationship, but also results in more damaged nuclei.

Table 9-2 summarizes the different components of a bone marrow examination and the various types of stains and studies applicable to the specific preparations.

Finally, when staining marrow touch imprints and aspirate preparations for routine morphologic examination, the laboratory should save several unstained preparations for potential additional but unforeseen studies that may arise during the course of the diagnostic evaluation, such as esterase or myeloperoxidase cytochemistry. Molecular testing can also often be successfully carried out using DNA extracted from scrapings of unstained aspirate smears.

Dry Tap

Approximately 2% to 7% of attempts at marrow aspiration yield no fluid, resulting in the so-called "dry tap."[18] In a review of over 1000 bone marrow aspirations and biopsies, Humphries found that faulty technique accounted for just 6.9% of dry taps.[18] Common reasons for dry tap include underlying bone marrow damage or diseases such as aplastic anemia, hairy cell leukemia, advanced-stage myeloproliferative neoplasms, acute megakaryoblastic leukemia, mastocytosis, or acute leukemia, among others. In these circumstances, one should ensure that sufficient touch imprints are made for cytologic examination, and if feasible, additional core

biopsies should be obtained for special studies such as cytogenetics, flow cytometry immunophenotyping, and molecular genetics.

Table 9-2

Components of a Bone Marrow Examination and Applicable Stains and Studies

Examination Component	Stain and Method of Analysis
Bone marrow trephine biopsy	H&E Reticulin PAS Immunohistochemistry When freshly collected and prior to fixation, can also be used for cytogenetics, flow cytometry immunophenotyping analysis, molecular diagnostics, and cultures in case of a “dry tap”
Marrow touch imprint	Wright-Giemsa Cytochemistry If unfixed and unstained, can be scraped for DNA extraction for molecular diagnostics
Bone marrow aspirate fluid	Flow cytometry immunophenotyping analysis Cytogenetics Molecular diagnostics Cultures

Examination Component	Stain and Method of Analysis
Bone marrow aspirate smear	Wright-Giemsa Cytochemistry Prussian blue If unfixed and unstained, can be scraped for DNA extraction for molecular diagnostics
Particle clot section	H&E PAS Immunohistochemistry In situ hybridization (FISH or CISH) Prussian blue Molecular diagnostic studies

H&E, Hematoxylin and eosin; *PAS,* periodic acid–Schiff.

Staining of Bone Marrow Aspirate Smears

Wright-Giemsa Stain

The importance of a well-stained marrow aspirate smear cannot be overemphasized (Figs. **9-4** and **9-5**). A poorly stained aspirate smear can mislead and frustrate. For air-dried marrow touch imprints and aspirate preparations, a Romanowski-type stain such as Wright-Giemsa or May-Grünwald-Giemsa is often used for morphologic evaluation. With either staining method, for optimal results, slides should be stained within 24 hours of preparation. Slides previously poorly stained with Wright-Giemsa can sometimes be salvaged by restaining within 1 to 2 months from the time of collection.

Iron Stains

For the assessment of storage iron, a Prussian blue stain can be performed on any marrow aspirate preparations with identifiable macrophages (see **Fig. 9-6A**). It is essential that adequate marrow particles be examined to avoid a false-negative interpretation. Although stainable iron may be found in a single particle, it is recommended that a minimum of seven particles be examined to accurately establish the absence of storage iron.[19] A grading system for iron assessed on bone marrow aspirate smears was proposed by Gale et al. (**Table 9-3**).[20] If necessary, an iron stain can be performed on the particle clot sections (**Fig. 9-6B**). The interpretation of iron stores on decalcified core biopsy sections should be undertaken with caution because the absence of storage iron in these specimens may be artifactual rather than true iron depletion.[16] Smears previously stained with Wright stain can be superimposed with Prussian blue reagent to assess storage iron and sideroblastic iron.

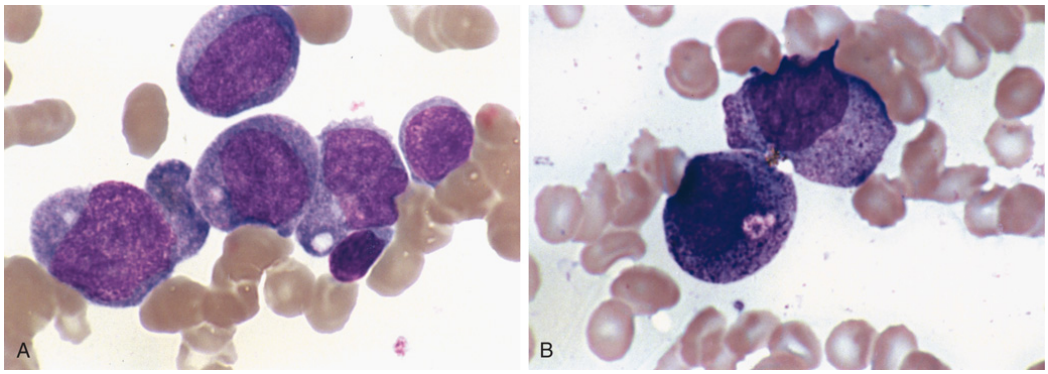

FIGURE 9-4 Wright-Giemsa–stained bone marrow aspirate smears of agranulocytosis in a patient who presented with profound neutropenia.**A,** The original stained smear shows a hypocellular specimen with a relative preponderance of early myeloid precursors, raising the differential diagnosis of blasts versus neutrophilic promyelocytes. **B,** Restaining of the smear with Wright-Giemsa shows the presence of azurophilic granules within the precursors, indicative of neutrophilic promyelocytes. Cytogenetic analysis subsequently revealed a normal karyotype. The neutrophil count recovered within 1 week.

BONE MARROW EVALUATION

Hematopoiesis

Adequate evaluation of the bone marrow requires a basic understanding of normal hematopoiesis and normal bone marrow composition and architecture.

Although hematopoietic stem cells circulate in small numbers, hematopoiesis, in steady-state conditions in adult life, is largely confined to the bone marrow. All hematopoietic cells are ultimately derived from pluripotent hematopoietic stem cells, which give rise to common lymphoid stem cells and multipotent myeloid stem cells.[21] The multipotent myeloid stem cells in turn give rise to lineage-committed progenitors. None of the stem cells or progenitor cells are morphologically distinguishable from one another, but some can be putatively identified clinically on the basis of immunophenotyping by flow cytometry or other methods. Stem cells in the marrow are located in stem cell "niches" adjacent to either bone or blood vessels, where they maintain a close relationship with stromal cells. With the exception of a subset of platelets derived from megakaryocytes lodged in the lungs, all mature blood cells in healthy adults are produced in the bone marrow (**Fig. 9-7**).

Bone marrow hematopoiesis occurs in a specific microenvironment: in the intertrabecular spaces occupied by stroma and hematopoietic cells and surrounded by bony trabeculae. The stroma is composed of stromal cells and a matrix of proteins such as laminin, thrombospondin, and fibronectin. Recognizable stromal elements and cells include blood vessels, nerves, adipocytes, other mesenchymal cells (e.g. reticular cells, macrophages, fibroblasts), and a delicate fiber network. The earliest recognizable granulocyte precursors—myeloblasts and promyelocytes—are located abutting the endosteum and surrounding arterioles. Myelocytes, metamyelocytes, and neutrophils are each found progressively farther from the endosteum. In contrast, the distribution of eosinophilic cells is random, and that of basophils is unknown.

Maturing erythroid cells are found centrally in the intertrabecular space, forming erythroid islands in which erythroid cells of varying maturity surround a central macrophage. Megakaryocytes are also found centrally in the intertrabecular space, preferentially adjacent to sinusoids. Other cellular components of the marrow include mast cells, lymphocytes, plasma cells, monocytes, and macrophages. The normal bone marrow architecture is shown diagrammatically in **Figure 9-8**.

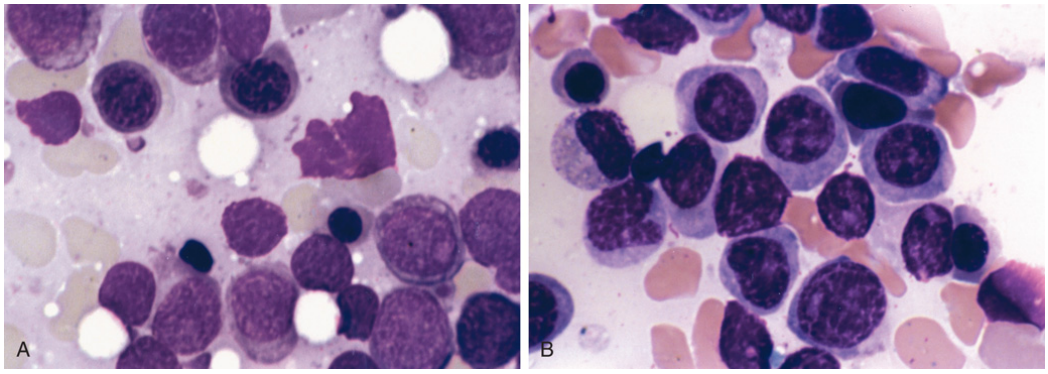

FIGURE 9-5 Wright-Giemsa–stained bone marrow aspirate smears of an adult who presented with anemia.**A,** The original stained smear shows an increased proportion of abnormal cells with overlapping features between plasma cells and basophilic normoblasts. Several polychromatophilic erythroblasts are also present. **B,** Restaining of the smear with Wright-Giemsa confirms the presence of abnormal plasma cells. Subsequent immunohistochemical studies of the core biopsy showed kappa-restricted plasma cell myeloma.

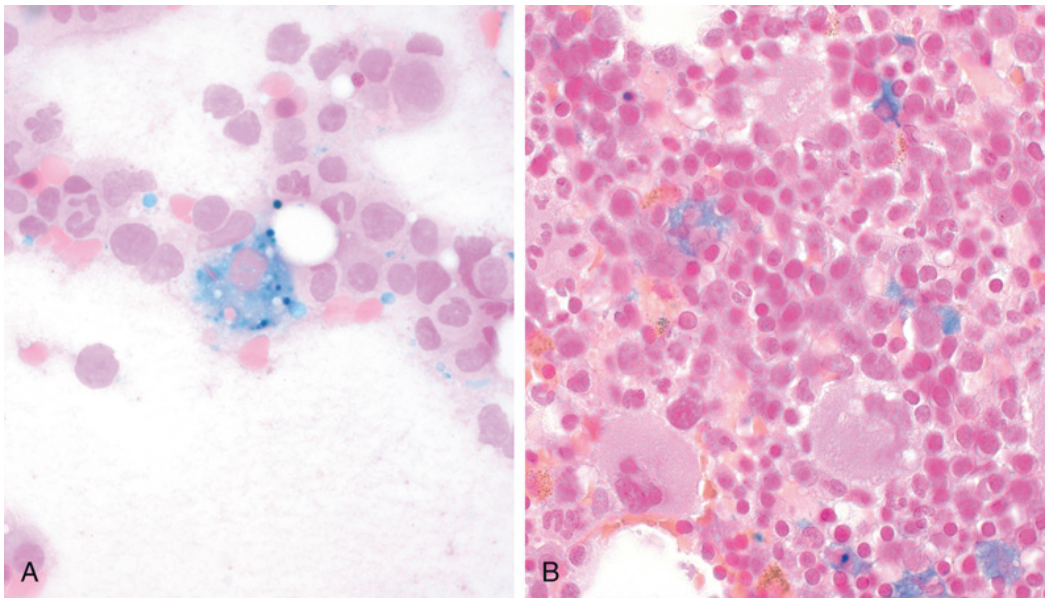

FIGURE 9-6 Iron stains of bone marrow.**A,** Perls stain of a bone marrow aspirate smear showing increased iron within a macrophage. **B,** Prussian blue reaction of a clot section.

Table 9-3

Grading of Iron in Bone Marrow Aspirate Smears

Grade	Description
0	No visible iron under oil immersion
1 +	Small iron particles just visible in macrophages under oil immersion
2 +	Small, sparsely distributed iron particles usually visible under low power magnification
3 +	Numerous small particles present in macrophages throughout the marrow particles
4 +	Larger particles throughout the marrow, with tendency to aggregate into clumps
5 +	Dense large clumps of iron throughout the marrow
6 +	Very large deposits of iron, both intracellular and extracellular, which obscure cellular detail in the marrow particles

Modified from Gale E, Torrance J, Bothwell T. The quantitative estimation of total iron stores in human bone marrow. *J Clin Invest*. 1963;42(7):1076-1082.

The regulation of hematopoiesis is highly complex, involving the interaction of adhesion molecules on hematopoietic cells with their ligands on stromal cells, and the action of hematopoietic growth

factors such as stem cell factor, interleukin (IL)-3, IL-4, IL-5, IL-6, granulocyte-macrophage colony-stimulating factor, granulocyte colony stimulating factor, monocyte colony-stimulating factor, erythropoietin, and thrombopoietin.[22] Growth factors may be secreted locally by bone marrow cells (e.g., granulocyte-macrophage colony-stimulating factor) or they may be secreted at distant sites (e.g., erythropoietin) (**Fig. 9-7**). The ultimate effects of growth factors on hematopoiesis are mediated by transcription factors, which coordinate the proliferation and differentiation signals that reach the cell and establish the ultimate characteristics and phenotype of the mature cell. Although diagrams of hematopoiesis often suggest a unidirectional differentiation along one lineage, evidence suggests that it may be possible to reprogram cells of one lineage to differentiate into another by altering the expression of various transcription factors.[21] It is unclear, however, whether this takes place in normal hematopoiesis, only under experimental conditions or in pathologic situations.

Bone marrow cellularity in healthy people is dependent on age. The proportion of the marrow cavity occupied by hematopoietic and lymphoid cells rather than adipose cells varies from essentially 100% at birth to between 30% and 65% after age 80 years. Between ages 30 and 70 years, cellularity is of the order of 40% to 70%. Except at the extremes of age, a rough estimation of expected cellularity can be derived by subtracting a patient's age from 100. An adequate core biopsy is required for the assessment of marrow cellularity. Subcortical bone marrow is normally hypocellular, and therefore, the first three subcortical spaces are usually not considered in the estimation of cellularity. **Figure 9-9** shows a bone marrow biopsy

section with normal cellularity in comparison with hypocellular and hypercellular bone marrow specimens.

After assessment of bone marrow cellularity, the three main cell lineages—granulocytic, erythroid, and megakaryocytic—should be evaluated and quantified. The normal bone marrow shows a granulocytic:erythroid ratio of 2 to 3:1. Enumeration of cell types and evaluation of cellular details is best performed on the aspirate smears. Evaluation of tissue architecture and cellular distribution is performed on the bone marrow core biopsy.

Erythropoiesis

The morphologic features of erythroid precursors in bone marrow smears and sections are summarized in **Table 9-4** and illustrated in Figures **9-10** to **9-14**. It must be remembered that cellular maturation is a continuum rather than a discrete, sudden change from one stage to the next. In normal bone marrow, cells of each successive stage of maturation are more numerous than those of the preceding. Erythroid islands may be noted in bone marrow aspirates (**Fig. 9-15**), but are more readily apparent in trephine biopsy sections, where they are localized to the intertrabecular space, away from the surface of the bone (**Fig. 9-16**). In trephine biopsy sections, an artifactual halo around round erythroid nuclei can aid in their identification.

Complete assessment of erythropoiesis in aspirate films requires not only a Romanowsky stain (e.g., Wright-Giemsa or May-Grünwald-Giemsa), but also a Perls Prussian blue stain to assess storage iron and determine the presence, number, and distribution of erythroblast siderotic granules. Perls stain identifies hemosiderin,

but not ferritin. Normal late erythroblasts and occasional intermediate erythroblasts have a small number of scattered fine hemosiderin granules (**Fig. 9-17**). A Perls stain on trephine biopsy sections may be informative on plastic-embedded sections to detect abnormal sideroblasts; however, it is less reliable on paraffin-embedded decalcified biopsies as siderotic granules cannot be assessed and storage iron may have been removed by the process of decalcification.

Granulopoiesis

The morphologic features of granulocytic (specifically neutrophil) precursors in bone marrow smears and sections are summarized in **Table 9-5** and illustrated in Figures **9-18** to **9-21**. Maturing cells of eosinophil and basophil lineage can be recognized morphologically from the myelocyte stage onward in aspirate smears. In trephine biopsy sections, eosinophils, neutrophils, and their precursors can be identified, but cells of basophil lineage cannot be easily recognized because their granules are lost during processing.

Megakaryopoiesis

Three stages of megakaryocyte maturation can be recognized in normal bone marrow. All recognizable normal megakaryocytes are large polyploid cells. The smallest immature megakaryocytes measure 30 μm or more in diameter and have a high nuclear-to-cytoplasmic ratio and basophilic cytoplasm, often with cytoplasmic "blebbing." Mature megakaryocytes are large, up to 160 μm in diameter, with a lobulated nucleus and pink or lilac granular cytoplasm (**Fig. 9-22**); sometimes platelets are apparent, budding

from the surface. A late megakaryocyte (**Fig. 9-23**) is similar in size to an immature megakaryocyte because virtually all the cytoplasm has been shed as platelets, leaving a somewhat pyknotic nucleus with a thin rim of cytoplasm. Caution should be exercised in interpreting cytologic features of megakaryocytes because they are prone to crushing during preparation, which may cause the nucleus to fragment or be extruded. The cytoplasm of megakaryocytes occasionally may appear to contain intact cells of other lineages; these are actually within the surface-connected canalicular system. This phenomenon is known as *emperipolesis* (**Fig. 9-24**) and is physiologic but may be exaggerated in various pathologic states. In histologic sections, mature megakaryocytes are readily recognized by their large size, abundant cytoplasm, and lobulated nuclei (**Fig. 9-25**). They can be highlighted by a Giemsa stain or a PAS stain. Late megakaryocytes are recognized as apparently bare megakaryocytic nuclei, which are larger than the nuclei of bone marrow cells of other lineages. Early megakaryocytes can be more difficult to recognize because they are not much larger than other bone marrow cells and their features are not very distinctive. They are more readily identified by immunohistochemistry directed to platelet antigens such as CD61 for platelet glycoprotein IIIa (**Fig. 9-26**) or CD42b for platelet glycoprotein Iba. Care should be taken in interpreting apparent abnormalities of nuclear lobation (e.g., monolobation) in examination of core biopsies, as tissue sectioning often results in an inability to visualize the entirety of a given megakaryocyte.

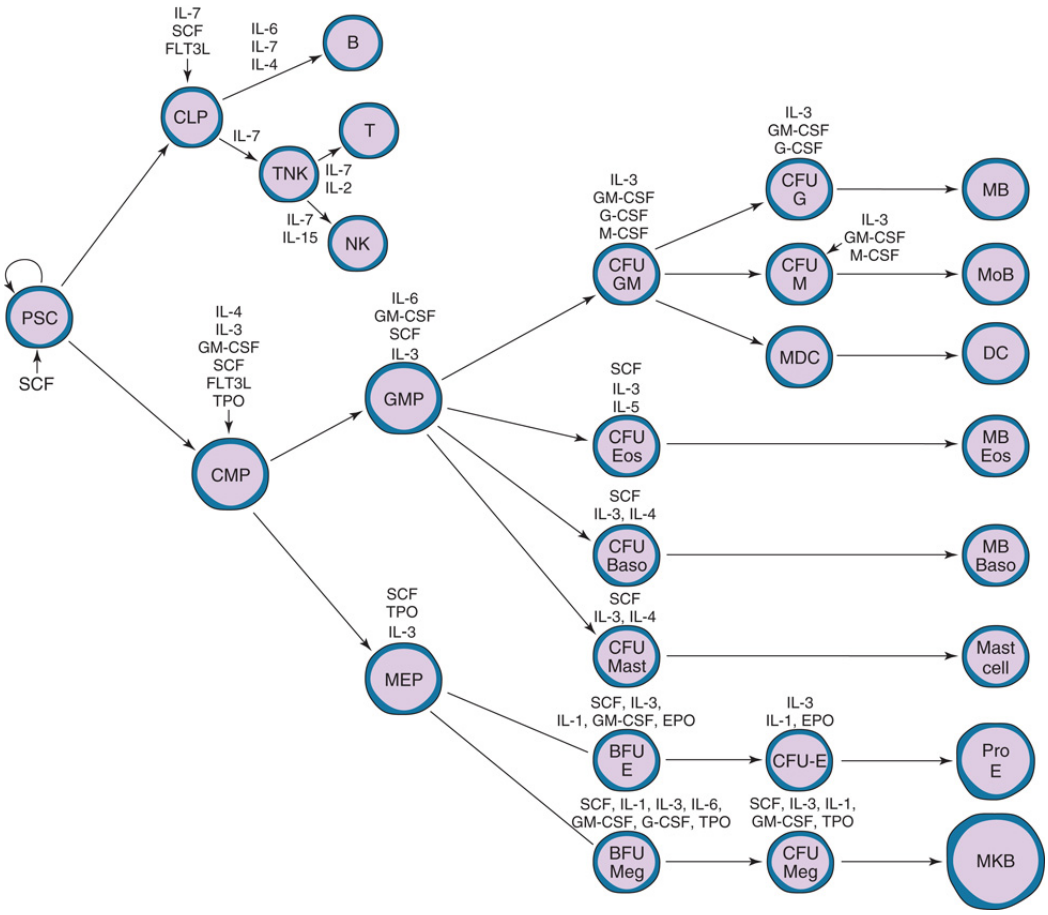

FIGURE 9-7 Diagrammatic representation of one proposed scheme of the stem cell hierarchy[1] showing the growth factors thought to operate at each stage.Alternative models of hematopoiesis have been proposed,[20,21] including one in which the common erythroid and megakaryocytic progenitor arises directly from the pluripotent lymphoid-myeloid stem cell (PSC; also known as the common lymphoid-myeloid progenitor) rather than from the common myeloid progenitor (CMP; also known as *multipotent myeloid stem cells*). *B,* B lymphocyte; *Baso,* basophil; *BFU,* burst-forming unit; *CFU,* colony-forming unit;

CLP, common lymphoid progenitor; *CMP,* common myeloid progenitor; *DC,* dendritic cell; *E,* erythroid; *Eos,* eosinophil; *EPO,* erythropoietin; *FLT3L,* ligand of FLT3; *G,* granulocyte (neutrophil); *G-CSF,* granulocyte colony-stimulating factor; *GM,* granulocyte-macrophage; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *GMP,* granulocyte-monocyte progenitor; *IL,* interleukin; *M,* macrophage; *Mast,* mast cell; *MB,* myeloblast; *M-CSF,* monocyte colony-stimulating factor; *MDC,* myeloid dendritic cell; *Meg,* megakaryocyte; *MEP,* myeloid-erythroid progenitor; *MKB,* megakaryoblast; *MoB,* monoblast; *NK,* natural killer; *ProE,* proerythroblast; *PSC,* pluripotent lymphoid-myeloid stem cell; *SCF,* stem cell factor; *T,* T lymphocyte; *TNK,* T/NK cell progenitor; *TPO,* thrombopoietin.

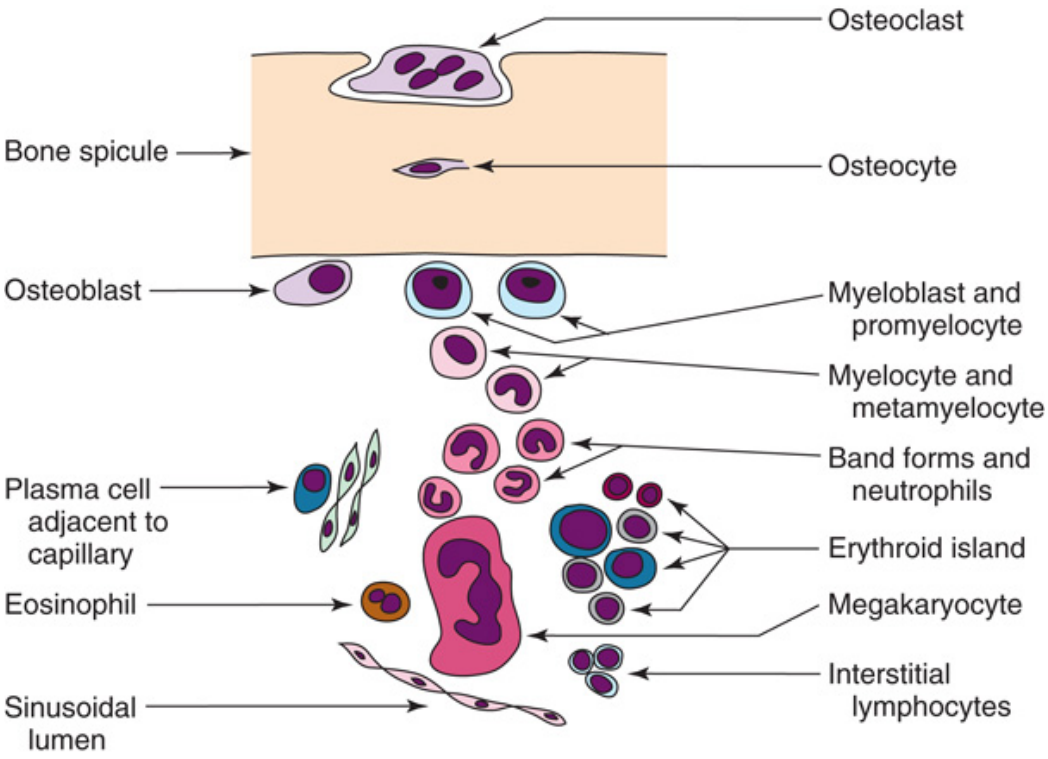

FIGURE 9-8 Diagrammatic representation of the topography of normal bone marrow.Osteoclasts, osteoblasts, myeloblasts, and promyelocytes are adjacent to the spicule of bone. Deeper in the intertrabecular space are maturing cells of neutrophil lineage, erythroid islands with a central macrophage, and interstitial lymphocytes. Eosinophils and their precursors are apparently randomly scattered, plasma cells are interstitial or form a sheath around capillaries, and megakaryocytes abut a sinusoid at one extremity of the cell.

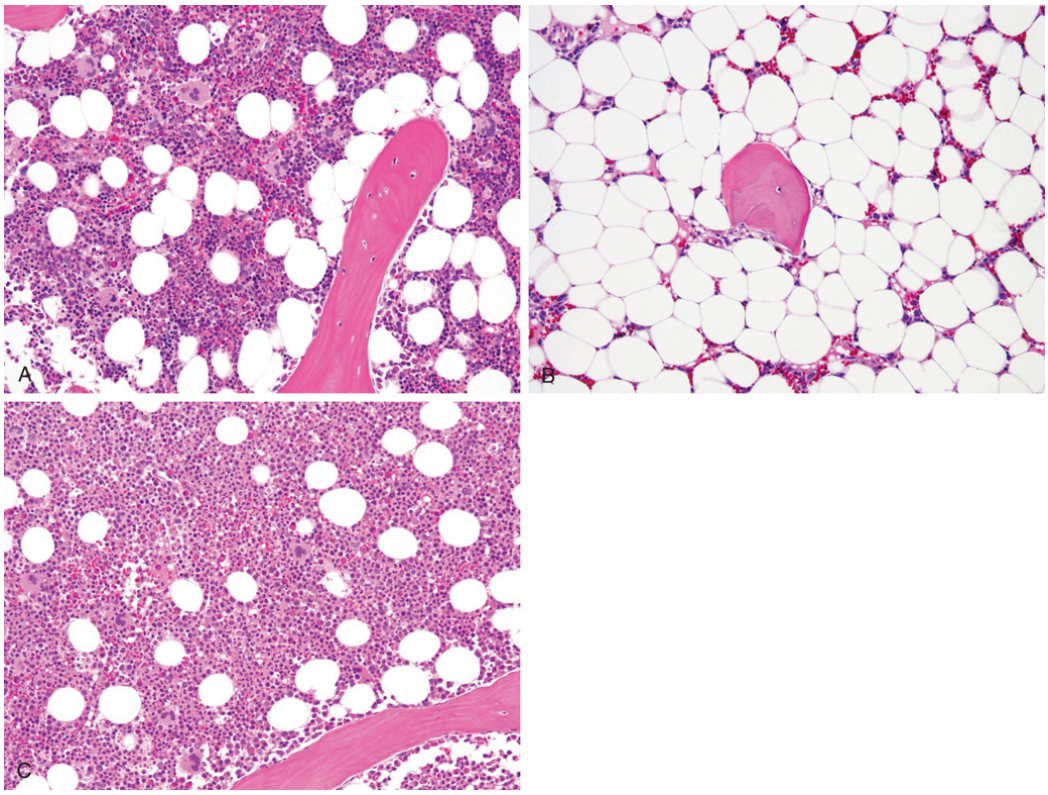

FIGURE 9-9 Bone marrow biopsy of normal cellularity **(A)** compared with hypocellular **(B)** and hypercellular **(C)** biopsies.

In the normal marrow, the megakaryocytes are adjacent to sinusoids and are not found in a paratrabecular localization. Determining whether the number of megakaryocytes present is normal can be difficult and subjective. On the marrow aspirate smears, they are often identified within or near the particles. In core biopsy sections from normal subjects, there are usually three to six megakaryocytes in each intertrabecular space. Clusters of three or more megakaryocytes are not normally seen, nor are tight clusters without intervening cells of other lineages.

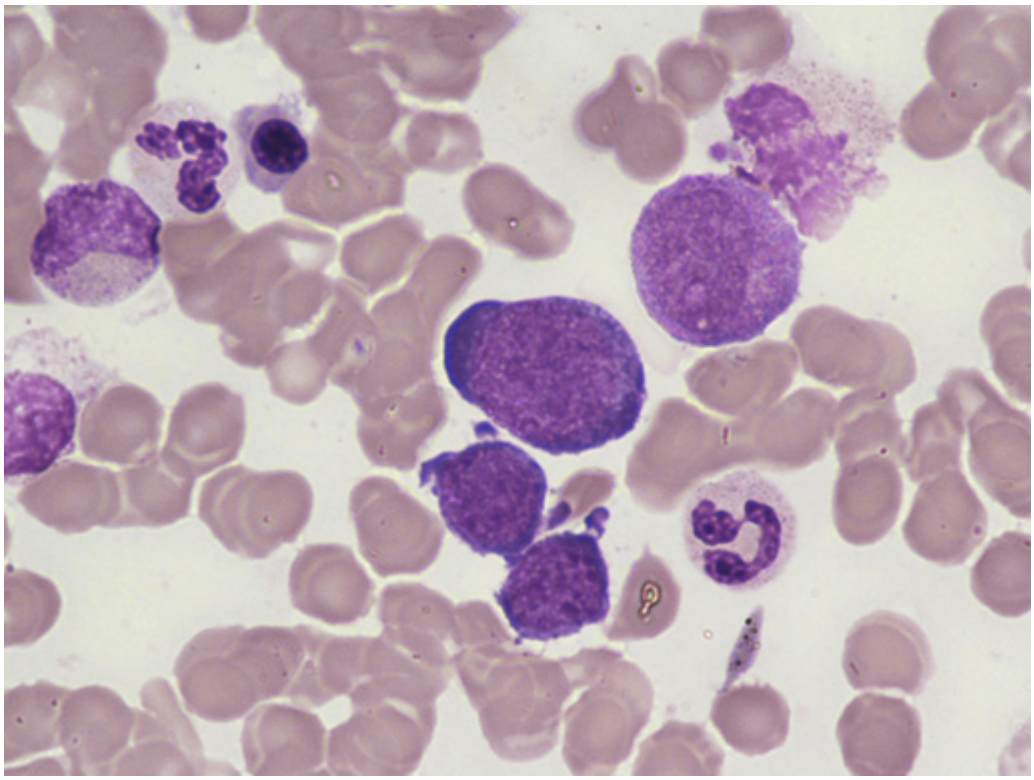

FIGURE 9-10 A proerythroblast *(center)* and two intermediate erythroblasts in a bone marrow aspirate from a healthy volunteer.*Above* and to the *right* of the proerythroblast is a promyelocyte.

Table 9-4

Cytologic Features of Erythroid Precursors in Bone Marrow Aspirates and Trephine Biopsy Sections

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section*
Proerythroblast	Large round cell, 12–20 μm in diameter, with finely stippled or reticular chromatin pattern and strongly basophilic (deep blue) cytoplasm; one or more nucleoli, which may be indistinct; there may be a perinuclear clear Golgi zone	Large round cell with round or slightly oval nucleus and one or more visible nucleoli, which are often linear or irregular and may abut on the nuclear membrane; cytoplasmic basophilia is marked and is most readily detected on Giemsa stain
Early erythroblast	Similar to proerythroblast but smaller, and	Somewhat smaller than a proerythroblast,

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section*
(basophilic erythroblast)	some chromatin clumping is now apparent; hemoglobin synthesis starts at this stage, but cytoplasm still appears deeply basophilic; perinuclear Golgi zone may be apparent	but otherwise with similar features
Intermediate erythroblast (polychromatic erythroblast)	Intermediate-sized cell with less basophilic cytoplasm than early erythroblast and lower nuclear-to-cytoplasmic ratio; moderate chromatin condensation into coarse clumps; paranuclear, often partly perinuclear	Intermediate-sized cell with less cytoplasmic basophilia than early erythroblast; moderate chromatin clumping; sections of paraffin-embedded biopsy

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section*
	Golgi zone may be apparent; if Golgi zone is paranuclear, nucleus may be somewhat eccentric	specimens may exhibit artifactual perinuclear halo owing to cytoplasmic shrinking
Late erythroblast (sometimes called orthochromatic erythroblast)	Small cell, not much larger than erythrocyte, with lower nuclear-to-cytoplasmic ratio and less cytoplasmic basophilia than intermediate erythroblast; chromatin clumping is marked, and cytoplasm is acquiring a pink tinge owing to increasing amounts of	Small cell with condensed chromatin, pink (eosinophilic) cytoplasm on hematoxylin-eosin stain, little basophilia on Giemsa stain, and prominent perinuclear halo; nucleus is rounder and more regular than that of a lymphocyte

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section*
	hemoglobin; however, when erythropoiesis is normoblastic, there is still some cytoplasmic basophilia, so this cell is not truly orthochromatic	

* Erythroblasts of various stages of maturation are found clustered around a macrophage to form an erythroid island.

Other Myeloid Cells

Monocytes, macrophages, mast cells, and osteoclasts are all of myeloid origin. Low but variable numbers of these cell types are recognized in the bone marrow of healthy subjects.

Monocytes and macrophages are a minor population in normal bone marrow aspirates. When monocytes are significantly increased, care should be taken to distinguish mature monocytes from those at the promonocyte stage of maturation, which may be considered to be equivalent to blasts for the purposes of disease diagnosis. Macrophages may be seen as isolated cells or in relation to erythroblasts in an erythroid island (so-called nurse cells). Macrophages may contain cellular debris or hemosiderin (**Fig. 9-**

27). The presence of intact cells of other lineages, often mature erythrocytes or lymphocytes, may occasionally be identified in the cytoplasm of macrophages. This phenomenon, known as *hemophagocytosis*, can be identified occasionally in normal bone marrow upon close inspection.

Normal mast cells, although infrequent, are readily recognizable in bone marrow aspirate smears because of their distinctive cytologic features. They generally have central, round, or oval nuclei, and their cytoplasm is packed with brightly staining purple granules (**Fig. 9-28**). In H&E-stained sections, mast cells in normal bone marrow are not readily recognizable, but they can be visualized on a Giemsa stain, which stains their granules purple, or by immunohistochemical stains such as mast cell tryptase. They are preferentially located adjacent to bone and around arterioles but are also scattered in low numbers throughout the marrow.

Osteoclasts are large, usually multinucleated cells with quite heavily granulated cytoplasm (**Fig. 9-29**). Their multiple, separate nuclei are oval and very uniform in appearance; each has a single lilac nucleolus. Only small numbers are seen in aspirates from healthy adults, but they are more numerous in aspirates from children. In histologic sections, osteoclasts are apparent as multinucleated cells adjacent to bone (**Fig. 9-30**).

Bone Marrow Lymphoid Cells

Bone marrow lymphocytes in healthy adults are small and mature, resembling those in the peripheral blood (**Fig. 9-31**). To assess their number accurately it is important to prepare smears from the first few drops of aspirated marrow to minimize hemodilution. Aspirates

from children not only have more lymphocytes than those of adults but also are likely to contain immature lymphoid cells. Often designated as hematogones, these immature lymphoid cells range from slightly larger than a mature lymphocyte with the nucleolus being more apparent, to larger cells that are cytologically indistinguishable from leukemic lymphoblasts, with a high nuclear-to-cytoplasmic ratio, a diffuse chromatin pattern, and nucleoli (**Fig. 9-32**). Hematogones can be seen in the marrow of healthy children and can be distinguished from leukemic cells by the spectrum of maturation from lymphoblasts to mature lymphocytes, best identified by flow cytometry, and even though they may constitute a high percentage of marrow cells (e.g., 20%–30%), normal hematopoiesis is not attenuated.

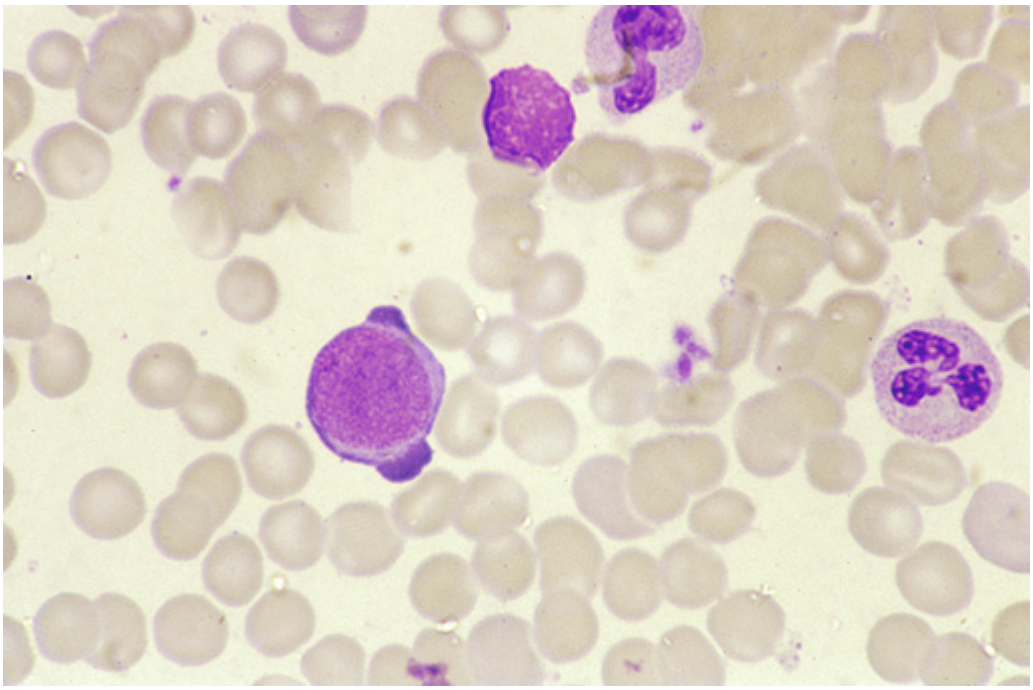

FIGURE 9-11 Early erythroblast and neutrophil in a bone marrow aspirate from a healthy volunteer.Note the perinuclear Golgi zone in the early erythroblast.

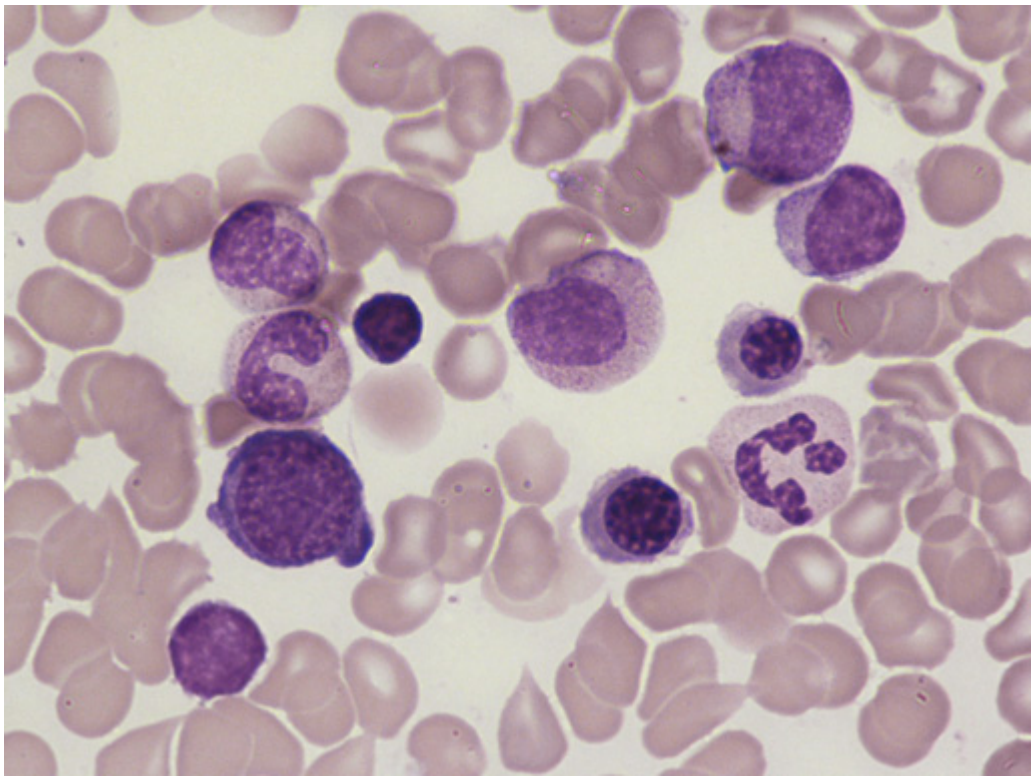

FIGURE 9-12 An early erythroblast (beneath the neutrophil band form on the left) and two late erythroblasts.Note that the early erythroblast has similar characteristics to the proerythroblast in Figure 9-10 but is smaller. There is also a myelocyte *(center)* and a promyelocyte *(top right)*.

In histologic sections, lymphocytes are predominantly interstitial and are fewer than in bone marrow aspirates. Studies show that around 2% to 10% of nucleated cells in trephine bone marrow sections are lymphocytes, with a T cell-to-B cell ratio of 4:1 to 6:1.[23,24] With increasing age, lymphoid aggregates composed mostly of T cells may be observed in the bone marrow of adult subjects without apparent relevant disease.[25] Although lymphoid aggregates

are most readily observed in sections of trephine biopsy specimens, they can occasionally be seen on crush preparations of bone marrow aspirate.

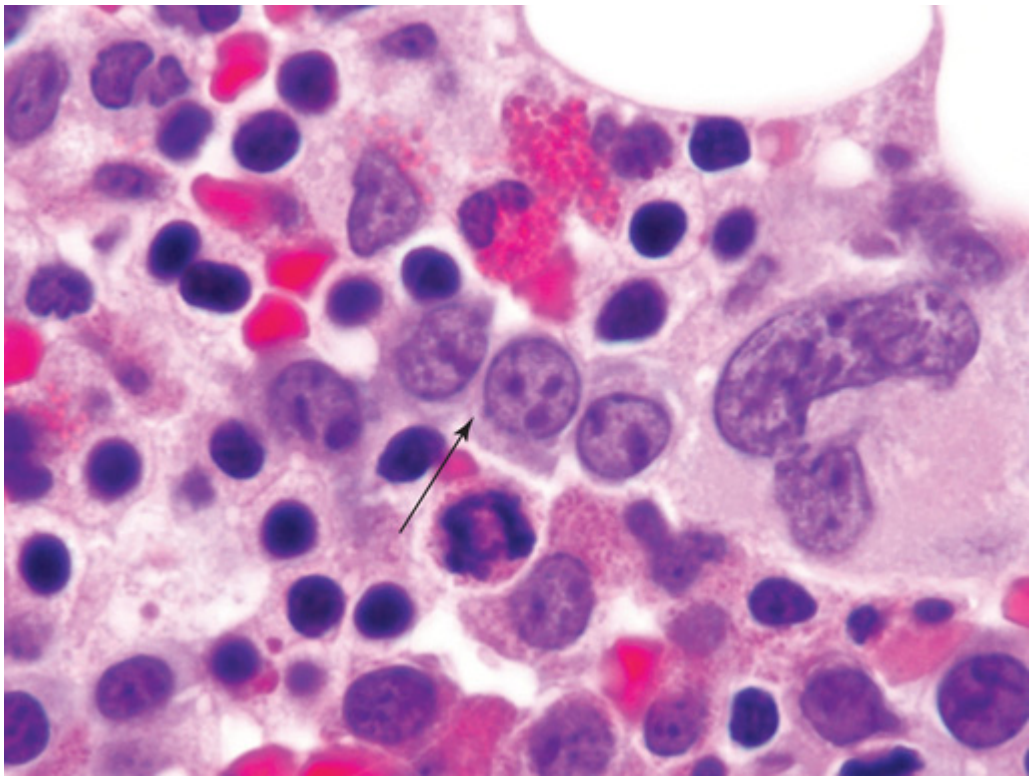

FIGURE 9-13 Four proerythroblasts *(arrow)* surrounded by erythroid precursors in later stages of maturation, a megakaryocyte, and some immature granulocytes in a trephine biopsy section from a hematologically normal man.Note the strongly amphophilic cytoplasm of the proerythroblasts and their linear or comma-shaped nucleoli, which often abut the nuclear membrane.

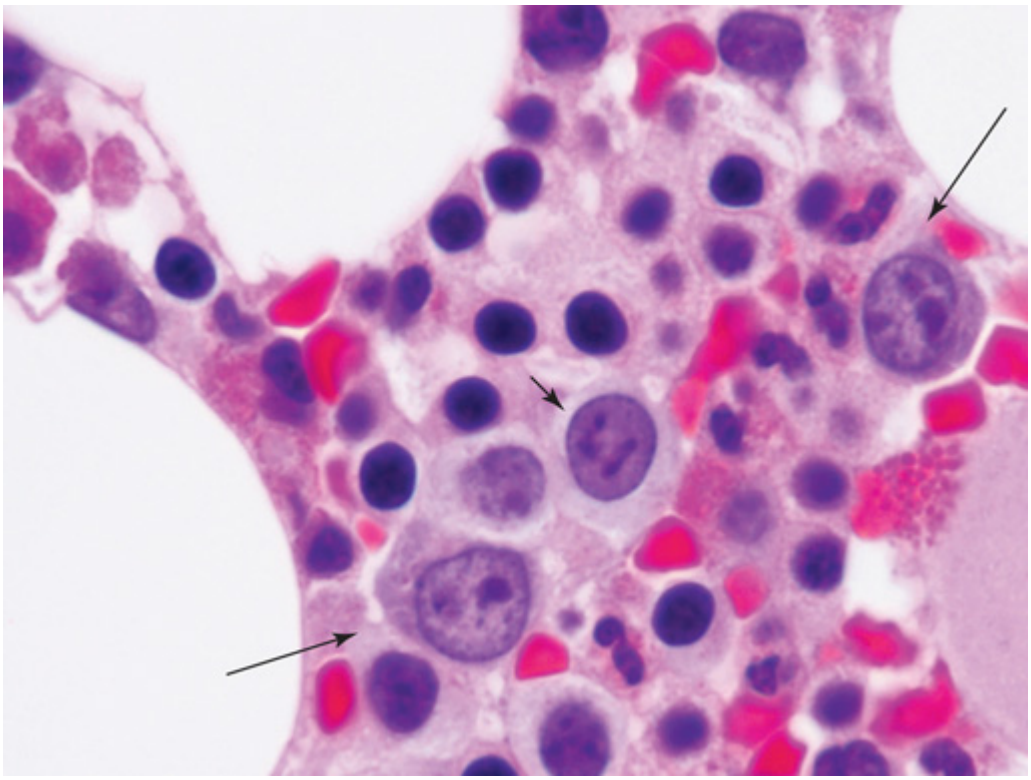

FIGURE 9-14 Two proerythroblasts *(long arrows)* and an intermediate erythroblast *(short arrow)* surrounded by late erythroid precursors.

Plasma cells (**Fig. 9-33**) are infrequent in aspirates and trephine biopsy specimens from healthy individuals, comprising less than 5% of nucleated marrow cells. They are often preferentially located adjacent to capillaries (**Fig. 9-34**) and may occasionally show binucleation.

Other Cells Present in Normal Bone Marrow

Small numbers of osteoblasts are present in normal aspirates (**Fig. 9-35**), with larger numbers often observed in aspirates from children. They can be distinguished from plasma cells by their slightly larger size and more voluminous cytoplasm, and the fact that

the readily apparent Golgi zone is not immediately adjacent to the nucleus as it is in plasma cells. Other stromal cells that can be recognized in aspirates include adipocytes and reticulum cells. Capillaries may also occasionally be aspirated and can be particularly visible in hypocellular marrow, being recognized as a parallel sequence of fusiform cells.

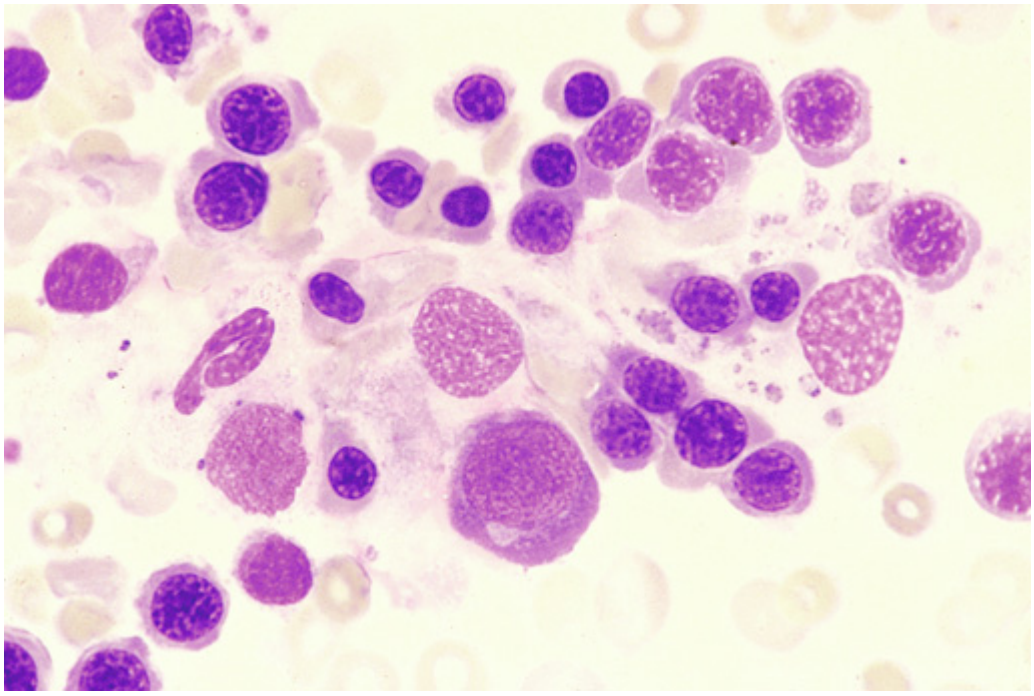

FIGURE 9-15 Disrupted erythroid island showing early, intermediate, and late erythroblasts in a bone marrow aspirate from a healthy volunteer.

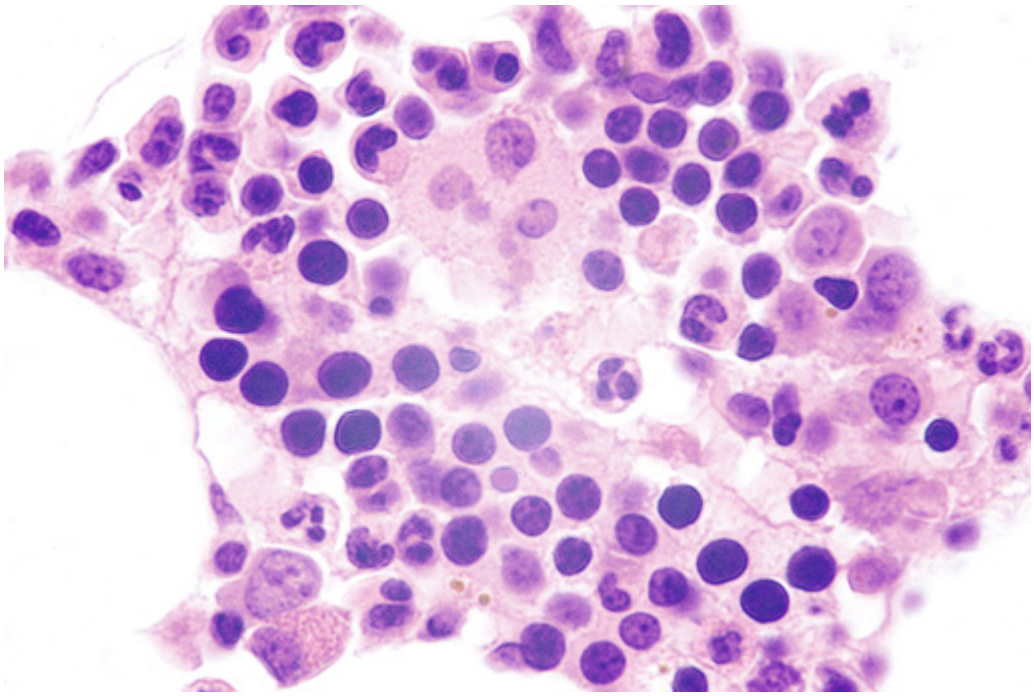

FIGURE 9-16 Erythroid island composed mainly of intermediate and late erythroblasts in a section of a trephine biopsy specimen from a hematologically normal patient.A megakaryocyte, eosinophil myelocyte, and several neutrophils are also apparent.

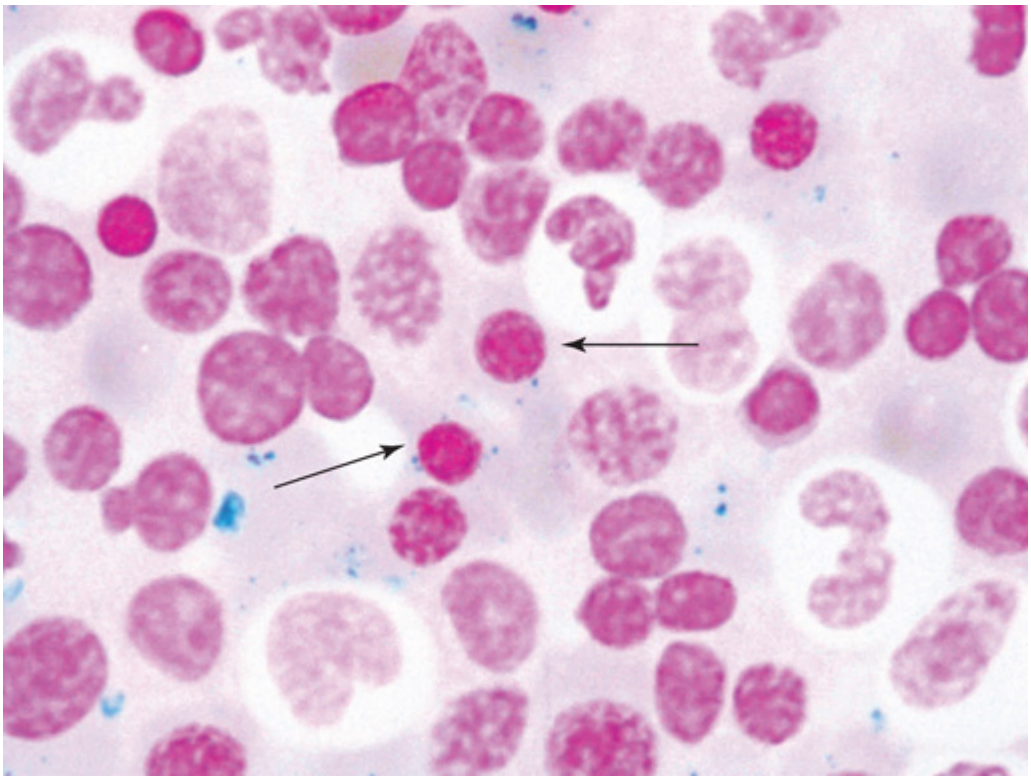

FIGURE 9-17 Late erythroblasts containing siderotic granules *(arrows)* in a bone marrow aspirate stained with Perls stain.

On trephine biopsy sections, osteoblasts can be recognized on the basis of their position and cytologic features (**Fig. 9-36**). Fat cells, capillaries, sinusoids, and arterioles are also readily recognizable.

It is important to recognize extraneous cells that are normal but have been introduced into the bone marrow during the biopsy procedure. In aspirates, these include epithelial and endothelial cells. In trephine biopsy sections, they include skin and its components such as epidermis, eccrine glands, and sebaceous glands.

CYTOCHEMISTRY AND HISTOCHEMISTRY

All the stains routinely performed on bone marrow aspirate smears and trephine biopsy sections are cytochemical or histochemical in nature. However, by convention, these terms are usually not applied to those routine stains such as Romanowsky stain on an aspirate smear or an H&E stain on a section.

With the exception of Perls stain for iron, cytochemical stains are losing importance in the era of advanced immunophenotyping techniques. If immunophenotyping is not available, cytochemistry may still yield valuable information. Similarly, histochemical stains with the exception of those used to evaluate iron, reticulin, collagen, amyloid, and microorganisms, are now of little importance in routine diagnosis.

Cytochemistry

The Perls stain for iron is diagnostically important and should be performed on the initial bone marrow aspirate in, at a minimum, all patients undergoing workup for cytopenias. Cytochemical stain for alpha-naphthyl butyrate esterase is helpful to identify monocytic cells. Other cytochemical stains are now less frequently performed in routine practice. The most useful of them are shown in **Table 9-6**.

Histochemistry

Besides routine stains such as H&E and Giemsa, reticulin stain and Perls stain are the only histochemical stains needed with any frequency. The normal findings with these and other histochemical stains are summarized in **Table 9-7**. If a particulate bone marrow aspirate slide is available, an additional Perls stain on histologic sections is unlikely to provide useful information. Reticulin and

trichrome stains are used to evaluate the degree of marrow fibrosis. A PAS stain can aid in distinguishing erythroblasts from granulocytic precursors and also highlights megakaryocytes.

Immunophenotyping Including Immunohistochemistry

Immunophenotyping on bone marrow specimens is now usually performed by flow cytometry on aspirates, or by immunohistochemistry on bone marrow trephine biopsy sections. The former permits the simultaneous labeling of cells with multiple antibodies and is more quantitative; however, the latter permits the evaluation of the expression of specific antigens in relation to the histologic features and bone marrow architecture. Both are of critical importance in hematologic diagnosis. Commonly performed immunohistochemical stains and their staining pattern in a normal bone marrow are shown in **Figure 9-37**.

Table 9-5

Cytologic Features of Granulocyte (Neutrophil) Precursors in Bone Marrow Aspirates and Bone Marrow Trephine Biopsy Sections

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section
Myeloblast	Large cell, 12–20 μm in diameter, with high nuclear-to-cytoplasmic ratio, moderate cytoplasmic basophilia, and diffuse chromatin pattern, often with one or more round or oval nucleoli; myeloblast is more irregular in shape than proerythroblast, and its cytoplasm is less basophilic; there may be small numbers of	Large cell with high nuclear-to-cytoplasmic ratio, located near the surface of a bony spicule or an arteriole; nucleolus is rounder than that of a proerythroblast and does not touch the nuclear membrane; on Giemsa stain, cytoplasmic basophilia is less

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section
	azurophilic (reddish-purple) granules	than that of a proerythroblast
Promyelocyte	Larger cell than a myeloblast, 15–25 μm in diameter, with more plentiful basophilic cytoplasm and more abundant reddish-purple azurophilic or primary granules; paranuclear Golgi zone; eccentric nucleus containing a nucleolus	Larger cell than a myeloblast, with a similar nucleus but more abundant granular cytoplasm, similarly located near a bony spicule or an arteriole
Myelocyte	Medium-sized to large-sized cell, 10–20 μm in diameter; nucleus lacks a nucleolus and shows some chromatin condensation; cytoplasm is more acidophilic (pinker)	Smaller cell than a promyelocyte, located farther away from the bone surface; the cytoplasm is granular, and the oval nucleus

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section
	than that of a promyelocyte and contains azurophilic granules (which now stain less strongly), and the cytoplasm is acquiring a pink-lilac tinge caused by the presence of granules below the level of resolution of the light microscope; the Golgi zone is not conspicuous, but its presence may lead to slight nuclear indentation	has no apparent nucleolus
Metamyelocyte	Medium-sized cell, 10–12 μm in diameter; resembles myelocyte, with granular acidophilic cytoplasm but indented or U-shaped nucleus	Medium-sized cell resembling a myelocyte and similarly situated, but with an indented or U-shaped nucleus

Cell	Bone Marrow Aspirate	Bone Marrow Trephine Biopsy Section
Band form and neutrophil	Medium-sized cells with granular pink cytoplasm and band-shaped or segmented nucleus, respectively; chromatin is coarsely clumped, particularly in the mature neutrophil	Medium-sized cells located some distance from a bony spicule or an arteriole, with granular cytoplasm and coarsely clumped chromatin in band-shaped or lobulated nuclei

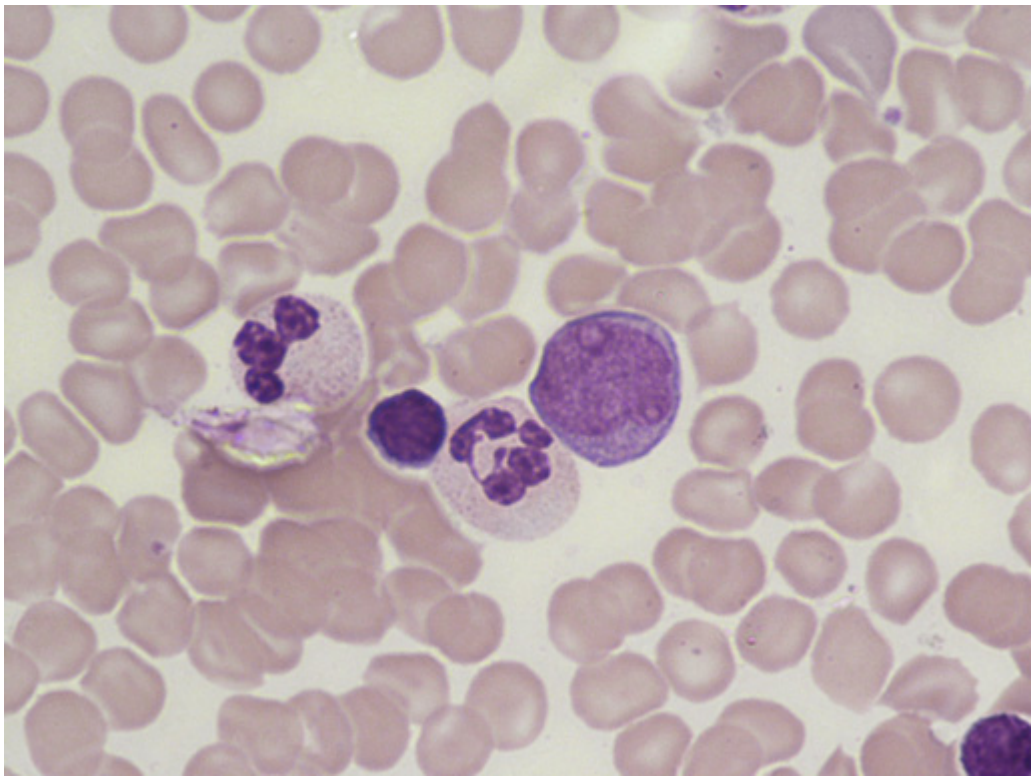

FIGURE 9-18 A myeloblast in a bone marrow aspirate from a healthy volunteer.Note the high nucleocytoplasmic ratio, the presence of nucleoli, and the presence of scanty granules, which do not preclude identification of this cell as a myeloblast. The nuclear outline is slightly irregular, contrasting with the perfectly round nuclear outline typical of early erythroid cells.

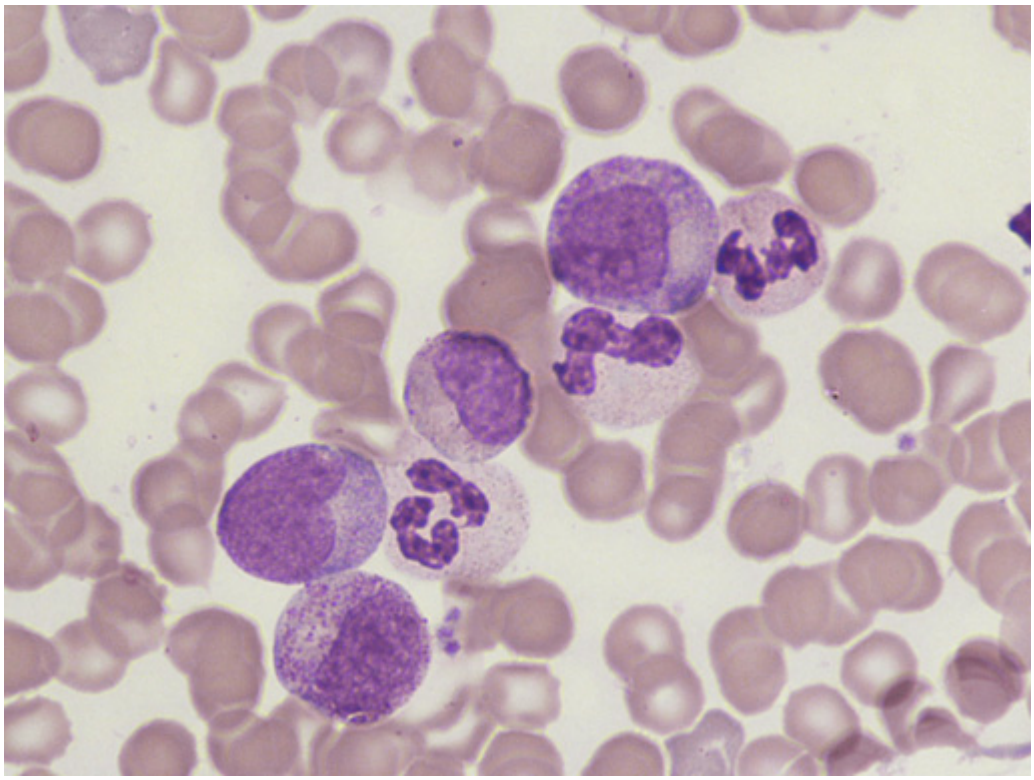

FIGURE 9-19 An early promyelocyte *(top right)* and a late promyelocyte *(bottom left)* in a bone marrow aspirate from a healthy volunteer.Note the basophilic cytoplasm, the nucleocytoplasmic ratio that is lower than that of a myeloblast, the eccentric nucleus, the Golgi zone, and the granules, which in the later cell are becoming abundant. The cell immediately above the more mature promyelocyte is a very early promyelocyte, showing eccentricity of the nucleus and the earliest signs of cytoplasmic maturation. The cell above the segmented neutrophil is a myelocyte.

BONE MARROW EXAMINATION AND REPORTING

A complete bone marrow evaluation entails a review of the relevant clinical and laboratory data and an examination of the peripheral blood smear, bone marrow aspirate, and core biopsy. The proportions and morphologies of different hematopoietic cells present in the bone marrow are best determined by examination of well-prepared bone marrow aspirate smears. Bone marrow trephine biopsy sections should be examined systematically, assessing the adequacy of the specimen, the bone structure, the cellularity, all cell lineages, lymphocytes, and plasma cells, stroma, and any abnormal infiltrates.

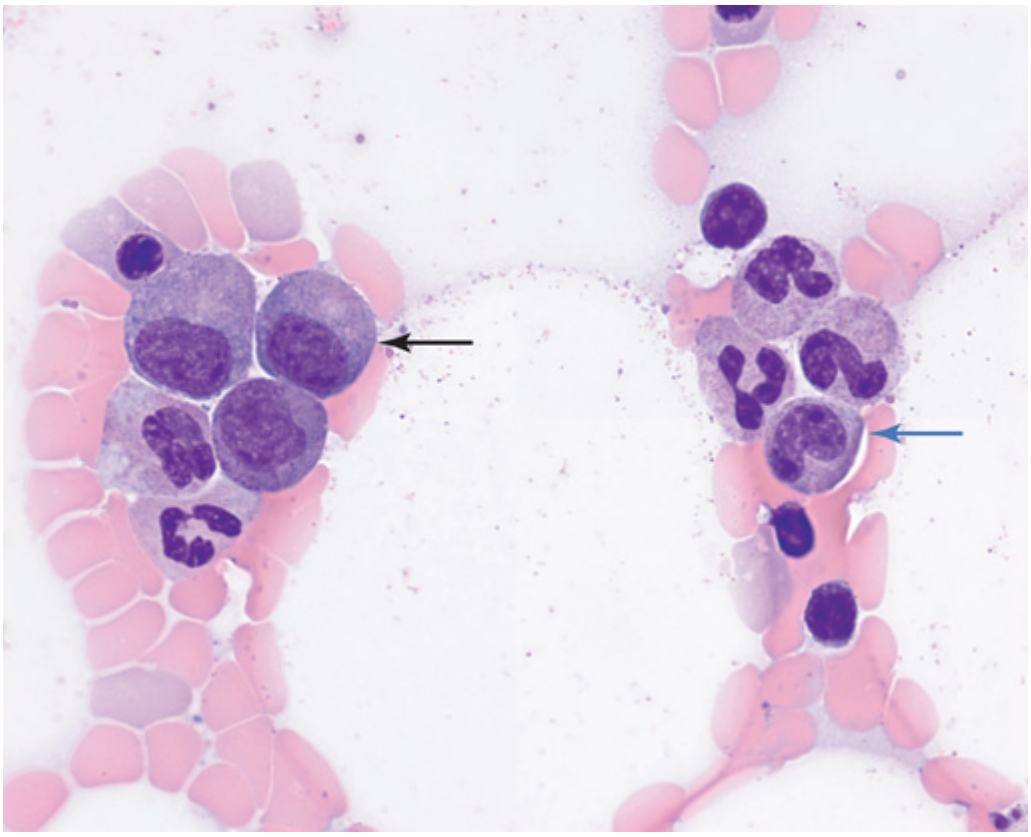

FIGURE 9-20 Myeloid maturation with myelocytes *(black arrow)*, metamyelocytes *(blue arrow)*, band forms, and neutrophils.

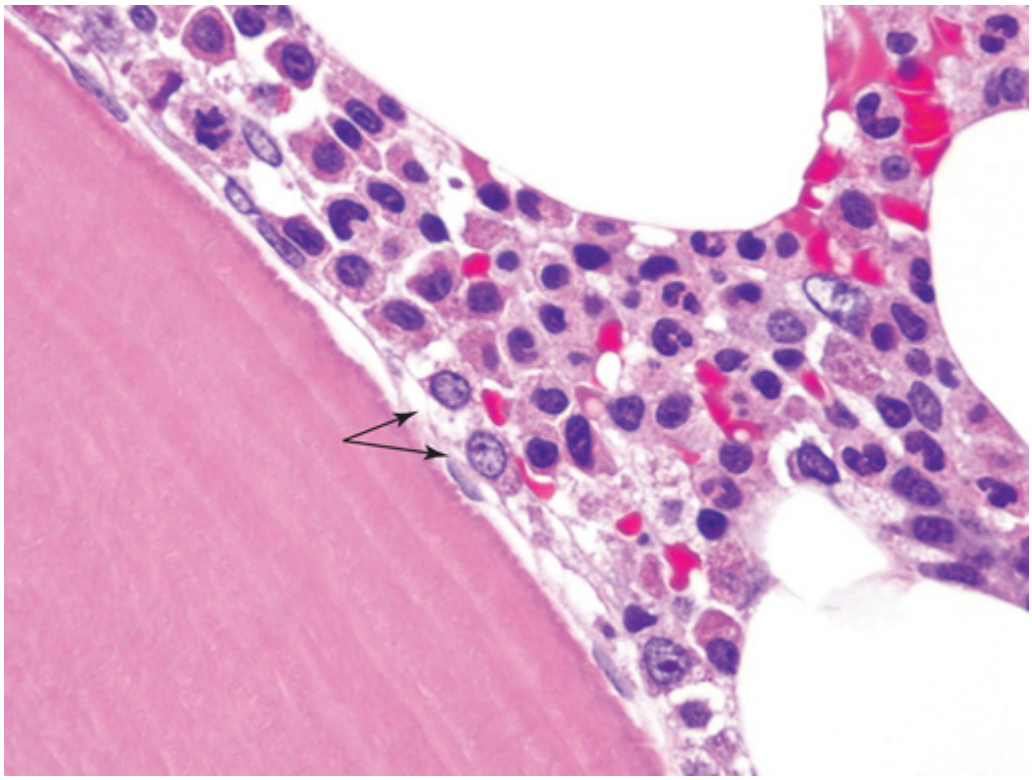

FIGURE 9-21 Immature granulocytes along a bony trabecula.The most immature cells are next to the bone, including blasts *(arrows)*, with more mature granulocytes deeper in the intertrabecular space.

The final report of a bone marrow examination should include the diagnosis, the pathologist's recommendation for further studies if necessary, and supporting data. When multiple laboratories are involved in the analysis and interpretation of a specimen, a concise summary of the salient results from these contributing laboratories should be integrated into the final report.[26,27] At the minimum, the hematopathology report should list the specialty laboratories to which aliquots of the specimen had been sent.

As noted earlier, examining either a bone marrow aspirate smear or core biopsy alone misses the correct diagnosis in a significant proportion of cases. Thus the final diagnosis should incorporate findings on both marrow aspirate smear and core biopsy. If it is not possible for the pathologist to examine both the marrow aspirate and core biopsy, each report must make note of the existence of the other so that the reader of such reports can collate them for the final interpretation.

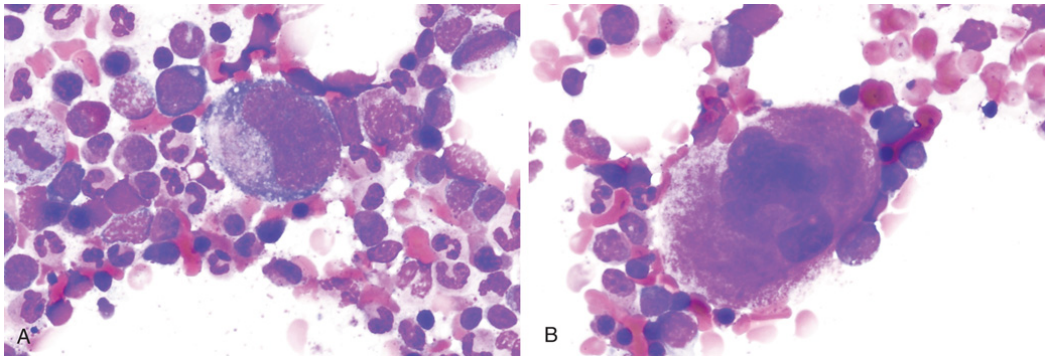

FIGURE 9-22 Immature **(A)** and mature **(B)** megakaryocyte in a bone marrow aspirate from a hematologically normal individual.

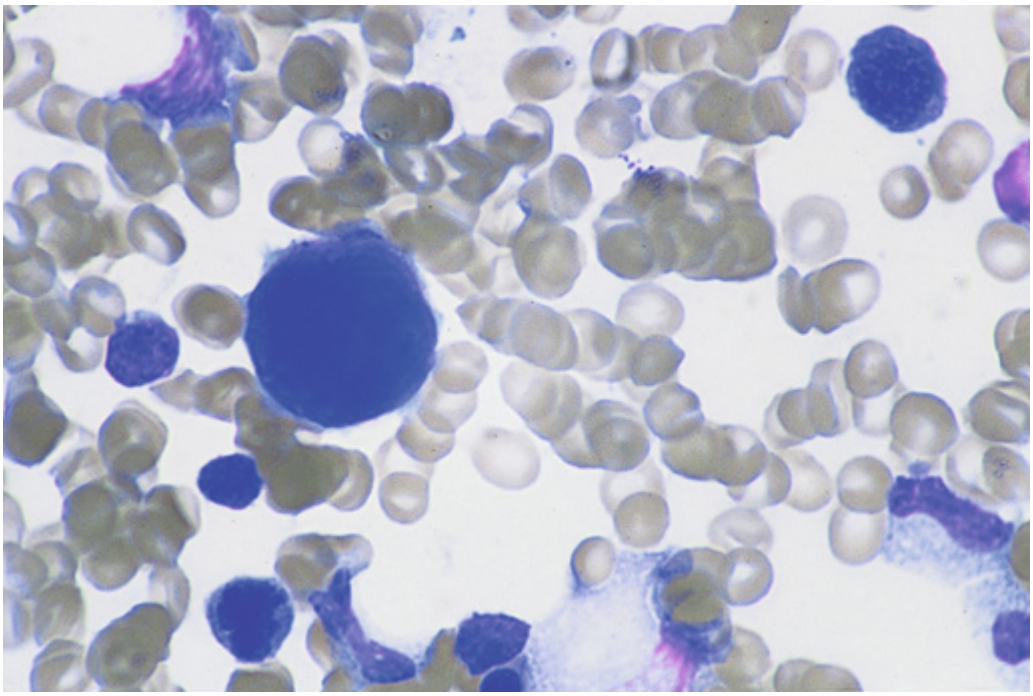

FIGURE 9-23 Late megakaryocyte, which has shed almost all its cytoplasm as platelets and appears as an almost bare nucleus, in a bone marrow film (May-Grünwald-Giemsa stain).

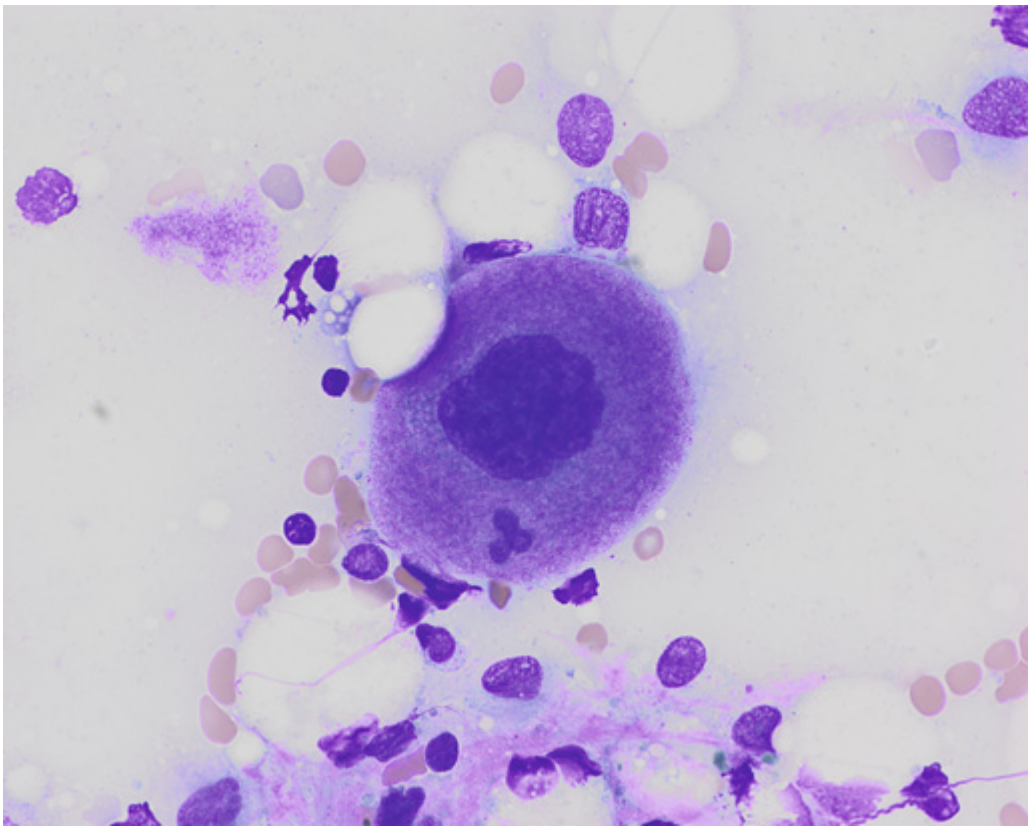

FIGURE 9-24 Megakaryocyte with emperipolesis; intact neutrophil within the cytoplasm of megakaryocyte.

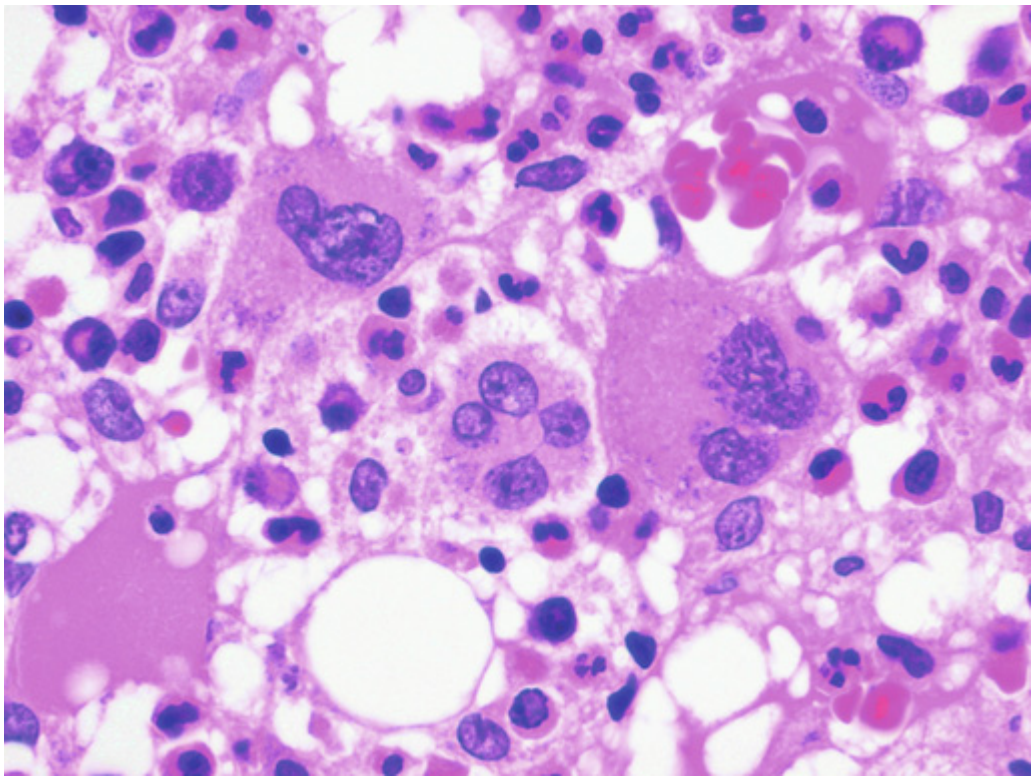

FIGURE 9-25 Three megakaryocytes in a section of a trephine biopsy specimen from a hematologically normal patient.The variation in size and nuclear lobulation are caused by sectioning across a large, three-dimensional megakaryocyte in the biopsy.

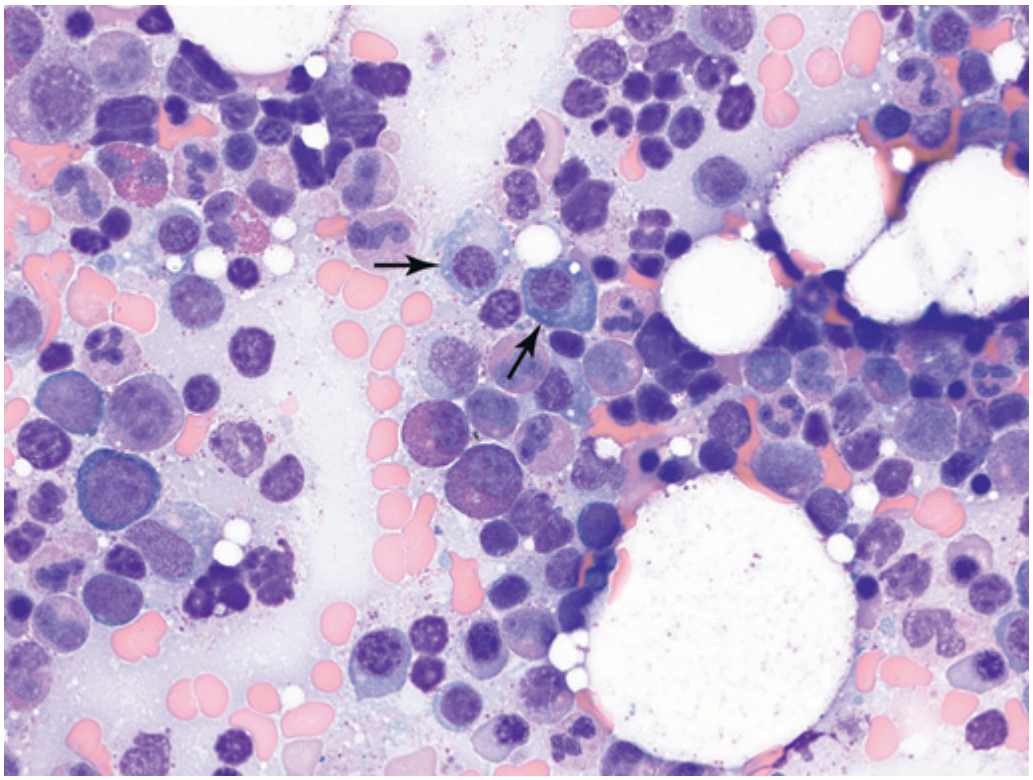

FIGURE 9-33 Plasma cells *(arrows)* in a background of maturing granulocytic and erythroid precursors.

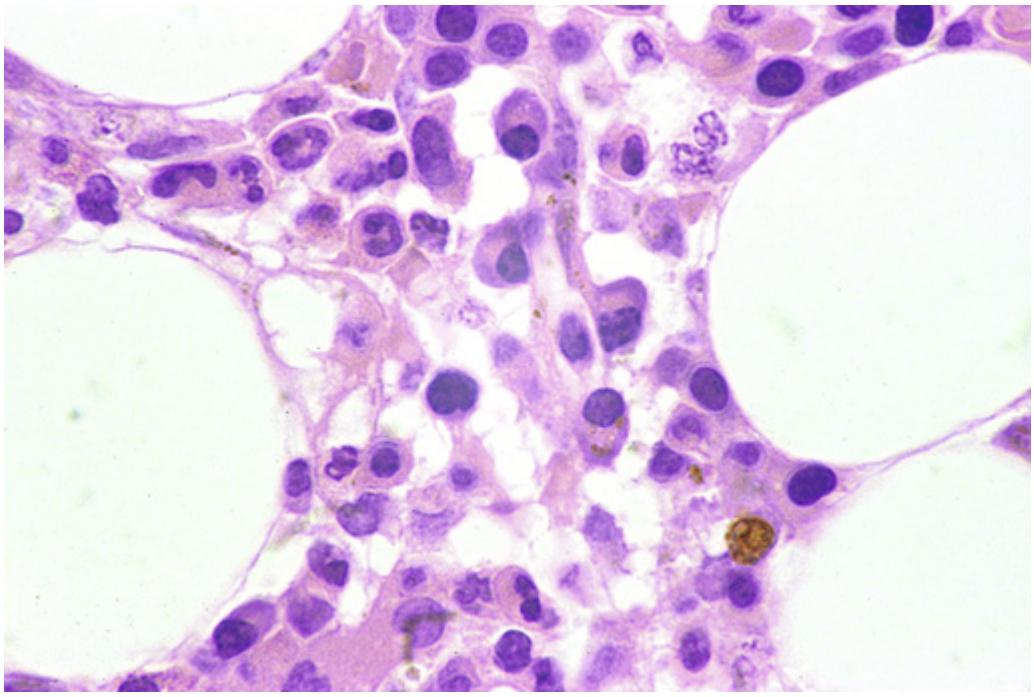

FIGURE 9-34 Pericapillary plasma cells in a section of a trephine biopsy specimen.

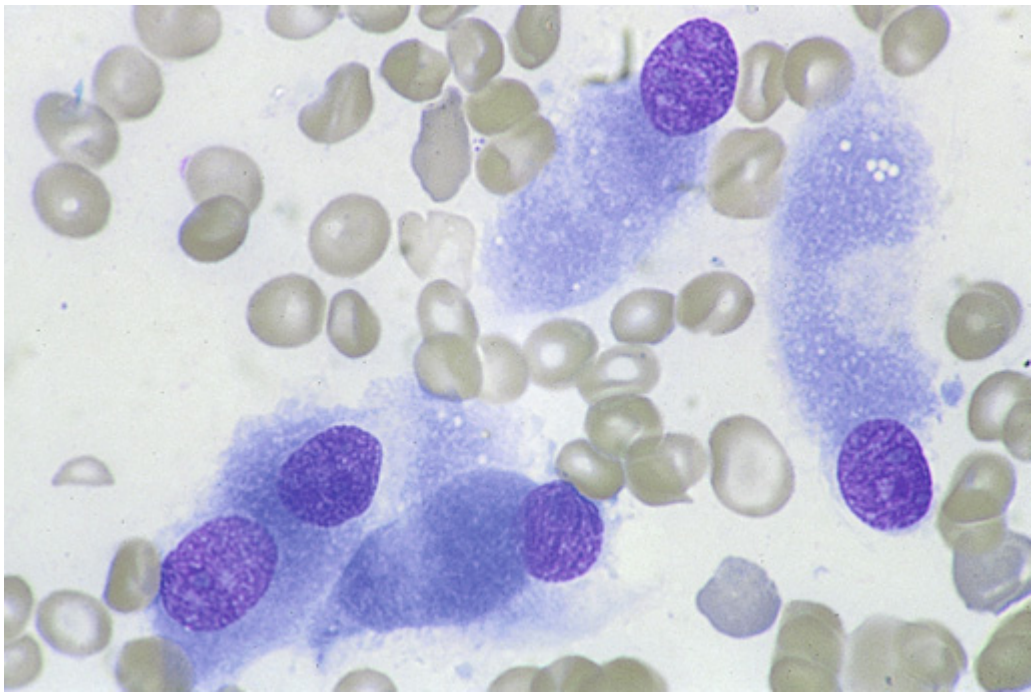

FIGURE 9-35 A cluster of osteoblasts in a bone marrow aspirate from a child.

Although not specifically discussed in this chapter, examination of a peripheral blood smear is an integral component in the evaluation of any hematologic abnormality, and indeed it is often an abnormality in the blood that triggers a bone marrow examination. Occasionally, the blood may show a greater proportion of blasts, more readily apparent dysgranulopoietic features, or a greater degree of differentiation of leukemic cells than the marrow. It is most efficient to obtain blood smears at the time of bone marrow aspiration and biopsy. If a blood smear is not available to the pathologist, at a minimum, hemogram data should be reviewed.

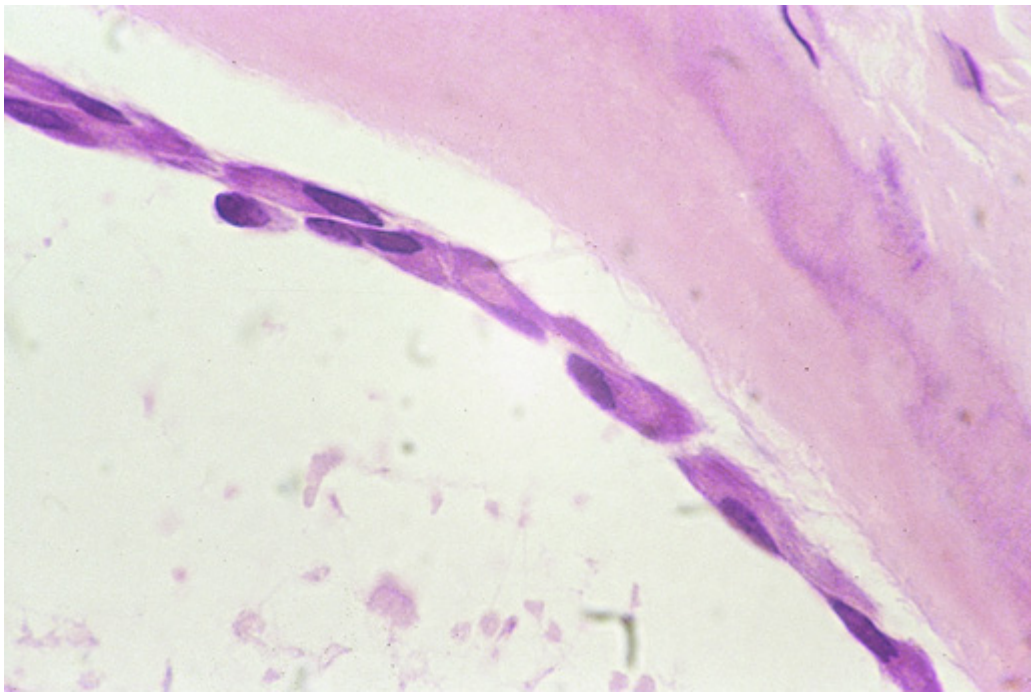

FIGURE 9-36 Osteoblasts lining bone in a section of a trephine biopsy specimen.

A detailed differential count of the marrow aspirate or blood is not always required to be included in the report, as in the case of examination for metastatic disease, when the hemogram is otherwise normal, when cellularity is markedly low, or there is severe pancytopenia. When a differential count may provide useful information but is not integral to diagnosis or subclassification, the International Council for Standardization in Hematology (ICSH) has indicated that a 300-cell count of the nucleated bone marrow cells is sufficient.[8] However, when the diagnosis or classification of a disease process, such as acute leukemia or myelodysplastic syndrome, relies on knowledge of the proportions of blasts and other abnormal cells, more detailed differential counts are justified. Differential counts of 200 leukocytes in the blood and 500 cells in the marrow are recommended for determining the percentage of

blasts,[4] with additional cells counted or additional smears examined if the proportion is at a “critical threshold” or if there is an uneven distribution of such cells.[8] The ICSH recommends that the bone marrow differential counts include blasts, promyelocytes, myelocytes, metamyelocytes, band forms, segmented neutrophils, eosinophils, basophils, mast cells, promonocytes, monocytes, lymphocytes, plasma cells, and erythroblasts. The nucleated cell count should not include megakaryocytes, macrophages, osteoblasts, osteoclasts, stromal cells, smudged cells, or non-hematopoietic cells such as metastatic tumor cells. If lymphoid aggregates are present, they should not be included in the count, but their presence should be commented upon.[8]

The suggested components that should be included in the bone marrow report are listed in **Box 9-1**. The clinical indication for the bone marrow examination, a complete hemogram, morphologic findings on the peripheral blood smear, bone marrow aspirate smear, and core biopsy, as well as results of all ancillary studies, should be included.

Table 9-6

Cytochemical Stains in Bone Marrow Aspirate

Stain	Reactivity in Normal Bone Marrow	Comments
Perls Prussian blue	Hemosiderin in macrophages and developing erythroid cells	Diagnostically important for evaluation of normoblastic and storage iron
Myeloperoxidase	Primary granules of promyelocytes and all later cells of neutrophil lineage (myeloblasts may have scattered fine granules); primary and secondary granules of cells of eosinophil lineage, from	Immunophenotyping with antimyeloperoxidase antibodies is more sensitive than a cytochemical reaction dependent on enzyme activity; uncommonly, there is a congenital peroxidase deficiency in hematologically normal subjects

Stain	Reactivity in Normal Bone Marrow	Comments
	promyelocyte stage onward; granules of basophil myelocytes but not normal mature basophils; granules of monocytes, finer and less numerous than granules of neutrophils	
Sudan black B	Stains lipids present in the primary and secondary granules of granulocytes and monocyte lysosomes	Immunophenotyping is more sensitive for detecting granulocytic differentiation; Sudan black B staining is negative in individuals with a congenital peroxidase deficiency

Stain	Reactivity in Normal Bone Marrow	Comments
Naphthol AS-D chloroacetate esterase (specific [neutrophil] esterase)	Granules of neutrophils and their precursors from promyelocyte stage onward (normal eosinophils are negative); mast cell granules	Less sensitive than myeloperoxidase or Sudan black B for detecting granulocytic differentiation; immunophenotyping is also more sensitive
Alpha naphthyl acetate esterase (non-specific esterase)	Granules of monocyte precursors, monocytes, and macrophages; granules of megakaryocytes and platelets; many T lymphocytes are positive; normal neutrophils and	Immunophenotyping is an alternative means of demonstrating monocytic differentiation (e.g., with CD14 monoclonal antibodies) and megakaryocytic differentiation (e.g., with CD42 and CD61

Stain	Reactivity in Normal Bone Marrow	Comments
	erythroblasts are negative	monoclonal antibodies)
Alpha naphthyl butyrate esterase (non-specific esterase)	Granules of monocyte precursors, monocytes, and macrophages; some T lymphocytes show focal paranuclear positivity	More specific for monocyte lineage than alpha naphthyl acetate esterase
Toluidine blue	Granules of mast cells and basophils	
Periodic acid–Schiff (PAS)	Neutrophil lineage, strongest in mature cells; eosinophil cytoplasm is positive, but granules of normal eosinophils are	Normal erythroblasts are PAS negative

Stain	Reactivity in Normal Bone Marrow	Comments
	negative; basophil cytoplasm may show large, irregular positive blocks, but granules are negative; monocytes show variable diffuse plus granular positivity; megakaryocytes and platelets usually show strong diffuse plus granular or block positivity; plasma cells have strong diffuse positivity; some lymphocytes	

Stain	Reactivity in Normal Bone Marrow	Comments
	show granular positivity	

Table 9-7

Histochemical Stains in Bone Marrow Trephine Biopsy Sections

Stain	Reactivity in Normal Marrow	Comments
Perls Prussian blue stain	Hemosiderin in macrophages	More useful in aspirate, as long as it contains bone marrow particles; decalcification procedure may remove iron from bone marrow trephine biopsy specimens
Gomori or Gordon-Sweet stain for reticulin	Scattered linear reticulin with no intersections; normal presence of reticulin fibers around arterioles	Important for highlighting abnormal areas of collagen type III in bone marrow and in the diagnosis of myeloproliferative neoplasms
Masson trichrome	Perivascular collagen	Important for highlighting collagen type I in the diagnosis of myeloproliferative neoplasms

Stain	Reactivity in Normal Marrow	Comments
Periodic acid–Schiff (with or without diastase)	Highlights plasma cells, megakaryocytes, and granulocytic cells	Can highlight organisms in immunosuppressed patients
Congo red	None	Amyloid shows positive staining with apple-green birefringence under polarized light

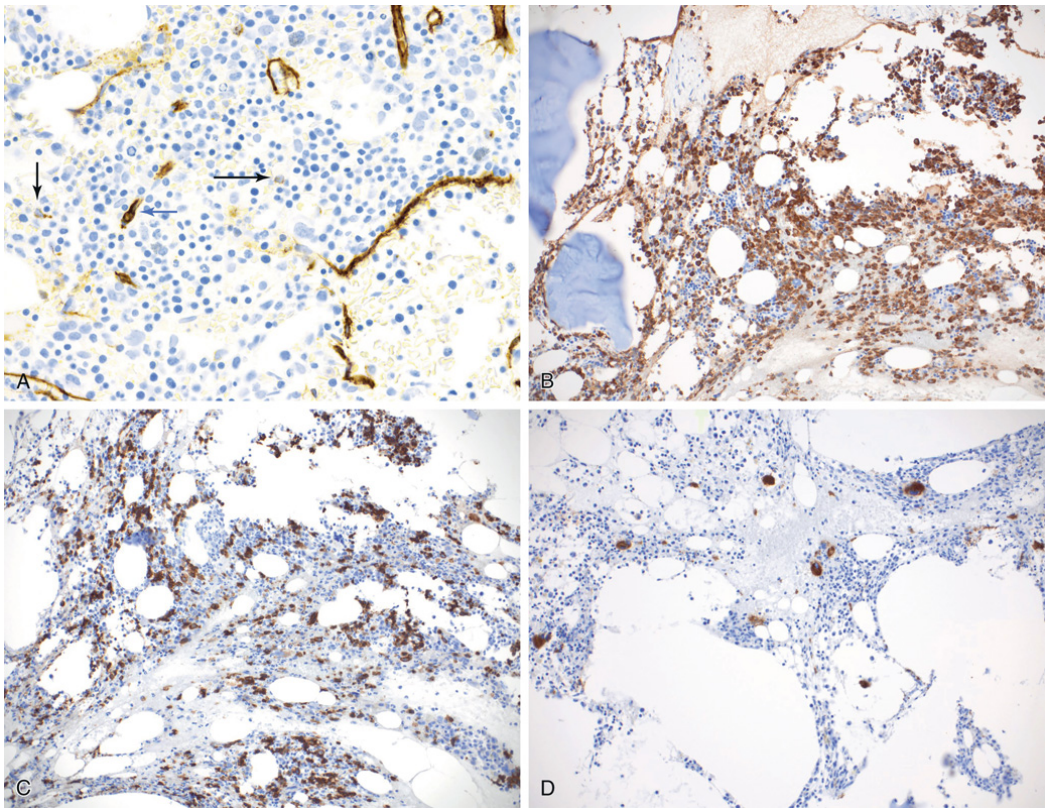

FIGURE 9-37 Immunohistochemistry of normal bone marrow.**A,** CD34 immunohistochemical stain highlighting endothelial cells *(blue arrow)* and rare weakly positive blasts *(black arrows)*. **B,** Myeloperoxidase immunohistochemical stain highlighting granulocytic precursors. **C,** CD71 immunohistochemical stain highlighting erythroid precursors. **D,** CD61 immunohistochemical stain highlighting scattered megakaryocytes.

Box 9-1 Components of a Bone Marrow Report

A brief clinical history including indication for bone marrow examination
Peripheral blood smear review including concurrent complete blood count (CBC) data
Bone marrow aspirate smear
Adequacy and relative cellularity
Granulocytic to erythroid ratio
Granulocyte precursors
Relative percentage, maturation, presence/absence of dysplasia
Percentage of blasts, morphologic description if increased
Erythroid precursors
Relative percentage, maturation, presence/absence of dysplasia
Megakaryocytes
Relative number and morphology
Other cell types: lymphocytes, plasma cells, monocytes, mast cells, eosinophils, and basophils
Differential cell count, if indicated
Bone marrow trephine biopsy or clot
Adequacy and marrow cellularity, including percentage and comparison to age expected cellularity: normocellular/hypocellular/hypercellular for age
Proportion of granulocytic (myeloid) and erythroid cells and relative number of megakaryocytes
Features of bone trabeculae
Stromal elements

Abnormal cellular infiltrates: granulomas, lymphocytic infiltrate, increased plasma cells, and metastatic tumor
Results of cytochemical, histochemical, or immunohistochemical stains, if performed
Results of flow cytometric immunophenotyping, if performed
Results of cytogenetic/molecular genetic studies, if performed
Can be reported as an addendum; however, the list of tests performed should be included in the initial report
Final diagnosis
Tissue examined and site of biopsy
Diagnostic interpretation including all available results of ancillary studies
Classification system used to render diagnosis, if applicable

CONCLUSION

Meaningful evaluation of the bone marrow requires a bone marrow specimen that is adequate for the clinical scenario, and which is well prepared. Correct and complete interpretation then relies on the integration of the morphologic findings of the bone marrow aspirate, trephine core biopsy, and peripheral blood with review of relevant ancillary studies and clinical data. Rigorous monitoring of the collection, processing, and staining processes ensures specimen adequacy and accurate morphologic evaluation. In interpreting the marrow, the pathologist should be aware of the range of normality and have a thorough knowledge of the cytologic and histologic features of bone marrow in a healthy subject.

Acknowledgments

The authors graciously appreciate and acknowledge the work from the prior authors, Dr. Phuong Nguyen and Dr. Barbara Bain, which has inspired and contributed significantly to this updated chapter.

Pearls and Pitfalls

- Before performing the marrow, determine what samples to collect. How many cores? Bilateral or unilateral? How many aspirate samples, for what studies, in what types of anticoagulant, and in what sequence?
- Obtain additional cores for special studies if the aspiration is hemodiluted or if it yields a dry tap.
- Smear should be made within 2 hours of aspirate collection in EDTA to avoid morphologic distortion.
- Dry all smears rapidly. A small tabletop fan can help when the humidity is high.
- The trephine biopsy should be adequately fixed. Sections must be sufficiently thin (≤4 μm) to permit the recognition of individual cells.
- Differential counts should be performed on well-stained marrow aspirate smears.
- Hemodiluted aspirate smears, thick smears, or poorly stained smears can lead to incorrect interpretation.
- Examine and report on both the aspirate and the core biopsy. Indicate the status of samples that have been sent to specialty

laboratories.

- The pathologist must be totally familiar with the appearance of all normal cells that can be found in the bone marrow.
- The morphologic findings in the marrow must be interpreted in conjunction with the peripheral smear and in light of the clinical history.

Chapter 10: Evaluation of Anemia, Leukopenia, and Thrombocytopenia

Maria (Ria) E. Vergara-Lluri, Ashley S. Hagiya, and Russell K. Brynes

OUTLINE

EVALUATION OF ANEMIA

- **Microcytic Anemia**
- **Normochromic Normocytic Anemia or Hypochromic Microcytic Anemia**
- **Normochromic Normocytic Anemia, Underproduction**
- **Normochromic Normocytic Anemia, High Output**
- **Macrocytic Anemia**

EVALUATION OF LEUKOPENIA

- **Neutropenia**
- **Lymphopenia**

EVALUATION OF THROMBOCYTOPENIA

Acquired Thrombocytopenia

Constitutional Thrombocytopenia

EVALUATION OF SPECIFIC BONE MARROW FAILURE SYNDROMES

Select Acquired and Constitutional Bone Marrow Failure Syndromes

Quantitative and qualitative abnormalities of the peripheral blood are routinely detected with an automated complete blood count (CBC) and examination of a peripheral blood smear. The peripheral blood evaluation serves as a screening test for potential bone marrow abnormalities and diseases that affect bone marrow function. When peripheral blood abnormalities are identified, the decision to perform an invasive bone marrow procedure is influenced by a moderate number of quantitative findings from the CBC and a greater number of qualitative abnormalities upon inspection of the peripheral blood smear. The decision also relies on a carefully obtained history, thorough physical examination, evaluation of current and historical laboratory values, and imaging studies. The utility of a thorough history in the evaluation of bone marrow specimens cannot be overemphasized. The history should include information about present and past illnesses, including how and when the cytopenia or cytosis presented and how it was discovered. Occupational history and a history of exposure to therapeutic or recreational drugs, alcohol, and toxins should be sought. Physical examination often provides a critical clue to the responsible

mechanism or disease process. Other laboratory studies pertinent to the case (e.g., inflammatory markers, autoantibodies, immunoglobulin levels, microbiologic studies) must be reviewed. Finally, in certain cases, review of radiologic data may yield additional useful information. Without integration of these various essential elements, interpretation of the bone marrow findings is often incomplete or misleading. This chapter focuses on nonmalignant anemia, leukopenia, and thrombocytopenia. The differential diagnosis of increased and decreased numbers of clonal red blood cells (RBCs), leukocytes, and platelets is discussed elsewhere in this book.

EVALUATION OF ANEMIA

The World Health Organization (WHO) defines anemia as a hemoglobin concentration of less than 12 g/dL in women, less than 13 g/dL in men, less than 11 g/dL in children aged 6 months to 6 years, and less than 12 g/dL in children aged 6 to 14 years.[1] Age-adjusted charts are available for the pediatric population. It is important to note that racial differences exist. Compared with individuals of European descent of similar age and sex, hemoglobin concentrations of individuals of African descent are almost 1 g/dL lower.[2] The effects of altitude should also be considered, as those residing at higher altitudes exhibit higher hemoglobin levels. The initial evaluation of anemia begins with the CBC data and comprehensive examination of a well-prepared peripheral blood smear. The blood smear should initially be evaluated at scanning power to detect abnormalities such as rouleaux formation and RBC agglutination, followed by observation of individual RBCs with a

high-powered lens. Review of pertinent history and physical findings can help determine what additional laboratory tests are needed and whether a bone marrow examination is required to further define the process.

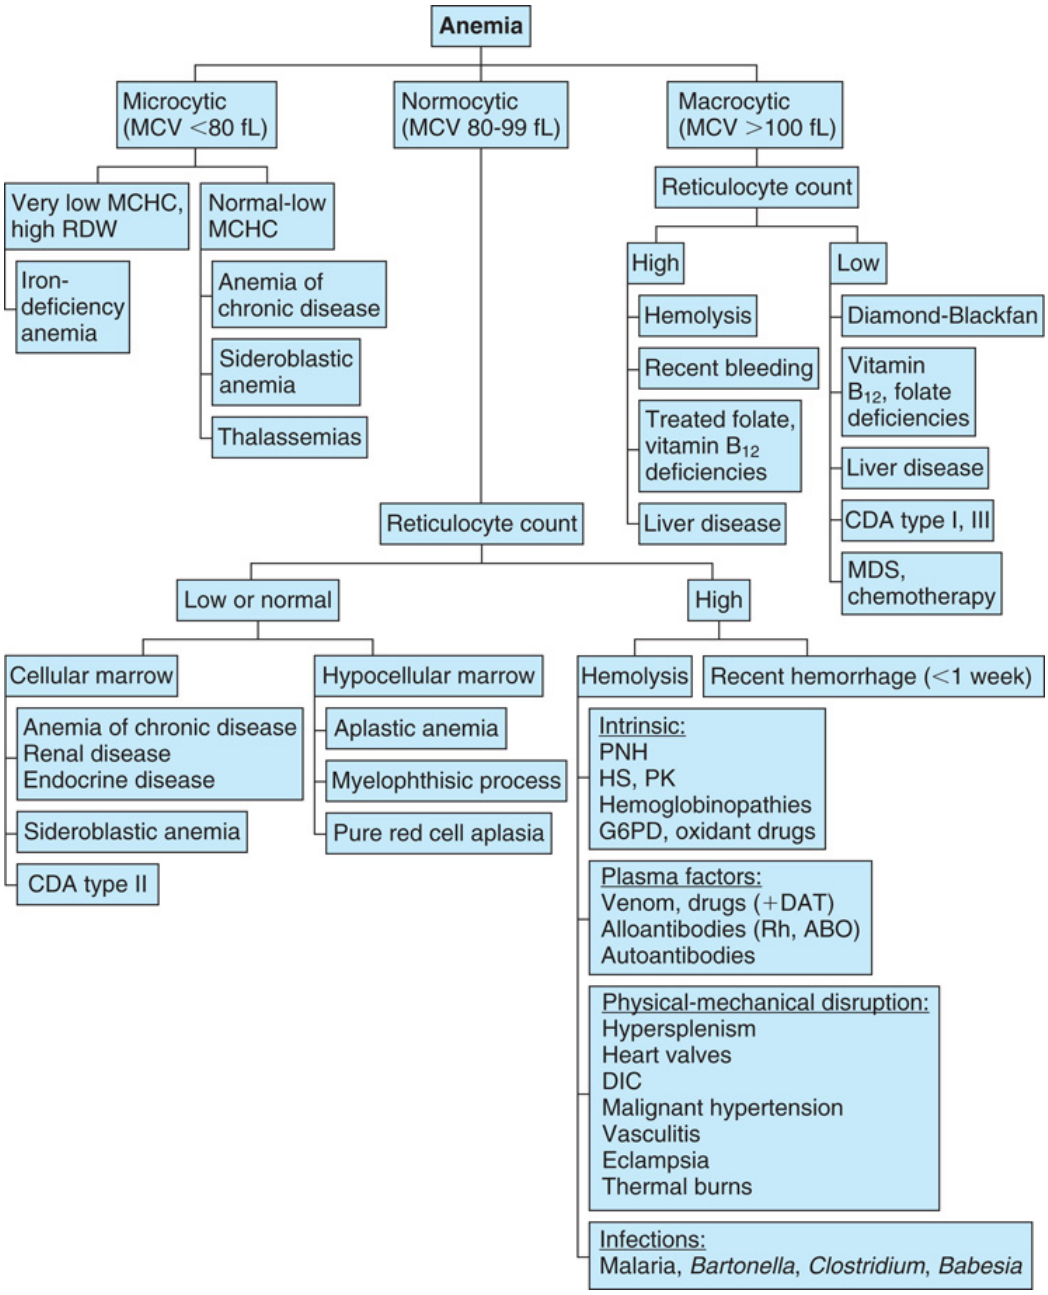

FIGURE 10-1 Anemia algorithm.Mean corpuscular volume (MCV) is based on adult values; reference ranges must be considered for pediatric patients. *CDA,* Congenital dyserythropoietic anemia; *DAT,* direct antiglobulin test; *DIC,* disseminated intravascular

coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *HS,* hereditary spherocytosis; *MCHC,* mean corpuscular hemoglobin concentration; *MDS,* myelodysplastic syndrome; *PK,* pyruvate kinase deficiency; *PNH,* paroxysmal nocturnal hemoglobinuria; *RDW,* red cell distribution width.

Anemias can be divided into those caused by production problems with insufficient or ineffective erythropoiesis and those caused by either blood loss or decreased RBC survival. The reticulocyte count is the best test to differentiate between abnormalities of production and survival, and it is often the first test considered in algorithms for the evaluation of anemia. Because the reticulocyte count may not be high during the initial stages of hemolysis and blood loss, anemia may be better stratified first by the CBC data, with size (mean corpuscular volume [MCV]), hemoglobinization (mean corpuscular hemoglobin concentration [MCHC] and mean corpuscular hemoglobin [MCH]), RBC count, and degree of anisocytosis (red cell distribution width [RDW]) (**Fig. 10-1**). This approach can then be extended with an algorithm that adds reticulocyte count, serum iron studies, and vitamin B_{12} and folate values, as needed. With this algorithm, bone marrow examination is required most frequently for normocytic or macrocytic anemias with low reticulocyte counts that cannot be explained by vitamin B_{12} or folate deficiency, liver disease, drug or alcohol effects, or other clearly defined causes. Bone marrow examination is essential in the diagnosis of aplastic anemia (AA), myelodysplastic syndromes (MDS), and myelophthisic anemia. Of

course, anemia is quite common in patients undergoing bone marrow examination for other indications, such as tumor staging.

Microcytic Anemia

In microcytic anemia, the MCV is less than the normal laboratory reference range, generally less than 80 fL for adults and dependent on age for children. The small RBCs result from defective or ineffective production of hemoglobin. Heme, the iron-containing porphyrin ring component of hemoglobin, is synthesized from succinyl coenzyme A (CoA) and glycine through a series of enzymatic steps that occur in the mitochondria (**Fig. 10-2**). Disorders affecting heme synthesis, the globin genes, iron acquisition by erythroid precursors, or iron availability prevent adequate hemoglobinization and maturation of RBC cytoplasm, resulting in hypochromic microcytic cells.[3,4] **Table 10-1** lists additional findings for hypochromic microcytic anemias.

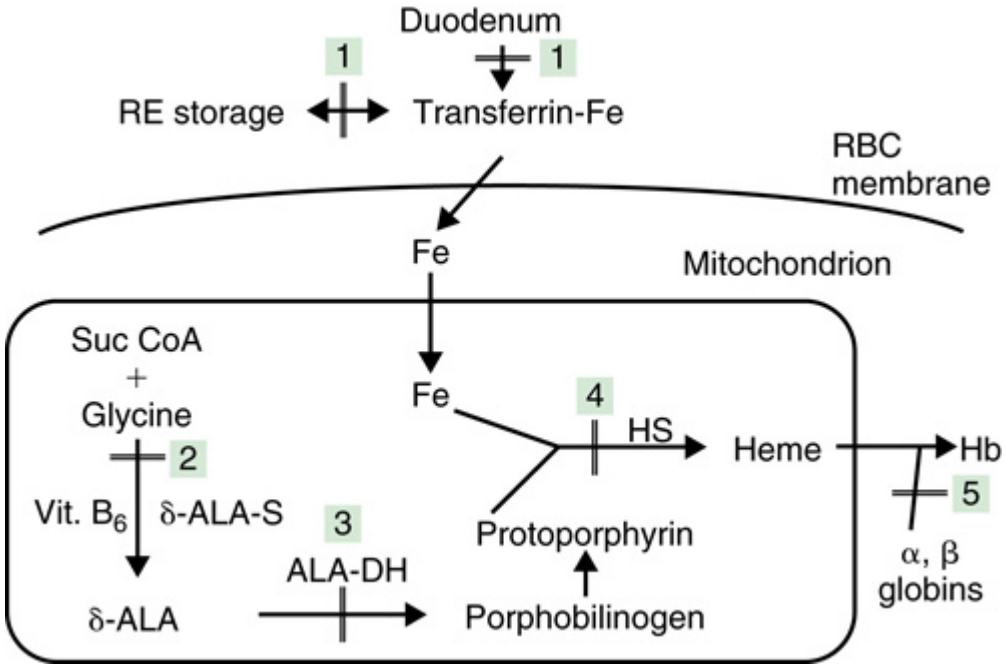

FIGURE 10-2 Defects causing microcytic anemias.Ferric iron is absorbed by the duodenum and transported via ferroportin receptors to serum transferrin (measured as total iron-binding capacity). Hepcidin, produced by the liver, regulates iron (Fe) uptake and transport through ferroportin in response to iron stores, inflammation, erythropoiesis, and hypoxia. The strongest extrahepatic hepcidin suppressor—erythroferrone (ERFE)—is secreted by more mature erythroid precursors stimulated by erythropoietin (EPO) production, thereby playing a key role in maintaining iron homeostasis. Most serum iron is delivered to the bone marrow for red blood cell (RBC) production. Erythroid precursors have classic transferrin receptors that selectively bind and internalize diferric

transferrin. When transferrin saturation exceeds 60%, iron is shunted into histiocyte storage in the bone marrow, spleen, and liver. **1,** Hepcidin excess leads to blockade of this pathway and inability to mobilize iron back into the serum through ferroportin receptors on histiocyte surfaces and on duodenal enterocytes. It is characteristic of anemias of chronic disease. Deficiency or blockade of key steps in heme synthesis by heavy metals and various drugs (e.g., isoniazid) causes iron to accumulate within mitochondria, producing sideroblastic anemias. **2,** Congenital deficiency and heavy metal (lead) inhibition of aminolevulinic acid dehydratase (ALA-DH) **(3)** or heme synthetase (HS) **(4)** produce a similar effect. **5,** Decreased synthesis of globin chains contributes to the microcytosis of thalassemia syndromes. Blood loss or dietary deficiency of iron ultimately produces iron-deficiency anemia. *Hb,* Hemoglobin; *RE,* reticuloendothelial.

Iron Deficiency

Iron homeostasis, including iron uptake from the intestine and release from stores, is regulated by the liver-secreted protein hepcidin.[5] Iron deficiency occurs when iron utilization or loss exceeds iron absorption and results in depletion of body stores. Early in iron deficiency, iron stores are decreased, but the red cells are

morphologically unaffected. Serum ferritin (normally 12 ng/mL to 300 ng/mL) is in equilibrium with tissue stores and serves as an indirect measure of the body's iron stores in uncomplicated cases; indeed, in the absence of inflammation, serum ferritin levels below the reference range are indicative of iron deficiency. However, ferritin is an acute-phase protein, and patients with chronic inflammation or liver disease may have elevated values even in the presence of iron deficiency. After iron stores are depleted, serum iron drops and the iron transport protein, transferrin, increases so that the total iron-binding capacity is increased. The red cells become microcytic and normochromic, then finally microcytic and hypochromic (**Fig. 10-3**).[6] Serum iron concentration has diurnal variation and should be measured in the morning, when it is at its highest level. Transferrin saturation (serum iron/total iron binding capacity) of less than 15% is virtually diagnostic of iron deficiency. The sensitivity and specificity of the CBC, transferrin saturation, and ferritin values are usually sufficient to make the diagnosis of iron deficiency without the need to perform a bone marrow study. Serum-soluble transferrin receptor (sTfR) levels, which are elevated in iron deficiency but usually unaffected by inflammation, and the sTfR-ferritin index (sTfR/log ferritin) may be helpful in interpreting iron status in patients with inflammatory disease; however, these tests are not widely available or standardized and are often not needed in routine practice.[7] Although many advances have been made in our understanding of iron metabolism and hepcidin, measurement of serum hepcidin levels continues to be mostly limited to research settings as a result of analytic challenges and difficulties in interpretation; however, it may be useful in assessing iron status and

erythropoietin resistance in states of inflammation and in determining the optimal route of iron supplement administration.[8-11] In ambiguous cases, such as patients with elevated acute-phase proteins or hepatic disorders, a bone marrow evaluation for iron assessment is indicated. Bone marrow iron stores and sideroblast iron should be evaluated on an aspirate smear (**Fig. 10-4A and B**) because iron is chelated by acidic decalcifying agents and is generally underestimated in clot or trephine biopsy sections. In normal bone marrow, one or two small siderotic granules are normally identifiable in at least 10% of the normoblasts (**Fig. 10-4A and B**). In iron deficiency, the Perls Prussian blue stain demonstrates loss of reticuloendothelial marrow stores and iron incorporation into normoblasts (**Fig. 10-4C and D**; **Table 10-1**). The absence of iron stores differentiates iron deficiency from advanced anemia of chronic disease, which may mimic an iron deficiency state. However, some authors suggest the evaluation of multiple marrow spicules before declaring the marrow as iron deficient, as the iron may be irregularly distributed.[12] If recent parenteral iron or RBC transfusion has been given to an iron-deficient individual, these findings may be misleading, because the bone marrow iron stores may appear adequate. Parenteral iron shows a characteristic staining pattern with numerous uniform fine particles that tend to form curvilinear arrays within reticuloendothelial/stromal cells in essentially all marrow spicules.[13] Bone marrow morphology is otherwise non-specific in iron deficiency. In severe anemia, the erythroid precursors may appear smaller, with only a narrow rim of cytoplasm. Rarely, individuals have iron-refractory iron-deficiency anemia that is congenital and caused by defects in the *TMPRSS6* gene that lead to

uninhibited hepcidin production.[14] Some cases result from gene mutations involving the transferrin gene or iron transport genes *(TF, DMT1)*.[15] Celiac disease, *Helicobacter pylori* gastritis, and autoimmune gastritis can also cause iron deficiency anemia that is refractory to oral iron treatment.[16] As iron is not normally excreted by the body, except in menstrual periods, the etiology for blood loss should be carefully sought. The leading cause of iron-deficiency anemia in adults is occult bleeding from the gastrointestinal tract. Exclusion of *H. pylori* infection as a cause of unexplained iron-deficiency anemia is also important because eradication of the organisms leads to amelioration of the anemia.[17]

Table 10-1

Classification of Hypochromic Microcytic Anemia

Disorder	Features	Comments
Iron deficiency	CBC: ↓ RBCs, ↓↓ MCHC, ↓↓ MCH, ↓ MCV, ↑ RDW, normal-↓ platelets, ↓ reticulocytes PBS: anisopoikilocytosis, especially elliptocytes (“cigar” or “pencil” cells), prekeratocytes, occasional target cells Iron studies: ↑ TIBC, ↓ TSAT, ↓ serum iron, ↓ ferritin Iron stain patterns on BM aspirate smear: 0 storage iron, 0 incorporated	Iron required for rate-limiting step in heme synthesis Deficiency caused by chronic blood loss (especially menstrual), GI dietary deficiency (breastfed children aged 6 months to 2 years at risk), postgastrectomy (gastric acid required for iron absorption), upper GI malabsorption, *Helicobacter*

Disorder	Features	Comments
	(sideroblast) iron	*pylori* infection
Iron refractory iron deficiency anemia	CBC: ↓ RBCs, ↓↓ MCHC, ↓↓ MCH, ↓ MCV Iron studies: ↓ serum iron, ↓ TSAT, ↓-normal ferritin Iron stain patterns on BM aspirate smear: ↓-absent storage iron, o incorporated (sideroblast) iron	*TMPRSS6* mutation leads to uninhibited hepcidin production Unresponsive to oral iron
β-Thalassemia	CBC: normal-↑ RBCs, ↓↓ MCV, ↓-normal MCHC, normal-↑ RDW PBS: target cells, coarse basophilic stippling	Absent or ↓ synthesis of β globin chains caused by gene mutations Frequent in Mediterranean populations

Disorder	Features	Comments
		↑ HbF has heterogeneous distribution in RBCs
α-Thalassemia	Similar to β-thalassemia	Absent or ↓ synthesis of α globin chains caused by gene deletions Frequent in Southeast Asian and African populations
Anemia of inflammation (also known as anemia of chronic disease)	CBC: ↓ RBCs, normal-↓ MCV, normal-↓ MCHC, ↓-normal MCH, normal-↑ RDW PBS: possible hypochromic cells even if normocytic Iron studies: ↓ serum iron, ↓-	More often presents as a normochromic normocytic anemia, caused by excess hepcidin secondary to cytokines (IL-6)

Disorder	Features	Comments
	normal TSAT, ↑ serum ferritin Iron stain patterns on BM aspirate smear: normal-↑ storage iron, ↓ incorporated (sideroblast) iron	Normal-↓ serum iron, normal transferrin saturation
Sideroblastic anemia	PBS: Dimorphic RBCs, moderate poikilocytosis, hypochromic teardrop forms, coarse basophilic stippling, Pappenheimer bodies Iron stain patterns on BM aspirate smear: ring sideroblasts	See **Box 10-1** ↓ Reticulocyte count Variable anisocytosis, but may be marked

↑, Increased; ↓, decreased or low; ↓↓, very decreased or low; *BM,* bone marrow; *CBC,* complete blood count; *GI,* gastrointestinal; *Hb,* hemoglobin; *IL,* interleukin; *MCHC,* mean corpuscular hemoglobin

concentration; *MCH,* mean corpuscular hemoglobin; *MCV,* mean cell volume; *PBS,* peripheral blood smear; *RBC,* red blood cell; *RDW,* red cell distribution width; *TIBC,* total iron binding capacity; *TSAT,* % transferrin saturation.

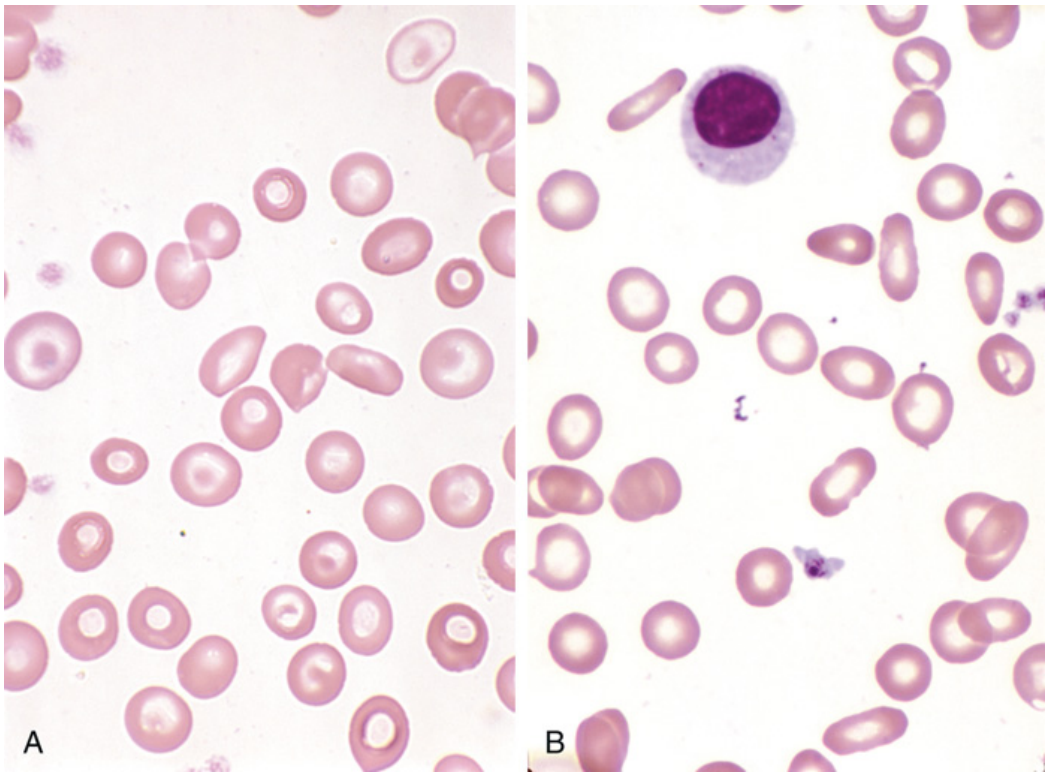

FIGURE 10-3 **A,** Iron-deficiency anemia in a child. The red blood cells are hypochromic and microcytic. Note the many target cells, a feature reported in long-standing iron deficiency. **B,** Severe iron-deficiency anemia. The red blood cells are hypochromic and microcytic. Their small size is apparent compared with the nucleus of the lymphocyte. Hypochromic elliptocytes are common in iron-deficiency anemia.

Thalassemias

Thalassemias are a common cause of hypochromic microcytic anemia in which adult hemoglobin (HbA [$\alpha_2\beta_2$]) synthesis is quantitatively affected by decreased α or β globin chain synthesis (**Table 10-2**; **Fig. 10-2**).[18,19] Thalassemia is common in Mediterranean regions, tropical Africa, and Asia; β-thalassemia is also seen in the Middle East and India. The diagnosis of β-thalassemia and severe forms of α-thalassemia is best made by high-performance liquid chromatography (HPLC) or electrophoretic techniques such as isoelectric focusing or capillary zone electrophoresis.[20,21] HPLC has been widely adopted worldwide.[22] However, these methods are not as useful in detecting milder forms of α-thalassemia; in these cases, molecular testing may be the only means for definitive diagnosis and may be indicated for genetic counseling.[22]

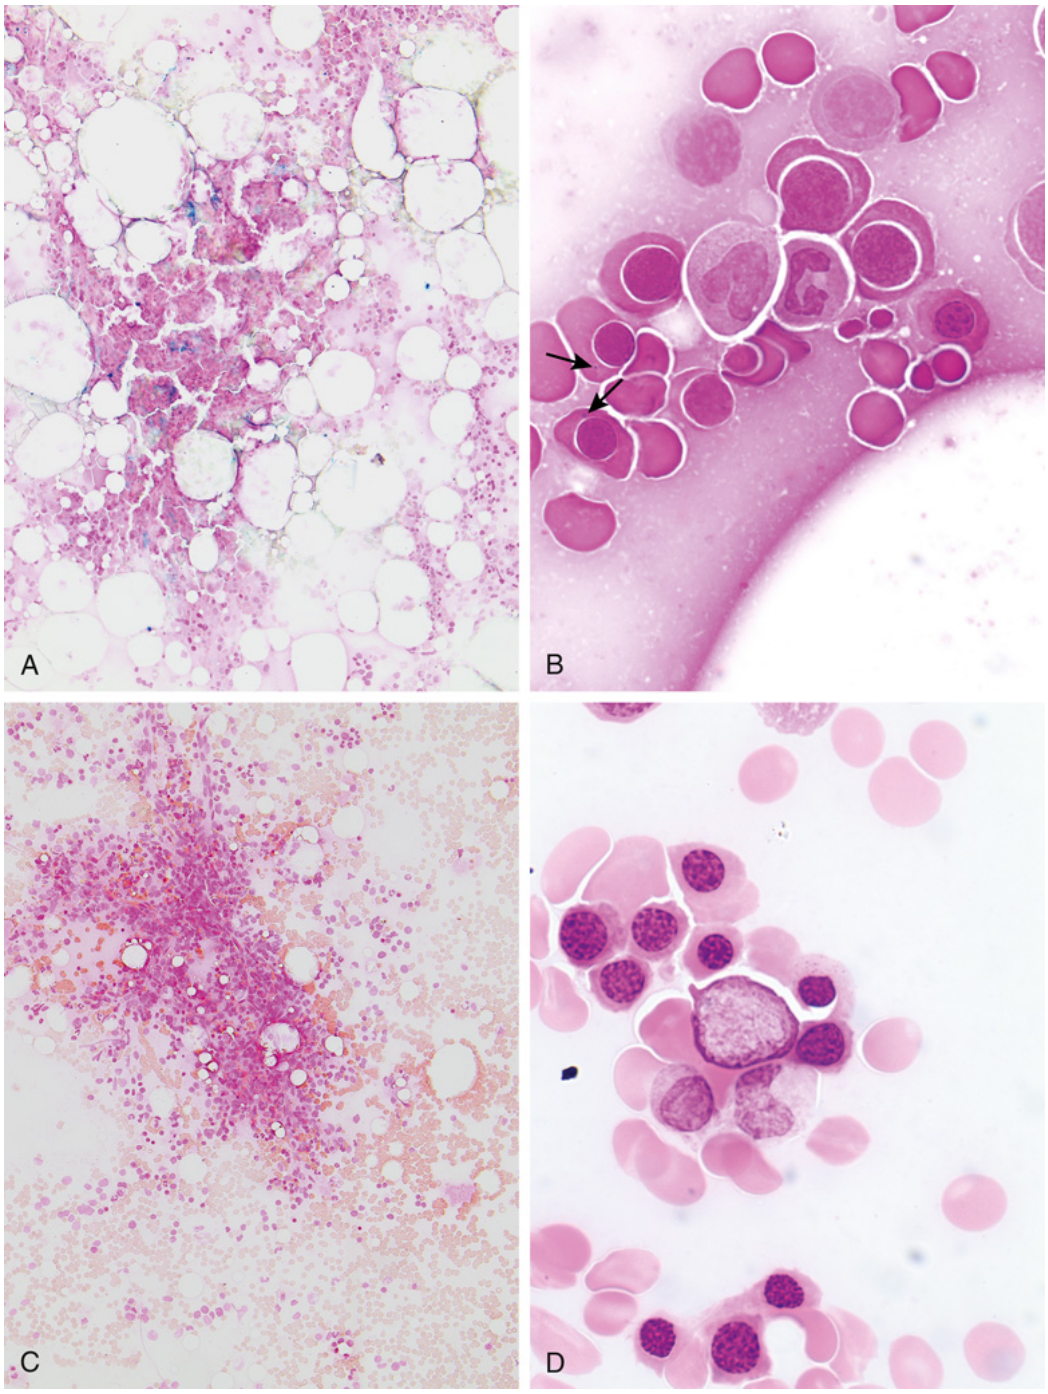

FIGURE 10-4 Bone marrow particle smear with normal iron stores and incorporation.**A,** Storage iron in stromal histiocytes stains blue with the Perls Prussian blue stain. **B,** Sideroblast (incorporated) iron granules *(arrows)* are seen in

10% to 20% of normoblasts. In a bone marrow particle smear in iron-deficiency anemia, both storage **(C)** and sideroblast **(D)** iron are absent.

β-thalassemia is caused by more than 350 different mutations that affect one or both of the β globin chain genes on chromosome 11.[23] These are primarily point mutations affecting transcription, splicing, or translocation of β globin messenger RNA. In its most benign form (β-thalassemia minor; **Fig. 10-5A and B**), only one of the two genes is mutated, causing either decreased (β^+) or absent (β^0) β globin protein synthesis by the affected allele.[18] The normally produced α chains have insufficient β chains with which to pair, and the excess combine with δ chains to produce HbA_2 ($\alpha_2\delta_2$). A mild elevation in fetal hemoglobin (HbF; $\alpha_2\gamma_2$) is also found in about one-third of patients. If both β chain genes are mutated, scant ($\beta^+\beta^+$ or $\beta^0\beta^+$) or no β chains ($\beta^0\beta^0$) are made, causing a serious childhood anemia, β-thalassemia major (Cooley's anemia). This is usually diagnosed in the first year of life as hemoglobin switches from HbF to HbA. It is associated with severe microcytic anemia, marked hemolysis, marked erythroid hyperplasia, hepatosplenomegaly, and failure to thrive. Leukopenia and thrombocytopenia may occur with progressive splenomegaly. Patients who are not transfusion dependent or who are diagnosed later in life are classified clinically as having β-thalassemia intermedia. Methyl violet highlights insoluble α chain inclusion bodies in the red cells, resembling Heinz bodies. They also occur in hemoglobinized erythroid precursors in the marrow and result in ineffective erythropoiesis. Erythropoiesis is also affected by red cell membrane abnormalities in the developing cells (abnormal ratios of spectrin to band 3 and abnormal band 4.1)

that promote increased intramedullary death of the red cell precursors. In addition to erythroid hyperplasia, the bone marrow may demonstrate erythrophagocytosis and increased hemosiderin as a result of excessive absorption of dietary iron, secondary to decreased hepcidin levels.[24]

Table 10-2

Hb, Hemoglobin.

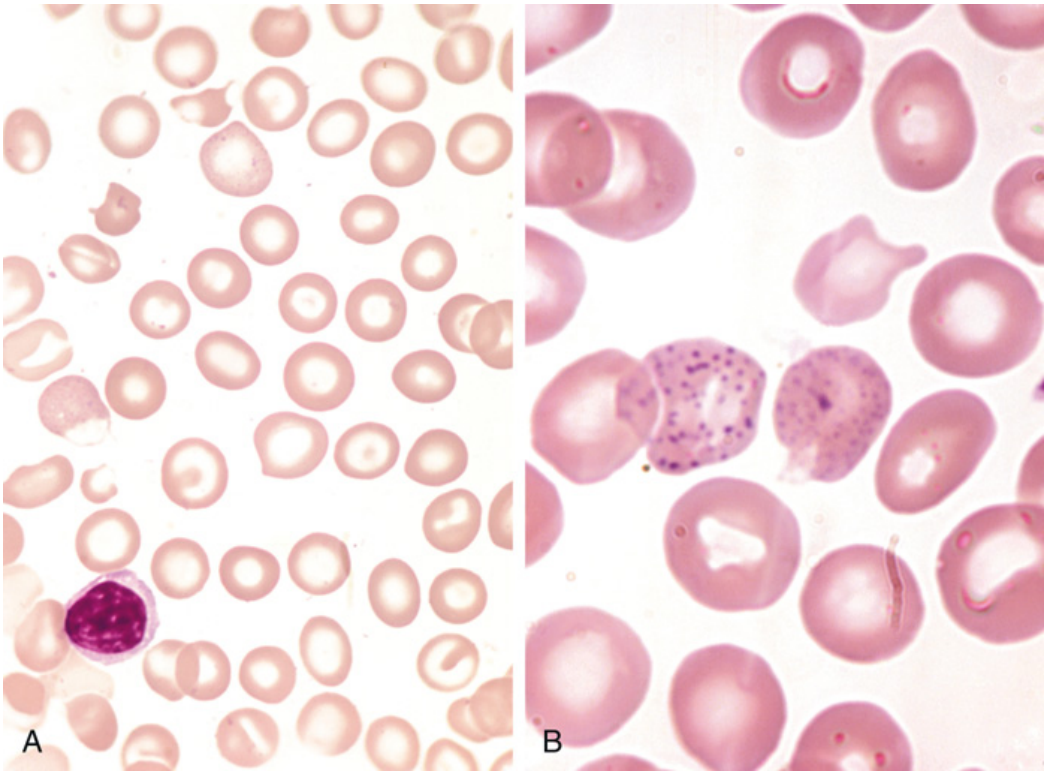

FIGURE 10-5 **A,** Blood smear in β-thalassemia minor illustrates hypochromic, microcytic red blood cells. Target cells are increased. **B,** Coarse basophilic stippling is a characteristic feature of β-thalassemias.

The α-thalassemias are primarily caused by deletions of one, two, or three of the four α chain (αα/αα) genes located on chromosome 16.[18] The number of deleted loci determines disease severity. A silent carrier has only one deleted gene (–α/αα), and the blood picture is normal. When two genes are involved (–α/–α in African populations or – –/αα in Asian populations), a mild hypochromic microcytic anemia is generally present (α-thalassemia trait) (**Fig. 10-6A**). Only one functioning α chain (– –/–α) results in HbH (β_4) disease (**Fig. 10-6B**). Neonates with this disorder have excess unpaired γ globin chains that form tetramers, called *hemoglobin Barts* (γ_4). They also produce small amounts of HbF until β chain synthesis develops and replaces γ chain synthesis. Adults and older children form β chain tetramers (HbH) with normal amounts of HbF. HbH disease is most common in Asian populations because of deletions of α chain genes in the cis configuration (– –/αα).[19] They present with variable symptoms and usually moderate hypochromic microcytic anemia with reticulocytosis, although severe anemia similar to β-thalassemia major may be seen. RBCs have HbH inclusions that can be seen best with brilliant cresyl blue or new methylene blue stains. Unlike the globin precipitates of β-thalassemia major, these β globin inclusions are not seen in bone marrow erythroid precursors. The remaining bone marrow findings are similar. Deletion of all four α chain genes (hydrops fetalis) is incompatible with life (**Fig. 10-6C**). With the absence of α chain production, only hemoglobin Barts is formed. This abnormal hemoglobin has very high oxygen affinity and deprives fetal tissues of needed oxygen. An acquired form of α-thalassemia may develop in elderly patients with myelodysplastic syndrome (MDS) and an associated *ATRX* gene mutation that

downregulates α chains.[25] In addition, microcytosis associated with abnormal α chain synthesis has been described in cases of classic Hodgkin lymphoma.[26]

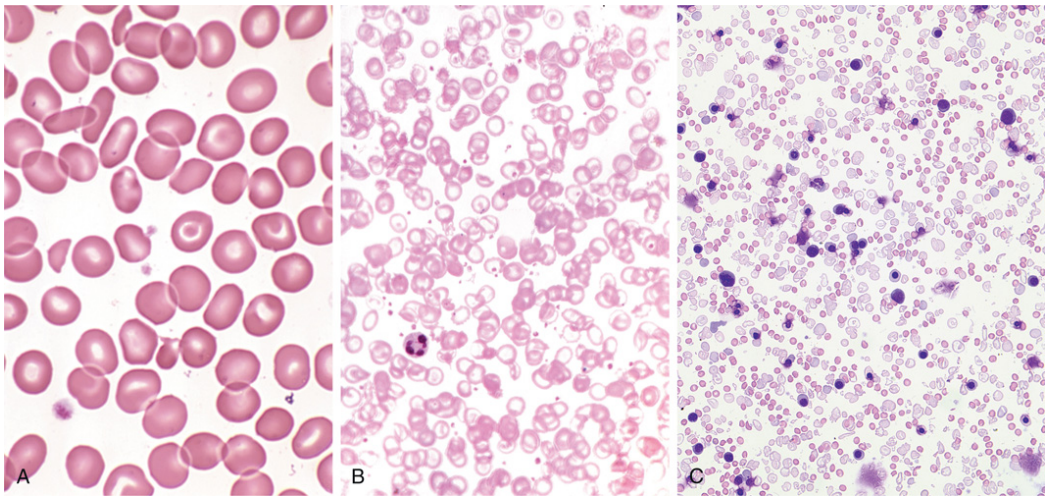

FIGURE 10-6 **A,** Blood smear in α-thalassemia minor (– –/αα or –α/–α) is slightly hypochromic or normochromic and microcytic. Rare target cells and spherocytes may be found in some cases. **B,** α-Thalassemia major or HbH disease (– –/–α) produces moderate anemia characterized by hypochromic microcytic red blood cells. Precipitated β globin chains can be detected with brilliant cresyl blue supravital staining. **C,** Hydrops fetalis results from the functional absence of all α chain genes (– –/– –) and the production of hemoglobin Barts (γ4). It is associated with severe hypochromic microcytic anemia. Target cells and normoblasts may be numerous. Spherocytes are also present in this case. Precipitated hemoglobin Barts is easily detected in the red blood cells with brilliant cresyl blue supravital staining.

A third form of thalassemia, termed *δβ-thalassemia,* is caused by deletions of large segments of DNA on chromosome 11, including both δ and β genes. Heterozygotes present as thalassemia minor with microcytosis and no anemia. Their HbF ($\alpha_2\gamma_2$) levels are typically elevated (5% to 20%), and HbA_2 ($\alpha_2\delta_2$) is normal or low.[27] Patients homozygous for the δ-β mutation have 100% HbF and clinical findings similar to those of thalassemia intermedia. Rarely, patients have a thalassemic picture as a result of structurally abnormal hemoglobins, such as hemoglobins Constant Spring, Lepore, and HbE.[28]

Normochromic Normocytic Anemia or Hypochromic Microcytic Anemia

The following anemias are most often normochromic and normocytic but may occasionally be hypochromic and microcytic.

Anemia of Inflammation

Anemia of inflammation (AoI), also known as *anemia of chronic disease (ACD),* is second only to iron-deficiency anemia in frequency. It is observed in patients with infectious, inflammatory, traumatic, or neoplastic disorders and is thus common among hospitalized patients. AoI is characterized by a low serum iron concentration in the face of normal or increased iron stores. It results from cytokine-induced hepcidin production that suppresses erythropoiesis and causes a mild shortening of RBC life span, impaired mobilization of iron from reticuloendothelial stores to erythroid precursors, lower than expected erythropoietin production, decreased erythrocyte survival, and an inadequate response of erythroid precursors to erythropoietin.[29] The relative contribution of each of these findings

may vary according to the underlying disease. For instance, in chronic renal failure, the anemia often has a multifactorial cause, including the effect of certain still ill-defined plasma factors. However, a primary cause is underproduction of erythropoietin by the damaged kidneys.

The liver peptide hormone hepcidin is a major regulator of iron homeostasis and plays a central role in the pathogenesis of AoI.[10] Hepcidin blocks the activity of ferroportin, a transport protein that facilitates basolateral movement of iron from the intestinal apical cells and from histiocytes. Thus, an increase in hepcidin in inflammation leads to hypoferremia, impaired delivery of iron to erythroid precursors, and hyperferritinemia (**Fig. 10-2**).[29] The expression of hepcidin is upregulated by interleukin (IL)-6 (which can be increased by IL-1) and inhibited by tumor necrosis factor-α and by erythroferrone, the erythroblast-produced modulator of iron homeostasis.[5]

Suppression of erythropoiesis in AoI may be reversible by exogenous erythropoietin (or derivatives), but responses depend on the type of cytokines involved in stimulating hepcidin production.[30] For example, erythropoietin treatment is less effective for correcting the anemia of malignancy than for treating the anemia of chronic renal failure.[31] The beneficial or detrimental effects of providing supplemental iron also appear to depend on the underlying condition.[32] Hepcidin antagonists are being explored as promising therapies for AoI.[29,33,34] Erythroferrone, the strongest extrahepatic negative regulator of hepcidin, may also be a candidate therapeutic target.[5,35]

The normochromic normocytic form of AoI is generally mild to moderate and is far more prevalent than the hypochromic microcytic type, which is usually seen with progression and exacerbation of the underlying disease (**Fig. 10-7A**). Iron studies are helpful to exclude iron deficiency. However, ferritin can be difficult to interpret, because it is an acute phase protein; a ferritin level greater than 60 μg/L should be considered indicative of adequate iron stores. The bone marrow is usually normocellular, with normal or slightly decreased numbers of erythroid precursors (**Fig. 10-7B**). Bone marrow examination is helpful primarily in assessing the iron status when iron studies are indeterminate. A Prussian blue stain of the aspirate shows increased accumulation of reticuloendothelial iron stores in histiocytes and decreased sideroblast iron (**Fig. 10-8**; **Table 10-1**). This staining pattern excludes iron deficiency; chronic blood loss also becomes a less likely cause.

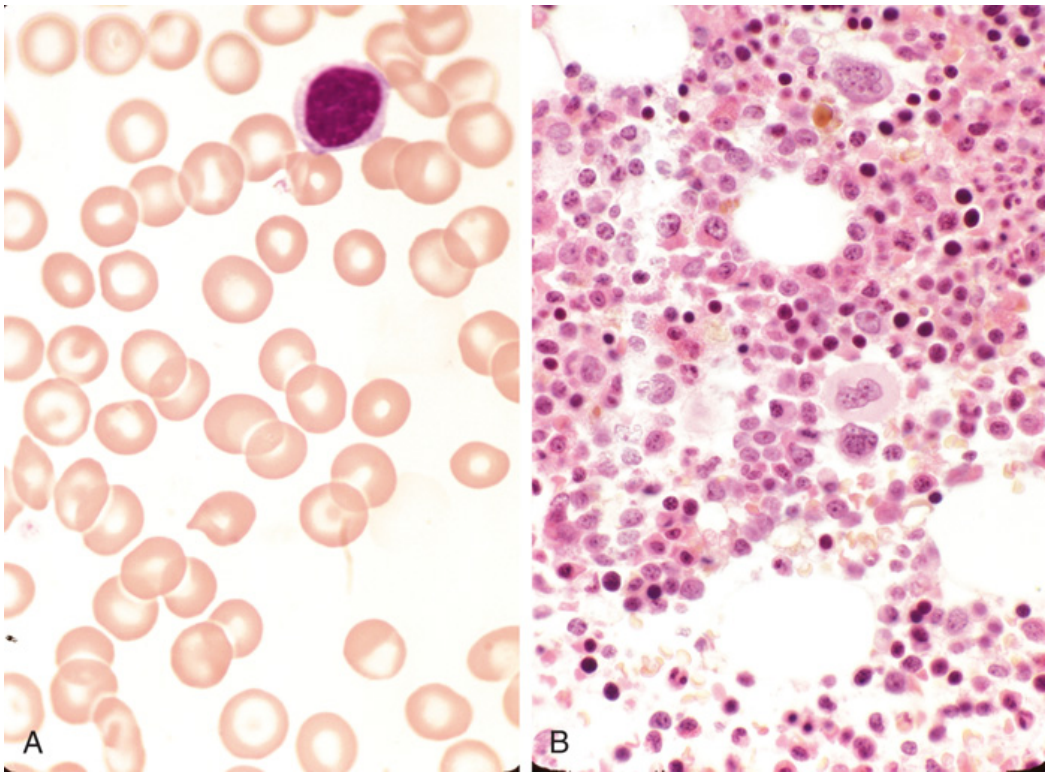

FIGURE 10-7 **A,** Slightly hypochromic normocytic red blood cells in anemia of inflammation associated with rheumatoid arthritis. **B,** Bone marrow erythroid precursors are present in normal numbers.

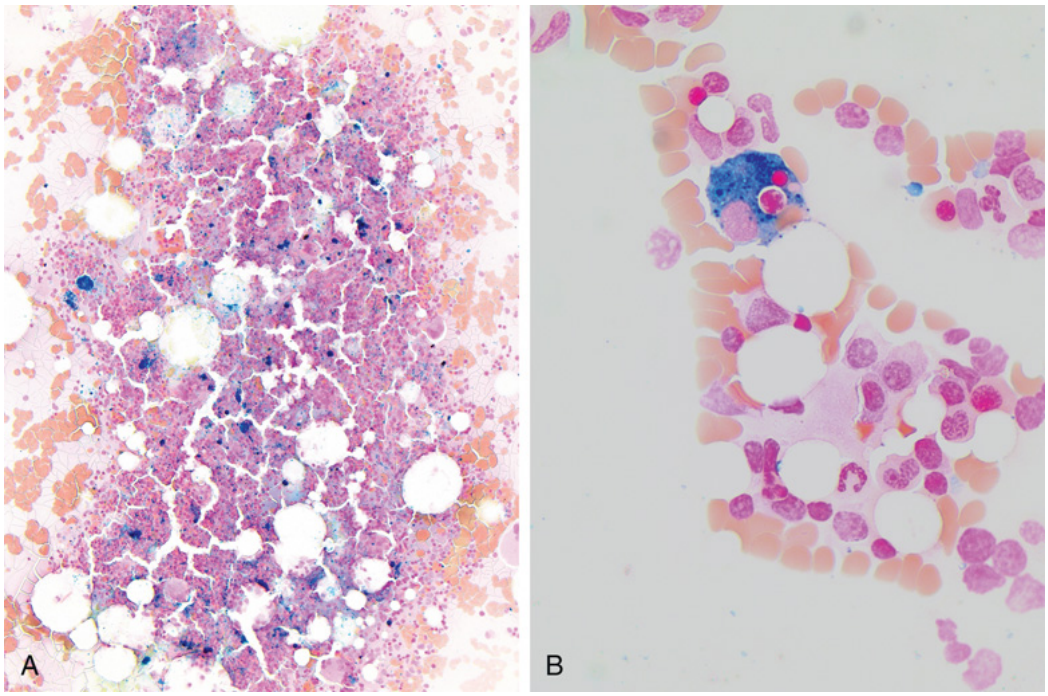

FIGURE 10-8 **A,** Anemia of inflammation, iron stores are increased in stromal histiocytes. **B,** Erythroid iron incorporation is decreased or undetectable.

Sideroblastic Anemias

Sideroblastic anemias are a heterogeneous group of disorders that are unified pathologically by abnormal accumulation of mitochondrial iron and impaired heme synthesis. The blood film often shows a striking dimorphic RBC picture with varying numbers of hypochromic and normochromic RBCs (Figs. **10-9 and 10-10**). The constellation of blood findings (**Table 10-1**) merits a bone marrow examination for definitive diagnosis. The bone marrow exhibits erythroid hyperplasia with normoblastic to megaloblastic maturation (Figs. **10-11** and **10-12**). Occasional dysplastic changes are seen, especially in the acquired clonal disorders. In some

congenital disorders, such as Pearson marrow-pancreas syndrome, large coalescent vacuoles may be found in the cytoplasm of bone marrow precursors (**Fig. 10-13**). The diagnostic feature is the presence of increased iron stores and ring sideroblasts, in which five or more large, siderotic granules are found in a perinuclear ring around one-third or more of the nucleus (**Fig. 10-14**). Sideroblastic iron granules are often more numerous and larger than normal. When examined by electron microscopy, large electron-dense deposits are found within mitochondria. Ineffective hematopoiesis is the primary cause of the anemia. Although the mechanisms responsible for sideroblastic anemia are not fully understood, the adverse effects of excess iron on mitochondrial heme synthesis and pyridoxine metabolism play a large role.[36]

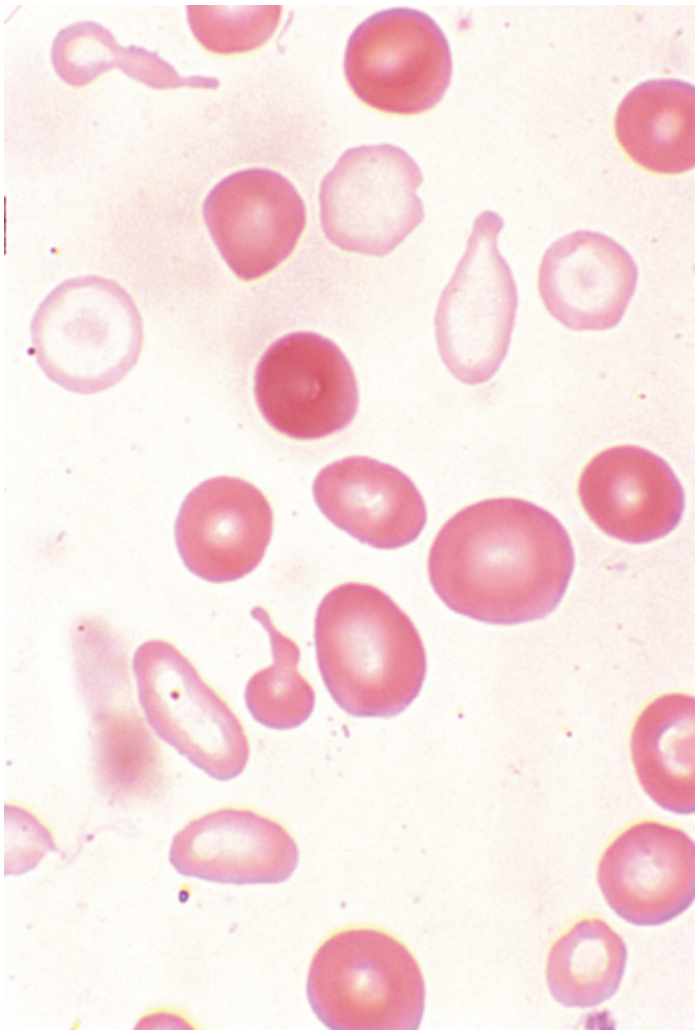

FIGURE 10-9 Pyridoxine-responsive sideroblastic anemia showing a dimorphic population of normochromic normocytic red blood cells and hypochromic microcytes. Hypochromic teardrop forms are common in sideroblastic anemia.

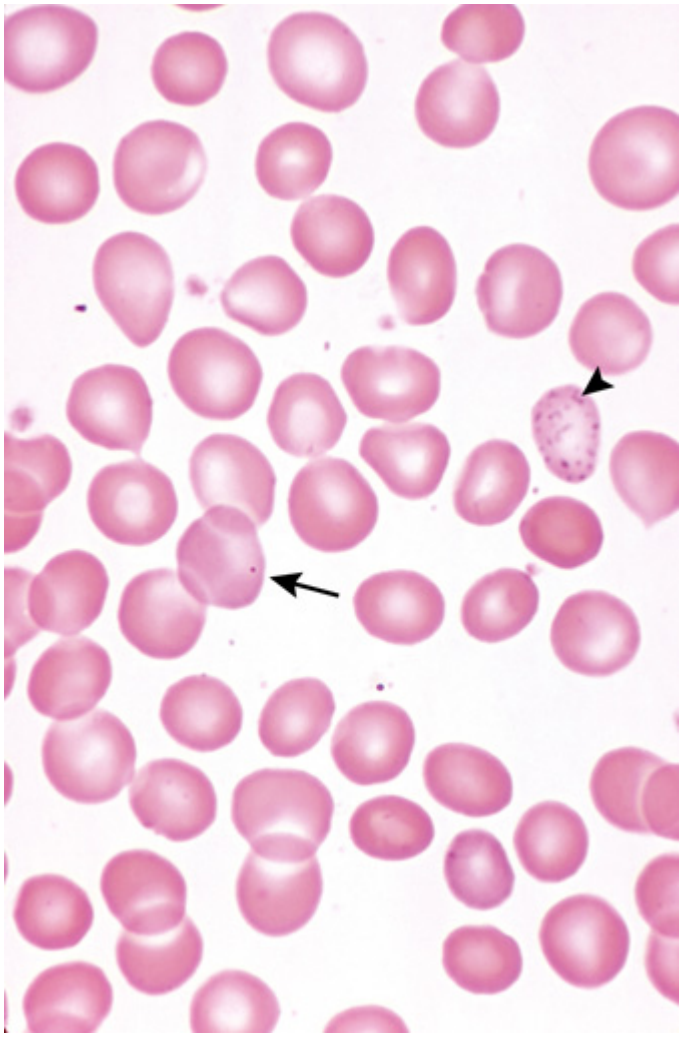

FIGURE 10-10 Coarse basophilic stippling *(arrowhead)* and Pappenheimer granules *(arrow)* are seen in this case of sideroblastic anemia associated with lead poisoning.

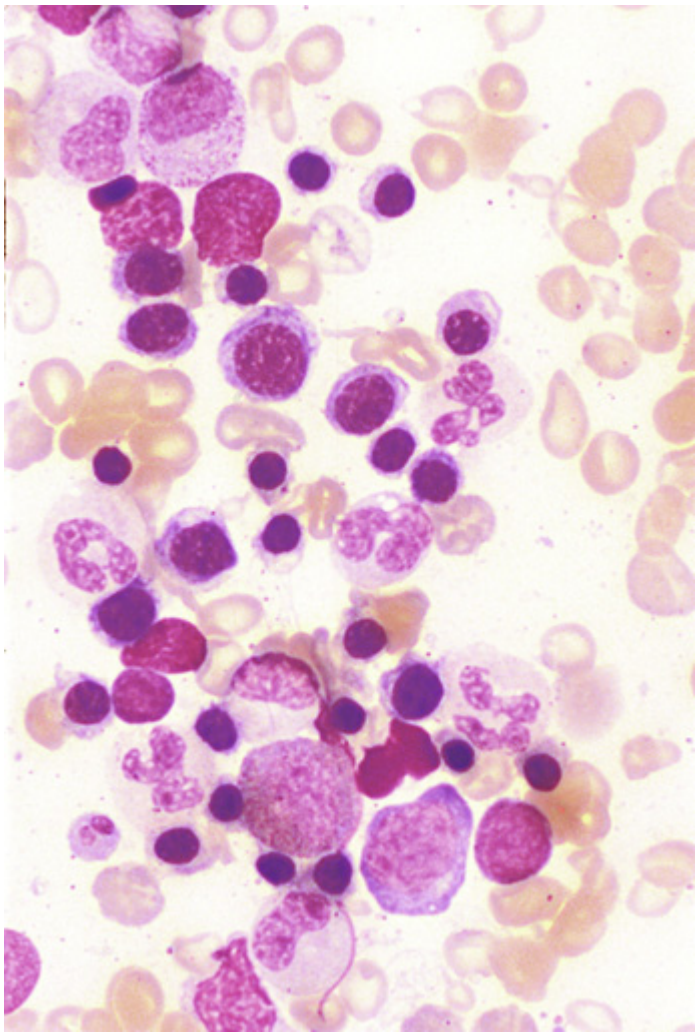

FIGURE 10-11 Ineffective erythropoiesis produces erythroid hyperplasia in most cases of sideroblastic anemia.

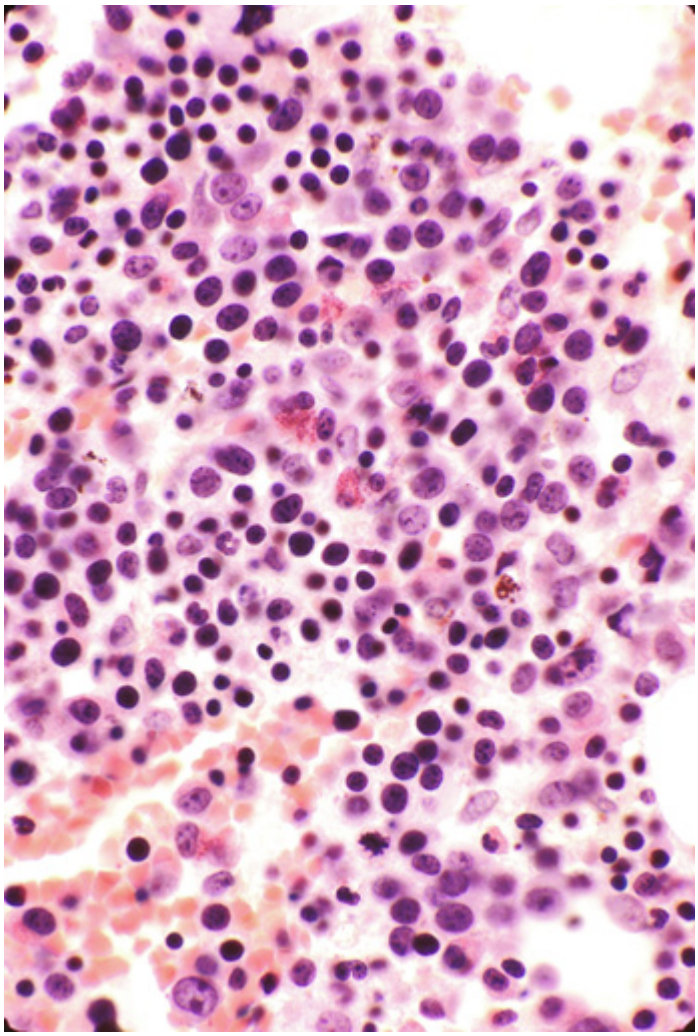

FIGURE 10-12 Markedly hypercellular bone marrow with erythroid hyperplasia in pyridoxine-responsive sideroblastic anemia.

Sideroblastic anemias can be classified as congenital or acquired (**Box 10-1**). The congenital sideroblastic anemias (CSAs) are most common in children, presenting soon after birth to later in childhood. They most often affect males and show an X-linked pattern of inheritance. The most common form of X-linked sideroblastic anemia is caused by a mutation in the gene that encodes δ-aminolevulinic acid (ALA) synthetase, an enzyme

important in the early steps of heme synthesis (**Fig. 10-2**).[37] The mutation affects the enzyme's affinity for its cofactor, pyridoxal-5′-phosphate. Some patients with this abnormality may respond to pyridoxine; in others, the mutation decreases the stability of the enzyme, and they are resistant to pyridoxine therapy. Another form, X-linked sideroblastic anemia with ataxia, is caused by a mutation in the gene that encodes the transporter protein ABCB7.[37] Autosomal recessive forms include sideroblastic anemias caused by defects in heme synthesis or iron-sulfur biogenesis. CSAs caused by abnormal mitochondrial protein synthesis have been identified.[37] Perhaps the best example is Pearson marrow-pancreas syndrome (**Fig. 10-13**), which occurs sporadically and is characterized by lactic acidosis, exocrine pancreatic insufficiency, sideroblastic anemia, and large deletions or duplications in mitochondrial DNA (mtDNA).[38] Another CSA, mitochondrial myopathy with lactic acidosis and ring sideroblasts, is caused by defective mitochondrial protein expression.[39] Point mutations in mtDNA have also been rarely reported.[37] Sideroblastic anemia, immunodeficiency, fevers, and developmental delay is a recently recognized entity caused by defects in cytosolic and mitochondrial protein translation.[37]

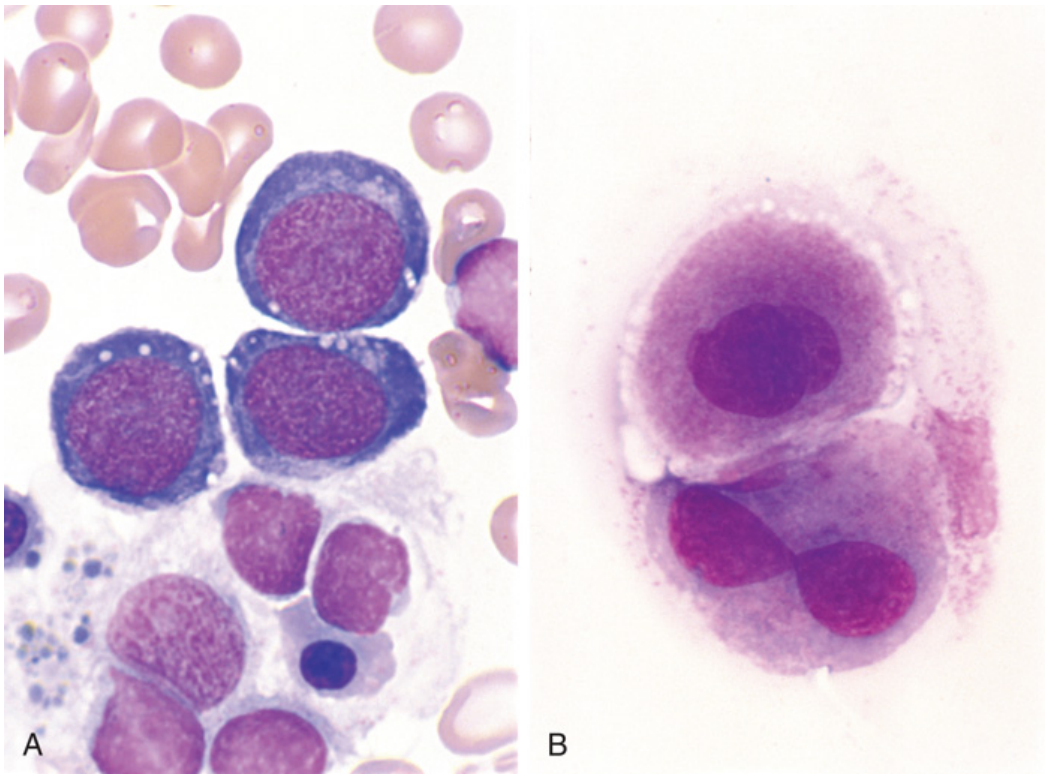

FIGURE 10-13 Cytoplasmic vacuoles in pronormoblasts **(A)** and megakaryocytes **(B)** are often found in Pearson marrow-pancreas syndrome. This rare form of sideroblastic anemia is associated with exocrine pancreas failure and is caused by deletions or duplications of mitochondrial DNA.

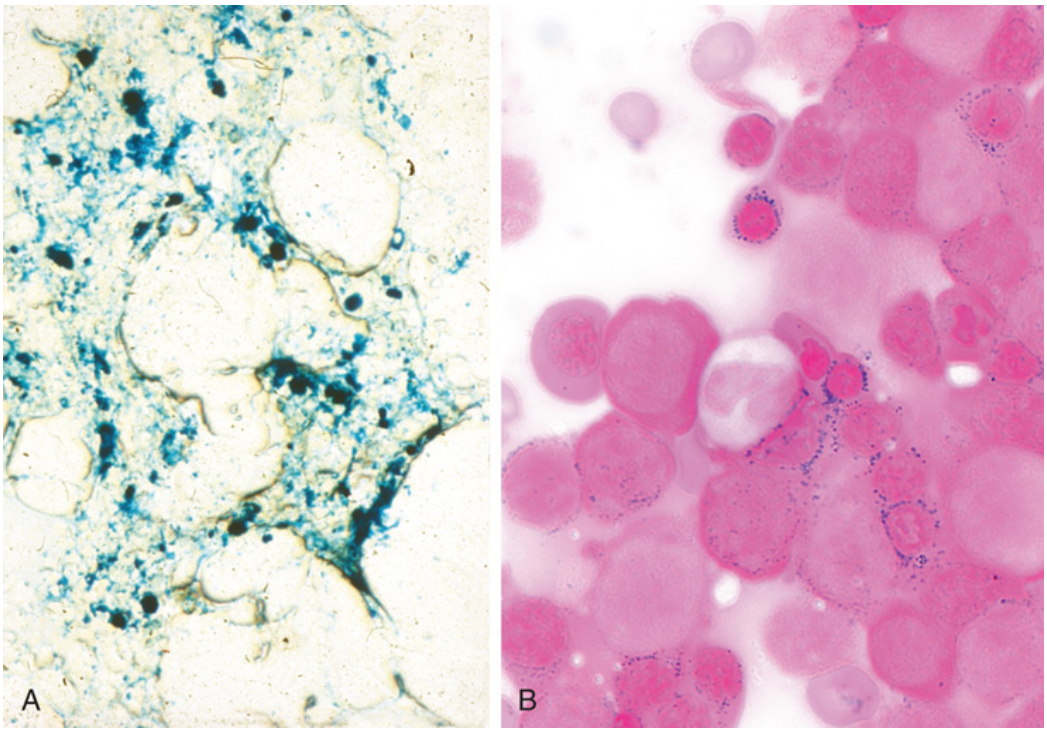

FIGURE 10-14 Increased iron stores **(A)** and numerous ring sideroblasts **(B)** are the diagnostic hallmarks of all forms of sideroblastic anemia.

Box 10-1 Classification of Sideroblastic Anemias

Congenital

- X-linked sideroblastic anemia (XLSA)
  - XLSA caused by ALAS2 deficiency
  - XLSA with ataxia caused by ABCB7 deficiency
- Autosomal recessive sideroblastic anemia (ARSA)
  - ARSA caused by mutations in *SLC25A38, GLRX5*

- Thiamine responsive megaloblastic anemia caused by mutations in *SLC19A2*
- Mitochondrial DNA mutations or deletions
  - Pearson marrow-pancreas syndrome
  - Mitochondrial myopathy with lactic acidosis and ring sideroblasts (MLASA) caused by mutations in *PUS1* or *YARS2*

Acquired

- Clonal (Often associated with *SF3B1* mutations)
  - Myelodysplastic syndromes
  - Myelodysplastic/myeloproliferative neoplasms
- Non-clonal
  - Drugs* (isoniazid, chloramphenicol, cycloserine, penicillamine, azathioprine)
  - Alcohol
  - Lead poisoning, arsenic
  - Copper deficiency

* Drug list is not all-inclusive.

The primary or idiopathic acquired forms of sideroblastic anemia include clonal disorders that fall in the spectrum of MDS and MDS/myeloproliferative neoplasms (MPN), which are often associated with somatic mutations in *SF3B1*.[40] They are discussed in **Chapter 44** and **Chapter 48**, respectively.

The secondary and less common forms of acquired sideroblastic anemia are the result of drugs and exposure to toxins, many of which have been characterized. For example, the drug isoniazid inhibits pyridoxine metabolism, lead inhibits δ-ALA dehydratase and heme synthetase, and alcohol produces a direct toxic effect on erythroid precursors (found in 30% of hospitalized alcoholics). The anemia can be reversed by administration of pyridoxal phosphate and discontinuation of the offending drug. Copper deficiency anemia, often secondary to zinc overload, displays red cells that may be microcytic, normocytic, or macrocytic.

Normochromic Normocytic Anemia, Underproduction

The normochromic normocytic anemias are characterized by red cells of normal size and hemoglobin content. They are most easily divided by reticulocyte count into disorders of underproduction (low or normal reticulocyte count) and increased production (high reticulocyte count) (**Fig. 10-1**).

Pure Red Cell Aplasia

Pure red cell aplasia is an isolated failure of erythropoiesis that results in anemia with reticulocytopenia in the setting of normal neutrophil and platelet counts. The marrow shows absent or diminished erythroid precursors, often with a left shift in erythroid maturation (**Fig. 10-15**). Pure red cell aplasia can be classified as congenital or acquired (**Box 10-2**). The congenital form, Diamond-Blackfan anemia (DBA), is classified as a macrocytic anemia. The acquired forms of pure red cell aplasia more frequently present with normochromic normocytic anemia and have been associated with

autoimmune/collagen vascular disorders, lymphoproliferative disorders, infections, pregnancy, myeloid malignancies, non-hematologic neoplasms, drugs, and toxic agents.[41] The anemia may be acute and transient or chronic, depending on the cause.

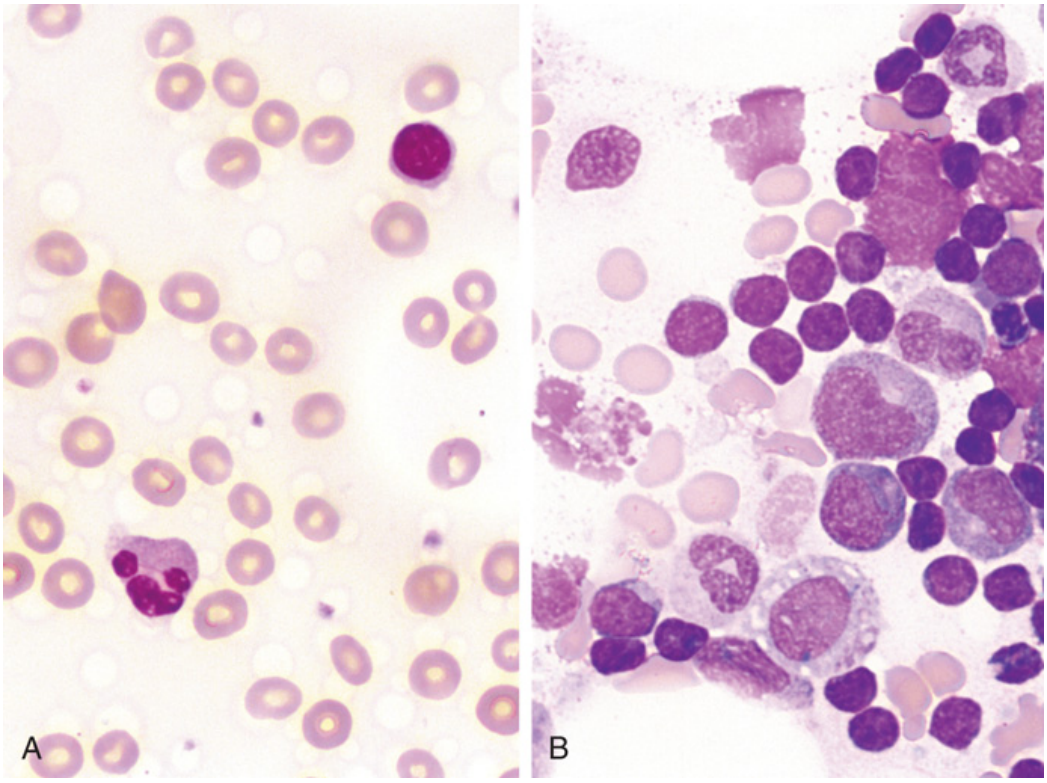

FIGURE 10-15 **A,** Severe anemia with reticulocytopenia was the presenting feature in this child with pure red cell aplasia. **B,** The bone marrow aspirate shows an absence of erythroid precursors. Granulocytic maturation is normal. Increased numbers of hematogones are present.

Parvovirus B19 is the most common identifiable cause of red cell aplasia in children and immunocompromised adults.[42] The virus selectively invades and replicates in erythroid progenitor cells,

causing direct cytotoxic effects with interruption of erythrocyte production. In children, it is associated with erythema infectiosum (fifth disease), a transient, asymptomatic drop in hemoglobin of about 1 g/dL, with recovery in 10 to 19 days. Children with a hemolytic disorder that shortens the RBC life span, such as red cell enzyme deficiencies, membrane abnormalities, hemoglobinopathies, or malaria infection, often have a more profound anemia and "aplastic crisis" (**Fig. 10-16**). Parvovirus B19 may persist in immunocompromised individuals who fail to produce neutralizing antibodies to eradicate the virus. Infection manifests as a chronic instead of acute pure red cell aplasia unless patients are treated with intravenous immunoglobulin therapy.[42] Bone marrow findings depend on the timing of the evaluation. Initial RBC depletion may be followed by a wave of early progenitors without maturation. Giant pronormoblasts with intranuclear viral inclusions are transient but may be occasionally identified, particularly in immunocompromised individuals. Viral-associated suppression of myelopoiesis and megakaryopoiesis occurs with rare cases of marrow necrosis. Serum polymerase chain reaction studies for parvovirus B19 DNA, elevated IgM antibody titers, and immunostaining for parvovirus on marrow biopsy sections are diagnostic.

Box 10-2 Classification of Pure Red Cell Aplasia

AIDS, Acquired immunodeficiency syndrome.

Congenital

- Diamond-Blackfan anemia

Acquired

- Transient erythroblastopenia of childhood
- Viral infection: parvovirus B19, hepatitis, Epstein-Barr virus, AIDS with parvovirus
- Drugs*

Azathioprine, cephalothin, chloramphenicol, dapsone, diphenylhydantoin, isoniazid, procainamide

- Solid tumors: thymoma
- Lymphoproliferative disorders: T-cell large granular lymphocyte leukemia, chronic lymphocytic leukemia
- Myelodysplastic syndrome
- Autoimmune disorders: rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome, myasthenia gravis
- Pregnancy
- Organ transplantation
- ABO-incompatible stem cell transplants

* Drug list is not all-inclusive.

The sudden onset of pure red cell aplasia is often associated with a history of recent respiratory or gastrointestinal viral infection or the use of drugs administered for infectious or inflammatory conditions. **Box 10-2** provides a partial list of drugs that may be responsible, with resolution of the aplasia typically occurring with drug cessation. The rare formation of anti-erythropoietin antibodies secondary to

erythropoietin treatment in patients with renal failure has been described. This phenomenon was eventually linked to the use of leachates in uncoated rubber stoppers of prefilled syringes; upon recognition, it is now even more rare.[41,43] Transient erythroblastopenia of childhood is an uncommon, acute, and transient anemia characterized by reduced or absent mature erythroid precursors in normocellular bone marrow.[44,45] The cause remains elusive.[41]

Most chronic, acquired pure red cell aplasia cases are idiopathic and believed to be caused by a cytotoxic T-cell mediated process resulting from unknown triggers, with destruction of early erythroid precursors.[43] Classic associations include thymoma, hematologic malignancies, and systemic autoimmune disorders. Despite the clearly established association between red cell aplasia and thymoma, less than 10% of individuals with aplasia are found to have thymomas upon radiographic evaluation. A significant proportion of idiopathic cases is likely secondary to the frequently underdiagnosed T-cell large granular lymphocyte leukemia (**Chapter 30**), a clonal proliferation of cytotoxic T-cells.[46] In refractory patients without a clear underlying cause and normal cytogenetic studies, pure red cell aplasia may be the initial presentation for MDS.[47,48]

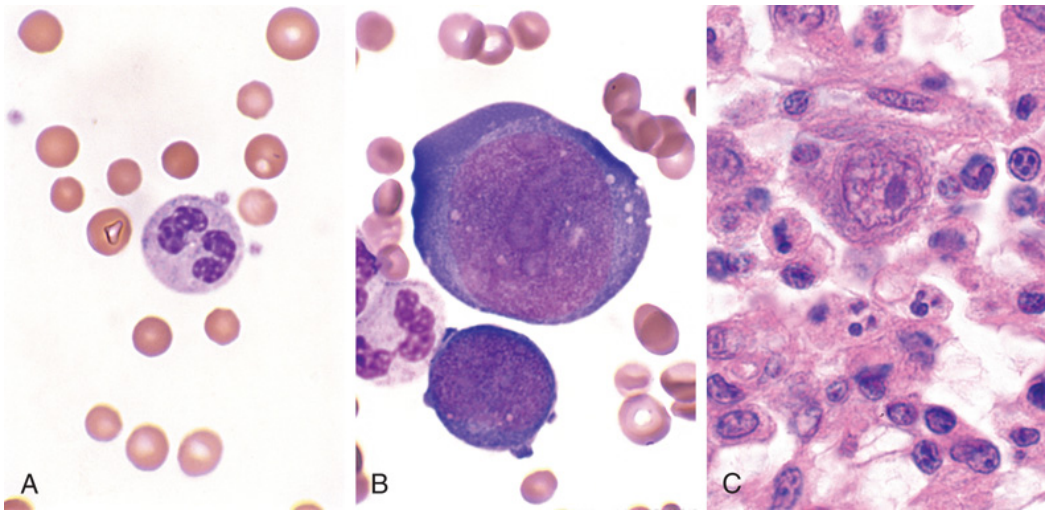

FIGURE 10-16 **A,** Peripheral blood smear from a patient with hereditary spherocytosis who developed severe anemia from a parvovirus B19–associated "aplastic crisis." The bone marrow aspirate **(B)** and trephine biopsy **(C)** contained giant pronormoblasts with large, nucleoli-like parvovirus inclusions.

Aplastic Anemia

Aplastic anemia usually presents with pancytopenia and is discussed in this chapter's section on bone marrow failure syndromes.

Myelophthisic Anemias

Myelophthisic anemias are caused by replacement of normal marrow cells by metastatic tumor cells or other types of malignancy, granulomas, histiocytes in storage disease, or fibrosis and usually exhibit bicytopenia or pancytopenia. Although the anemia is typically normochromic and normocytic, red cell fragmentation, spherocytes, and teardrop forms are frequently encountered. Normoblasts and

left-shifted granulocyte precursors produce a “leukoerythroblastic” blood picture in most cases associated with a metastatic tumor or fibrosis (**Fig. 10-17**). Bone marrow evaluation is essential to identify the underlying disorder.

Normochromic Normocytic Anemia, High Output

The remaining normochromic normocytic anemias, which include acute posthemorrhagic anemia and hemolytic anemias, show increased erythropoiesis with elevated reticulocyte counts.

Posthemorrhagic Anemia

Posthemorrhagic anemia caused by recent blood loss is normochromic and normocytic and is accompanied by a reticulocytosis that first manifests 3 to 5 days after blood loss. By 7 to 10 days, the reticulocytes may be so numerous that they increase the MCV up to 100 to 110 fL. Shortly after the hemorrhage, the first notable change in the blood is thrombocytosis, followed by demargination of neutrophils from the release of adrenergic hormones. Finally, the hemoglobin falls as extravascular fluids enter the vascular space.

Hemolytic Anemias

Hemolytic anemias are usually normochromic normocytic anemias in which an elevated reticulocyte count reflects compensation for increased RBC destruction. The process may be episodic or persistent. Hemolysis is caused by four basic abnormalities: intrinsic red cell defects, plasma factors, disruption of the cells by mechanical or thermal damage, and infectious agents (**Table 10-3**; **Fig. 10-1**). Patients with hemolytic anemia often have similar clinical and

laboratory findings: normochromic normocytic anemia, reticulocytosis, shortened red cell life span, elevated erythropoietin level, increased indirect bilirubin, increased lactate dehydrogenase, markedly decreased haptoglobin, and jaundice. Those with chronic extravascular hemolysis also develop splenomegaly and gallstones. Bone marrow evaluation invariably shows erythroid hyperplasia, even in patients with only mild compensated hemolysis. Circulating red cells with characteristic shape changes (e.g., sickle cells, spherocytes, or schistocytes) are helpful in the diagnosis, whereas the erythroid precursors in the marrow usually have an unremarkable appearance. Identifying or confirming the cause of a hemolytic anemia relies on the patient's history (including the family history) and on definitive laboratory studies, as summarized in **Table 10-3**.

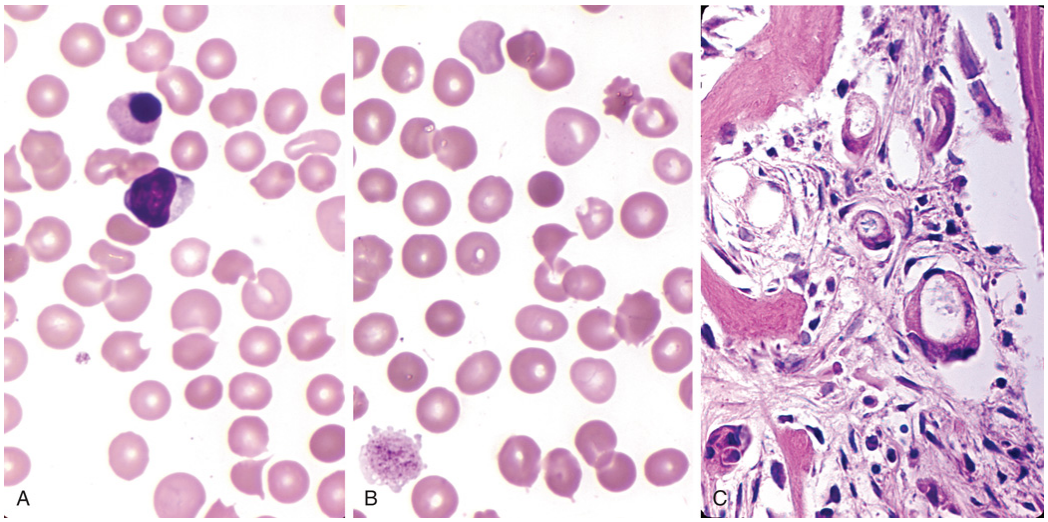

FIGURE 10-17 **A,** Myelophthisic anemia typically shows circulating normoblasts and red blood cell fragmentation. A left shift in all cell lines is common. **B,** Note the giant platelet. **C,** Metastatic adenocarcinoma produced the myelophthisic picture.

Hemolysis Caused by Intrinsic Red Cell Disorders

As these anemias are inherited, a history of lifelong anemia or a family history of anemia, cholelithiasis, jaundice, or mild splenomegaly is helpful in the diagnosis. A notable exception is paroxysmal nocturnal hemoglobinuria (PNH), an acquired defect described later in this chapter's section on bone marrow failure syndromes.

Red Blood Cell Membrane Disorders

Many advances have been made in understanding the molecular basis of a number of RBC membrane disorders (**Table 10-4**).[49-51] The red cell membrane is composed of a lipid bilayer, a network of "horizontally" positioned skeletal proteins on the inner surface, and transmembrane proteins that "vertically" traverse the lipid bilayer. The skeletal proteins maintain shape and deformability, and the transmembrane proteins provide membrane cohesiveness. Among the more than 50 transmembrane proteins are transport proteins, receptors, and antigens. Mutations in genes encoding key membrane proteins, particularly spectrin, ankyrin, protein 4.1R, protein 4.2, and band 3, lead to inherited red cell membrane disorders. Membrane disorders can be caused by structural defects or defects in membrane transport.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is a common cause of nonimmune hemolytic anemia caused by abnormalities in the RBC transmembrane proteins.[49] The defect leads to local discohesion of the membrane skeleton from the lipid bilayer, which creates a microvesicle with subsequent loss of membrane and formation of a spherocyte. Spherocytosis is the hallmark of HS and should be

suspected if the red cell indices include a normal or low MCV and the MCHC after warming remains 36 g/dL or greater (**Fig. 10-18**). The less deformable spherocytes are selectively trapped in the spleen and are vulnerable to further surface membrane loss and destruction. Genetic defects vary among different racial groups, and heterogeneous molecular abnormalities are often family specific. Gene mutations typically shift the normal reading frames or introduce premature stop codons that result in mutant alleles that fail to produce protein. The specific gene involved (i.e., the molecular phenotype) may not strictly relate to the biochemical phenotype (i.e., the abnormal protein produced).[52] For example, an ankyrin gene defect may manifest as a spectrin protein deficiency. It is usually the spectrin content of the red cell that best correlates with the degree of anemia, percentage of circulating spherocytes, reticulocyte count, and increased osmotic fragility.

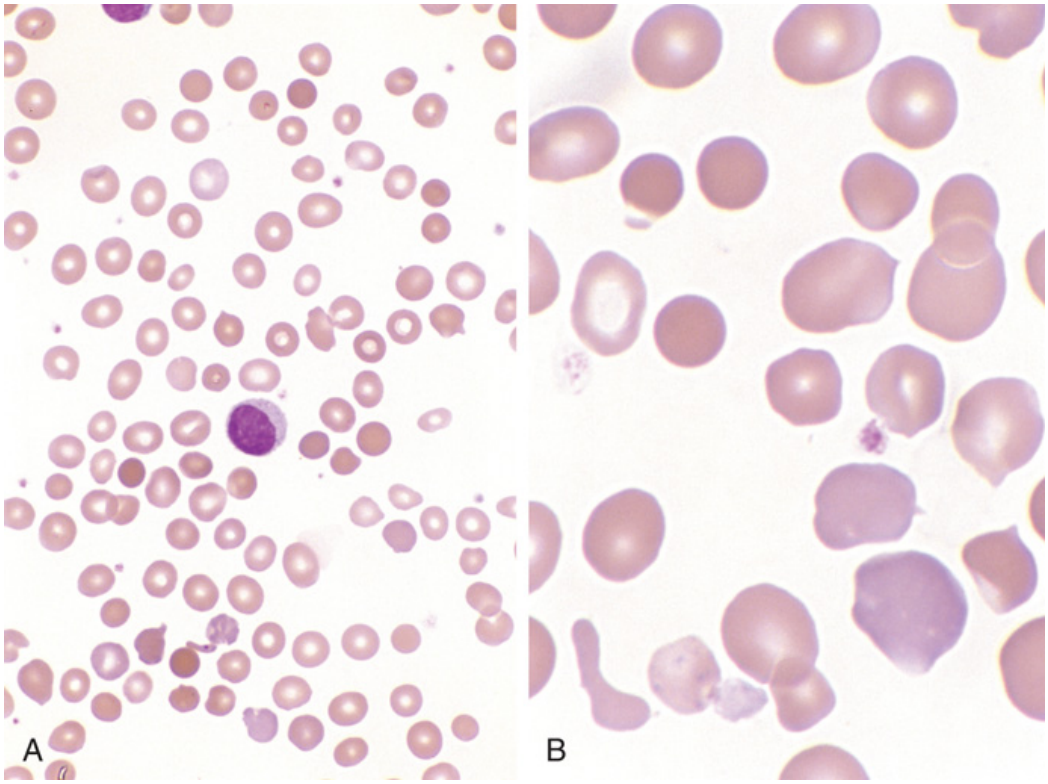

FIGURE 10-18 **A,** In this case of hereditary spherocytosis, the number of red blood cells is moderately decreased, and spherocytes are readily apparent. **B,** Spherocytes are smaller and stain more darkly than the surrounding normocytes and large polychromatophilic red blood cells.

Table 10-4

AD, Autosomal dominant; *AR,* autosomal recessive; *RBC,* red blood cell; *MCV,* mean corpuscular volume; *MCHC,* mean corpuscular hemoglobin concentration.

Clinically, anemia is the presenting feature in nearly half of patients with HS, although disease severity varies widely among

individuals. Mild compensated hemolysis is observed in about 20% of individuals, with most affected people (60%) having moderate hemolysis with a hemoglobin level of 8 to 11 g/dL and reticulocyte percentage generally higher than 8%. At birth, patients with HS usually have a normal hemoglobin value that may sharply and transiently decrease during the first 20 days of life to a level that requires blood transfusions.[53] The more asymptomatic forms of HS may not be identified until a hemolytic crisis develops during childhood, often triggered by a viral infection. Less commonly, an aplastic crisis develops secondary to parvovirus B19 infection (**Fig. 10-16**). Although a family history of HS is often elicited in individuals suspected of having HS, the most severe forms of the disease are recessive and associated with α-spectrin and some ankyrin defects.[54] Sporadic mutations are particularly common in the autosomal recessive forms of HS. Several diagnostic methods for HS are available, including osmotic fragility studies, flow cytometric analysis of eosin-5′-maleimide (EMA)-labeled RBCs, and osmotic gradient ektacytometry; yet, each test may have considerable false positives and false negatives. Osmotic gradient ektacytometry has the advantage of producing distinct deformability profiles for several types of red cell disorders, but it is not widely available.[55] EMA analysis exhibits the greatest disease specificity for HS at 98%; however, a subset of cases of HS may still be unrecognized with this test alone.[56] Although EMA binds specifically with band 3 protein, membrane protein abnormalities in HS other than band 3 deficiency affect binding and therefore the fluorescent intensity of the dye measured by flow cytometry. Coupled with peripheral blood smear review and depending on availability of testing, the recommended

laboratory tests include flow cytometry for EMA binding and the cryohemolysis test.[57] A recently proposed diagnostic algorithm suggests using a combination of EMA testing, osmotic fragility testing, and/or acidified glycerol lysis tests in combination with genetic testing for difficult cases; however, not all of these tests are widely available.[58] Splenectomy has been the primary mode of therapy, but it is not without complications.[59]

Hereditary Elliptocytosis and Hereditary Pyropoikilocytosis

Hereditary elliptocytosis (HE) and hereditary pyropoikilocytosis (HPP) were originally described as distinct entities, but molecular studies have established that HPP is a subset of HE (Tables **10-3** and **10-4**).[60] They are caused by defects in the horizontal protein interactions that hold the membrane skeleton together. The abnormality that best correlates with disease severity is a failure of spectrin homodimers to self-associate into heterodimers, the basic building blocks of the membrane skeleton. Differences in the clinical severity of HE cannot always be explained by a specific genetic defect. The most prevalent form of the disease is a single gene defect (heterozygous) that causes the red cells to elongate and form elliptocytes in circulation, without anemia or significant splenomegaly. The more severe form of the disease, HPP, is caused by a combination of two defective membrane protein genes that result in marked spectrin deficiency in addition to functionally abnormal proteins. The MCV may be very low because of marked RBC fragmentation, rendering the clinical presentation atypical for a hemolytic anemia, with possible microcytic rather than normocytic

RBC indices (**Fig. 10-19**). A disorder related to HE called *Southeast Asian ovalocytosis* is found in people from Malaysia, Indonesia, the Philippines, and Papua New Guinea.[61] Only a subset of affected individuals has hemolytic anemia, with distinctive oval stomatocytes and theta cells, which have two central pallors.[62] This variant red cell may protect individuals against cerebral malaria.

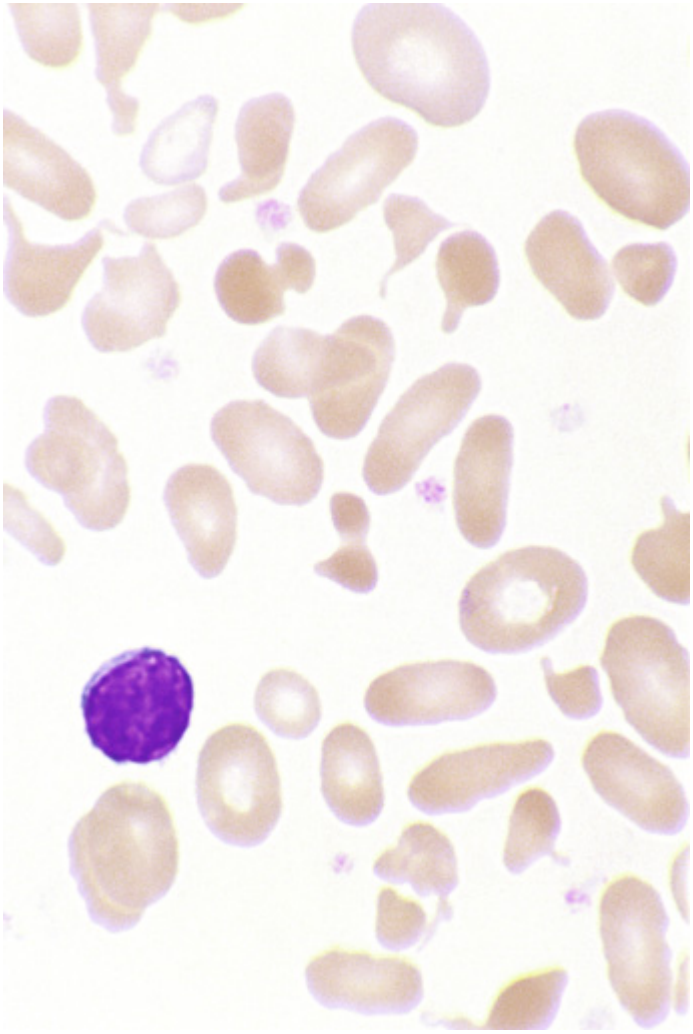

FIGURE 10-19 Hereditary pyropoikilocytosis.Numerous elliptocytes, fragmented red blood cells, and teardrop forms were found in this child's blood. The mother's blood looked similar. The father's blood was normal.

Hereditary Stomatocytosis Syndromes

Hereditary stomatocytosis syndromes are a group of disorders of the RBC membrane characterized by a mouth-shaped central area of

pallor and abnormal permeability to sodium and potassium (**Fig. 10-20**).[63] This rare red cell disorder is subdivided into four entities: xerocytosis or dehydrated hereditary stomatocytosis (DHSt), overhydrated hereditary stomatocytosis (OHS), cryohydrocytosis (CHC), and familial pseudohyperkalemia (FP).[49,55] Loss of potassium leads to RBC dehydration and mild-to-moderate anemia in the more frequent form, DHSt. Automated counts show an increased MCHC and normal MCV (falsely elevated on some automated counters). A misdiagnosis of atypical HSt is often made. Mutations in *PIEZO1* and *KCNN4* have been identified in DHSt.[49] The PIEZO protein may play a critical role in red cell cation and volume homeostasis. The second subtype, OHS, caused by mutations in *RHAG,* is rare and leads to a severe hemolytic phenotype. It is characterized by a 20-fold to 40-fold increase in cation leak, leading to hydrated red cells, a large increase in MCV, and decreased MCHC. Patients with DHSt and OHS have severe thrombotic complications after splenectomy; thus, avoidance of this procedure is important.[55] CHC is characterized by increased permeability to sodium and potassium at low temperatures. Gain-of-function mutations in *SLC4A1* are associated with CHC.[64] FP is an asymptomatic trait caused by mutations in the *ABCB6* gene, which presents with artifactually high potassium levels resulting from red cell leak at low temperatures.[49,55] Of note, stomatocytes can also be seen as an artifact of slowly dried peripheral blood smears.

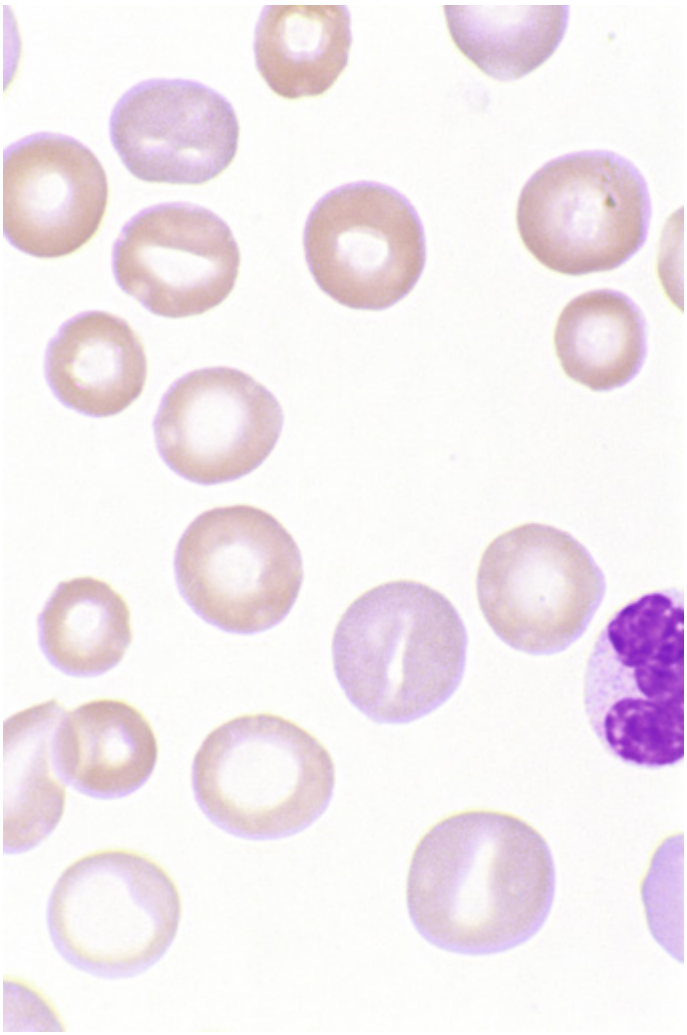

FIGURE 10-20 Hereditary stomatocytosis.Stomatocytes are often darker than surrounding red blood cells and have a slitlike central pallor from the loss of intracellular fluid.

Red Blood Cell Enzyme Defects

RBC energy requirements are met primarily through the metabolism of glucose by the Embden-Meyerhof glycolytic pathway. Alternatively, approximately 10% of glucose is metabolized by the

hexose monophosphate shunt. Erythrocyte disorders caused by enzyme deficiencies of the glycolytic pathway are extremely rare, and approximately 90% of these are deficiencies of pyruvate kinase caused primarily by *PK-LR* gene mutations on chromosome 1q21 (**Table 10-3**).[65] The majority are inherited as autosomal recessive traits and first detected in infancy or childhood with the clinical presentation of chronic hemolysis. Pyruvate kinase deficiency can be diagnosed by enzyme analysis and DNA studies. The direct antiglobulin test (Coombs test), hemoglobin electrophoresis, and osmotic fragility are normal. The peripheral blood film shows normochromic normocytic RBCs without spherocytes. The remaining morphologic findings are non-specific but include reticulocytosis and erythroid hyperplasia.

Hereditary disorders of the hexose monophosphate shunt enzymes are also rare, except glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD deficiency is one of the most prevalent inborn errors of metabolism.[66] There are at least 230 variants of G6PD with known mutations; all but two of them are either missense mutations or small in-frame deletions (**Table 10-5**). It is particularly prevalent in populations from geographic areas with endemic malaria, suggesting evolutionary polymorphisms developed to counteract the effects of this parasite. The *G6PD* gene is carried on the X chromosome, and full expression of G6PD deficiency is found only in males; female carriers may have partial deficiency. Clinical manifestations of G6PD deficiency include neonatal jaundice and hereditary nonspherocytic hemolytic anemia. The most serious consequence of G6PD deficiency is neonatal jaundice leading to kernicterus, which is worsened by associated Gilbert's disease.[67]

Although a few patients have chronic hemolytic anemia, the majority have episodic anemia induced by increased oxidative stress in erythrocytes from certain foods (fava beans), a number of drugs (sulfonamides, nitrofurans, quinine derivatives, aspirin, rasburicase), and chemicals (naphthalene, toluidine blue).[68,69] Erythrocytes deficient in G6PD are unable to maintain sufficient reduced glutathione for the generation of nicotinamide adenine dinucleotide + hydrogen (NADH), a cofactor that maintains hemoglobin integrity. The WHO has classified G6PD variants based on their degree of enzyme deficiency and severity of hemolysis: class I, less than 10% enzyme activity with severe chronic (nonspherocytic) hemolytic anemia, to class V, increased enzyme level with no hemolysis or clinical sequelae. Oxidant damage is reflected by marked anisopoikilocytosis with "bite" cells and increased polychromatophilia on the peripheral blood film (**Fig. 10-21**). Supravital staining demonstrates denatured hemoglobin precipitates (Heinz bodies) (**Fig. 10-22**). The bone marrow most commonly demonstrates erythroid hyperplasia.

Table 10-5

Common Glucose-6-Phosphate Dehydrogenase (G6PD) Variants

Isoform	Ethnic Group	Comments
G6PD B	All	Most common, normal variant
G6PD A	African descent (20%)	Normal variant, no hemolysis
G6PD A–	African descent (11%)	Group of variants with same mutation as G6PD A, but with one additional mutation Moderate hemolysis Unstable enzyme, ↑ decay
G6PD^{MED}	Greek, Arabian, Sicilian, Sephardic Jewish descent	Severe hemolysis Protects against *Plasmodium falciparum*
G6PD^{CANTON}	Asian descent	Moderate hemolysis

Hereditary pyrimidine 5′-nucleotidase deficiency is the third most common cause of chronic nonspherocytic hemolytic anemia related to red cell enzyme defects, after deficiency of PK and G6PD. The peripheral blood smear is characterized by red cells with prominent

coarse basophilic stippling secondary to accumulation of precipitated pyrimidine nucleotides.[70,71]

Hemoglobinopathies

Hemoglobinopathies are abnormalities of hemoglobin structure caused by abnormal amino acid sequences in either the α or β globin chains. The most prevalent abnormal hemoglobin is HbS, produced by the substitution of glutamate for valine at the sixth position of the β globin chain. The gene for HbS has autosomal dominant inheritance and is found in areas of the world where malaria is common.[72] Approximately 8% to 10% of the African American population carries at least one HbS gene.[73] Sickle cell disease occurs in individuals with homozygous sickle mutations (termed *HbSS* or *sickle cell anemia*) or compound heterozygous mutations, most commonly sickle cell β-thalassemia or hemoglobin S-C (HbSC) disease. RBC sickling is induced under conditions of deoxygenation, vasoconstriction, acidosis, increased HbS concentration, and infection. The clinical symptoms of the sickle cell disorders vary greatly in severity among individuals,[74] but they are often a result of the increased tendency of sickle cells to adhere to vascular endothelium and to the ensuing vaso-occlusive complications.[75] Cells become irreversibly sickled and are removed by the reticuloendothelial system. The hallmark of these disorders is morphologically altered red cells (**Fig. 10-23**). In addition to the sickle cells, irregularly shaped cells, targets, spherocytes, and polychromatophilic cells may be found on the blood film. Howell-Jolly bodies are usually identified in older individuals as a result of autosplenectomy. A left-shifted neutrophilia with toxic features and

thrombocytosis are common during an acute crisis. Heterozygous disorders may additionally show microcytosis (Sβ-thalassemia) or intracellular crystals (HbSC disease) (**Fig. 10-24**). Patients with sickle cell anemia may also develop acute splenic sequestration, parvovirus-related red cell aplasia, and bone marrow necrosis. In addition to erythroid hyperplasia, bone marrow biopsies frequently show increased arterial fibrosis.[76] Patients with sickle cell disease with a genotype other than HbSS (e.g., Sβ-thalassemia) appear to be at risk for bone marrow necrosis and fat embolism syndrome.[77]

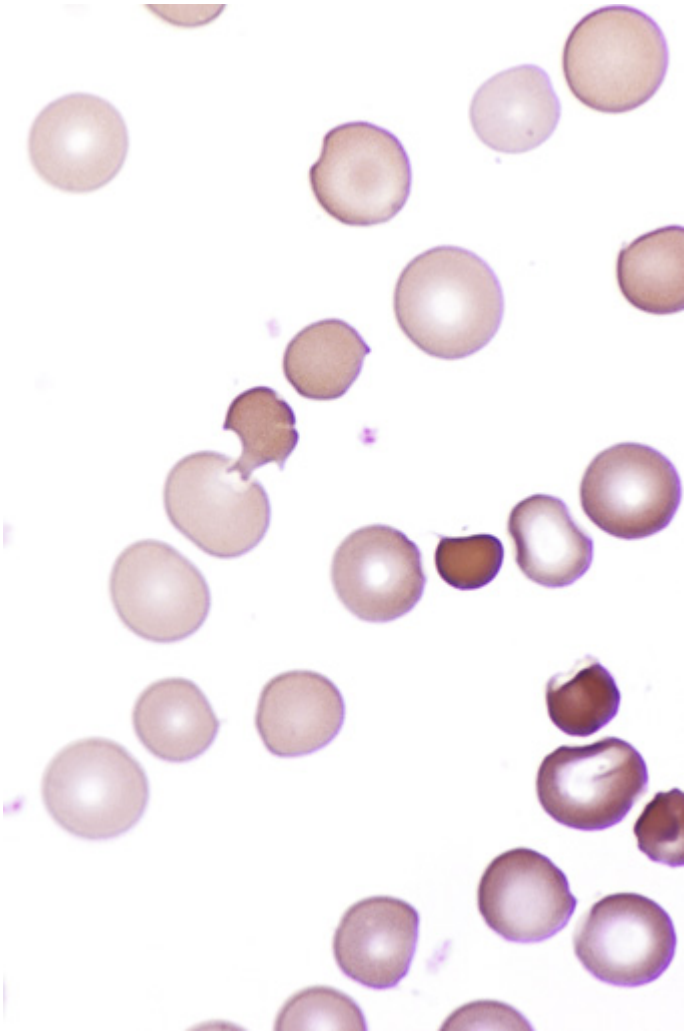

FIGURE 10-21 Oxidant hemolysis causes hemoglobin to precipitate at the cell membrane. The spleen removes the aggregates of hemoglobin and associated membrane, producing “bite” cells and spherocytes.

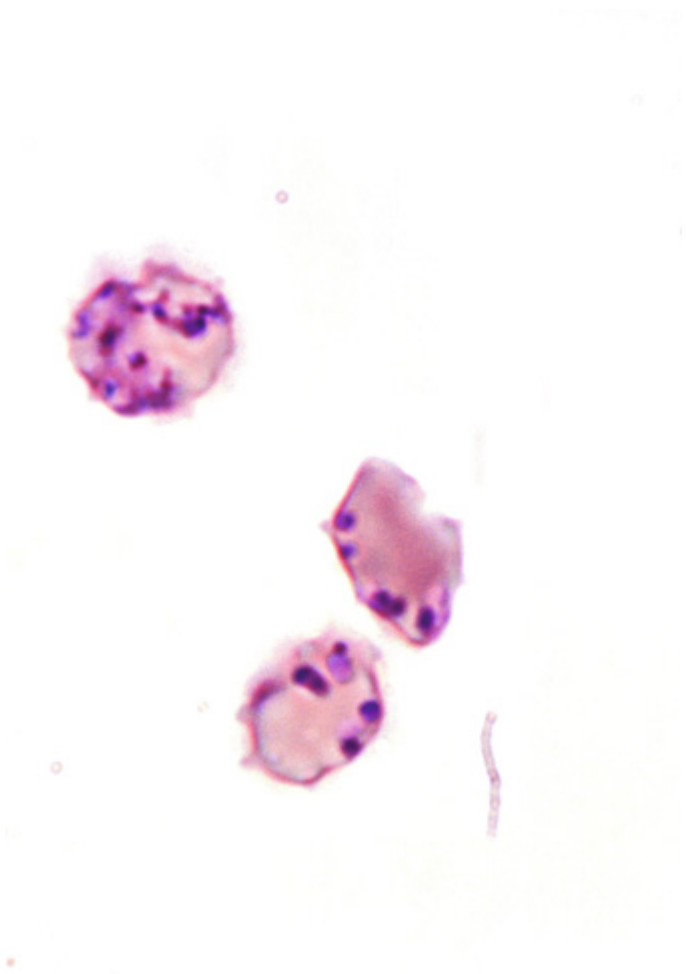

FIGURE 10-22 This wet mount stained with methylene blue illustrates membrane-associated Heinz bodies seen in oxidant hemolysis.

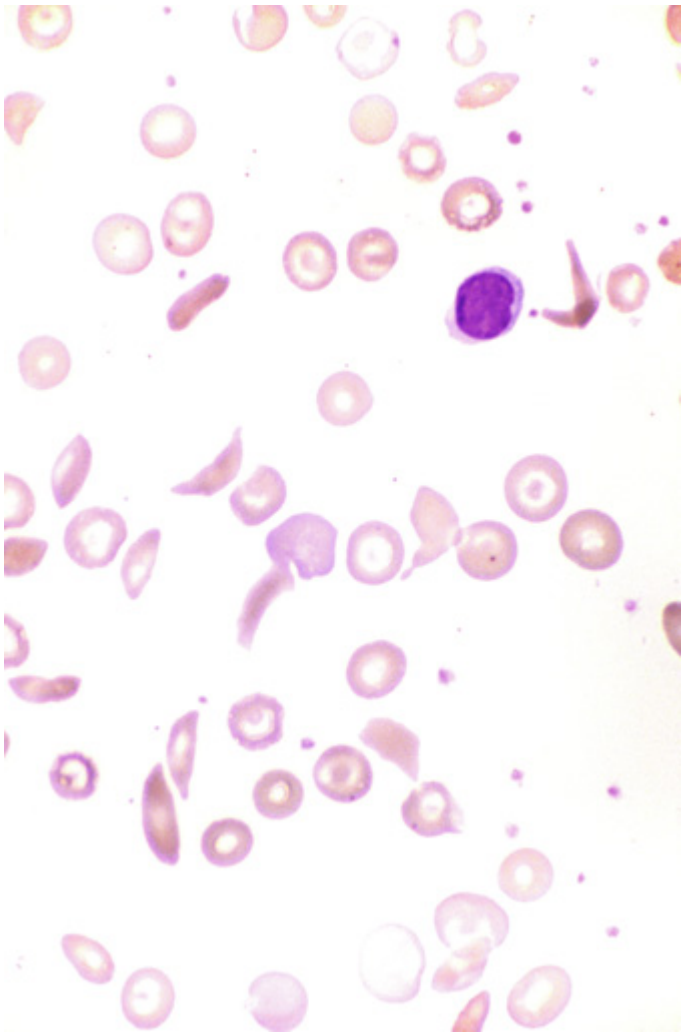

FIGURE 10-23 Numerous sickled red blood cells and target cells are seen in this patient with sickle cell anemia.

Among the numerous other known hemoglobinopathies, HbC and HbE are the next most common causes of chronic hemolysis. The *HbC* gene mutation is most prevalent in people of West African ancestry; the *HbE* gene is found primarily in people of Southeast Asian ancestry. Homozygous HbE is unusual in its presentation as a mild-to-moderate hypochromic microcytic anemia (MCV 50 to 65

fL). HbC is recognized morphologically by the unique intracellular crystalline structures in erythrocytes on the blood film (**Fig. 10-25**).

Immune-Mediated Hemolytic Anemia

Autoimmune Hemolytic Anemias

Autoimmune hemolytic anemias (AIHAs) are categorized by the temperature at which the autoantibody has the greatest avidity for the target red cell antigen, and they are detected by a positive direct antiglobulin test.[78] Warm AIHA is most common (70% of AIHAs) and is clinically significant because it occurs at body temperature. IgG antibody (or occasionally IgA antibody) coated RBCs act to bind Fc receptors on splenic macrophages and, with or without subsequent complement fixation, are removed from circulation. Partial phagocytosis of the RBC membrane produces spherocytes (**Fig. 10-26**). Cold AIHA is caused by IgM coating of red cells at low temperatures, leading to RBC agglutination and complement fixation.[79] The antibody is most often directed at the I antigen on the red cell membrane. Some hemolysis occurs secondary to intravascular destruction of the agglutinated cells. However, if the antibody is active at temperatures approaching 37° C, complement becomes activated, and clinically significant intravascular and sometimes extravascular complement-mediated hemolysis occur in the liver (80% of the time).[80] Smears typically show agglutinated cells unless the blood tube was previously warmed; spherocytes are less frequent (**Fig. 10-27**). Autoantibody formation in both warm-type and cold-type AIHA most likely represents a derangement of normal immune function. Approximately 50% of AIHA is idiopathic (primary) and observed in older patients.[81] In contrast, secondary

AIHA develops in patients with underlying disease, predominantly lymphoproliferative disorders but also autoimmune disorders, infections, and carcinoma. Young patients, in particular, develop a self-limited cold-type AIHA after *Mycoplasma pneumoniae* infection or infectious mononucleosis.

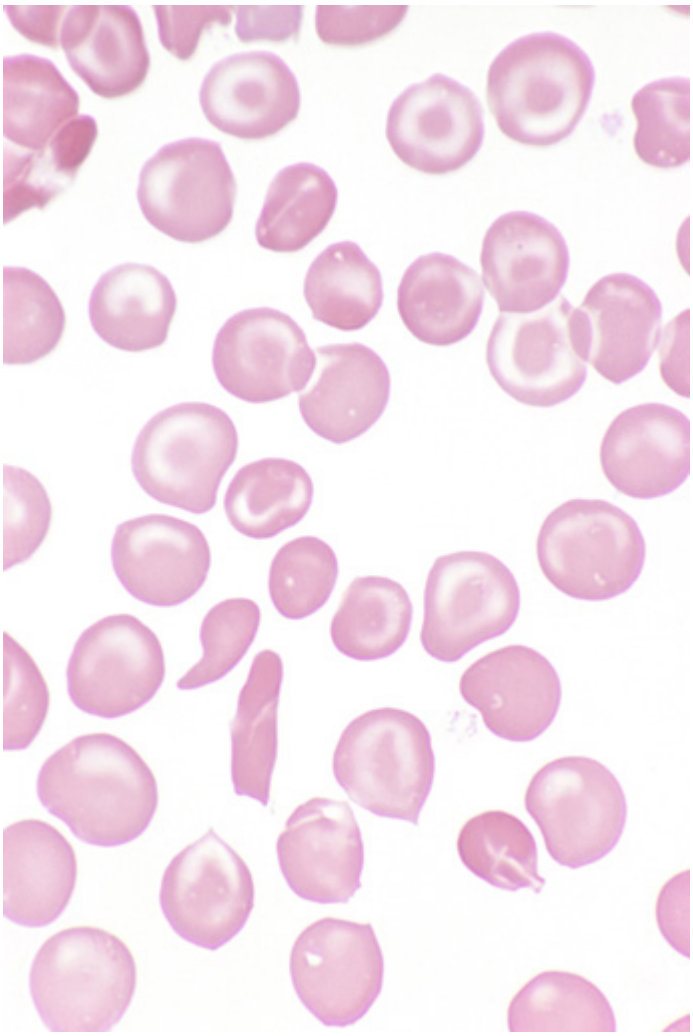

FIGURE 10-24 In hemoglobin S-C (HbSC) disease, target cells predominate, and plump, darkly stained cells contain precipitated HbS and HbC.

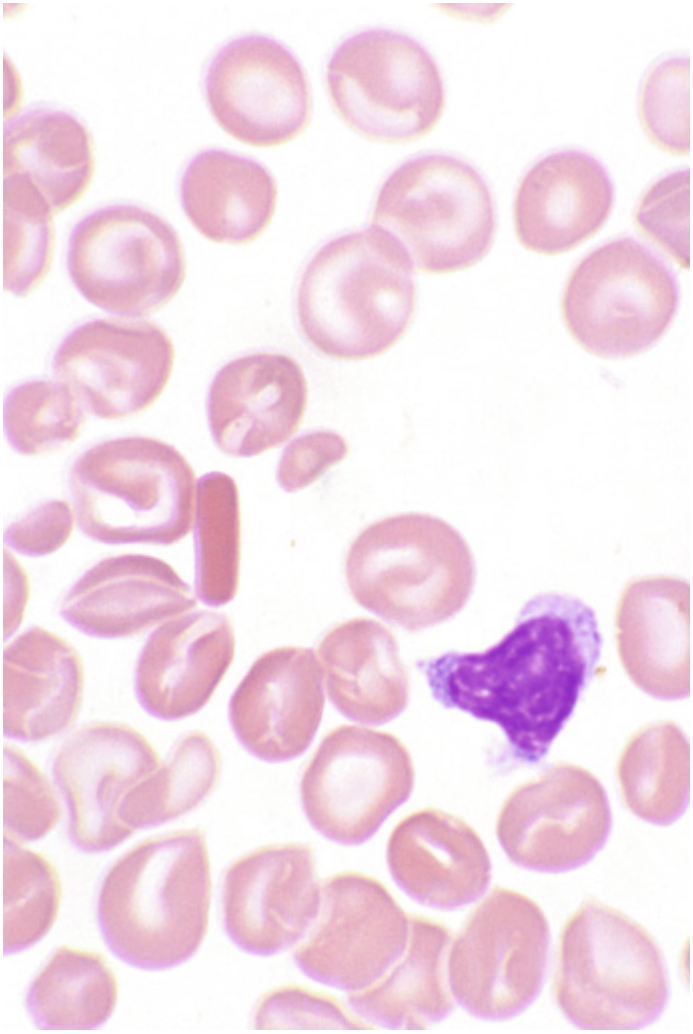

FIGURE 10-25 In hemoglobin C disease, target cells are numerous. Note the rod-shaped crystal in the “boxcar” cell.

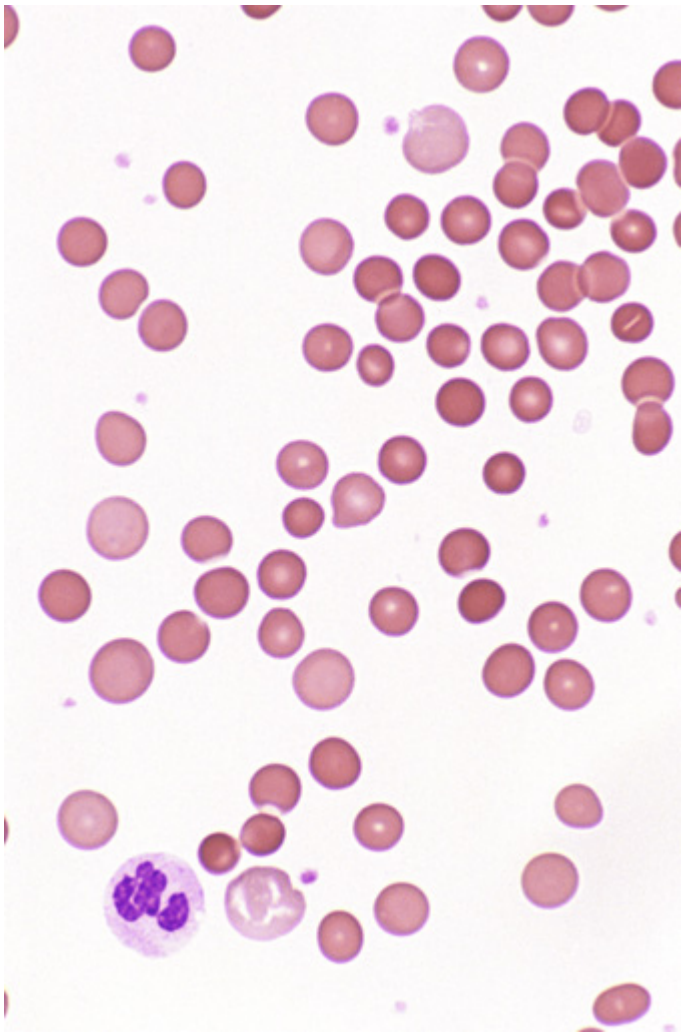

FIGURE 10-26 In warm antibody hemolytic anemia, numerous spherocytes are seen.

Drug-Induced Immune Hemolysis

Drug-induced immune hemolysis occurs through three main mechanisms: autoantibody formation (warm-type AIHA), often directed at the Rh locus of the red cell; hapten formation with IgG antibody to the drug that is adsorbed on the red cell surface; and drug–antibody complex that attaches to the RBC surface and activates complement.[82] Examples of drugs that typify these

mechanisms are α-methyldopa; penicillin and cephalosporins; and quinine, isoniazid, and insulin, respectively. Certain drugs, such as the cephalosporins and methyldopa (Aldomet), can alter RBC membranes, causing non-specific binding of IgG or IgM. RBCs are lost through splenic sequestration and destruction. The direct antiglobulin test is positive, and bone marrow evaluation is not required.

Hemolysis Caused by Physicomechanical Disruption

Hemolysis caused by physicomechanical disruption develops when red cells are exposed to mechanical trauma or to heat above body temperature. Mechanical trauma occurs through a variety of mechanisms, including disruption by fibrin strands in disseminated intravascular coagulation, vasculitis, possibly thrombotic thrombocytopenic purpura, and the effects of vortexing in aortic insufficiency, malignant hypertension, and eclampsia. The blood smear typically contains numerous schistocytes and small numbers of spherocytes (**Fig. 10-28**). These anemias are commonly referred to as *microangiopathic hemolytic anemia,* even though red cell destruction may occur in the left ventricle, aorta, or other large vessels. When blood is heated to greater than 50° C, red cells fragment into microspherocytes (**Fig. 10-29**). This phenomenon is typical of patients suffering severe thermal burns of the skin.

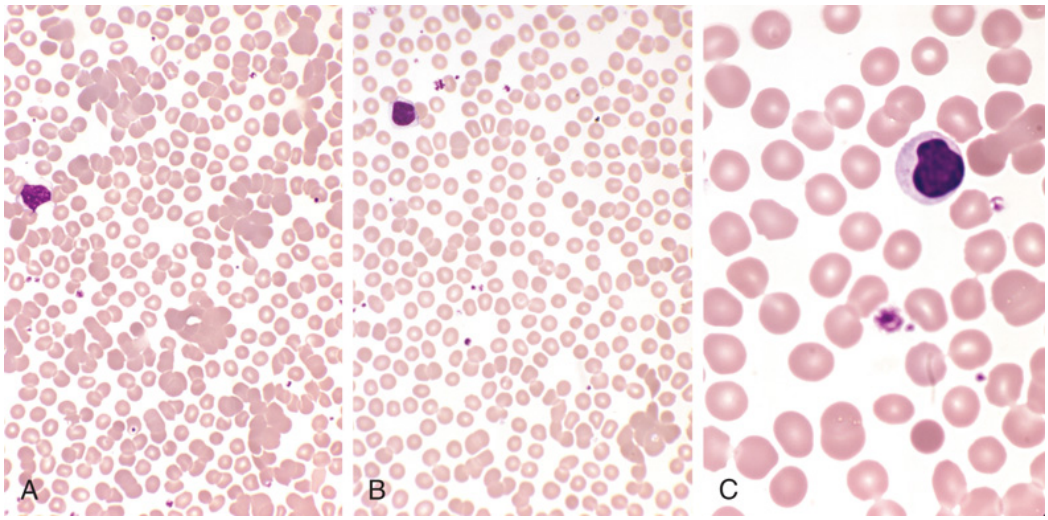

FIGURE 10-27 **A,** In cold agglutinin disease, numerous aggregates are seen in blood smears made from blood at room temperature. **B,** When the blood is warmed to 37° C, the agglutination phenomenon is reversed. Red cell morphology is essentially normal in cold agglutinin disease. **C,** Only a rare spherocyte is seen.

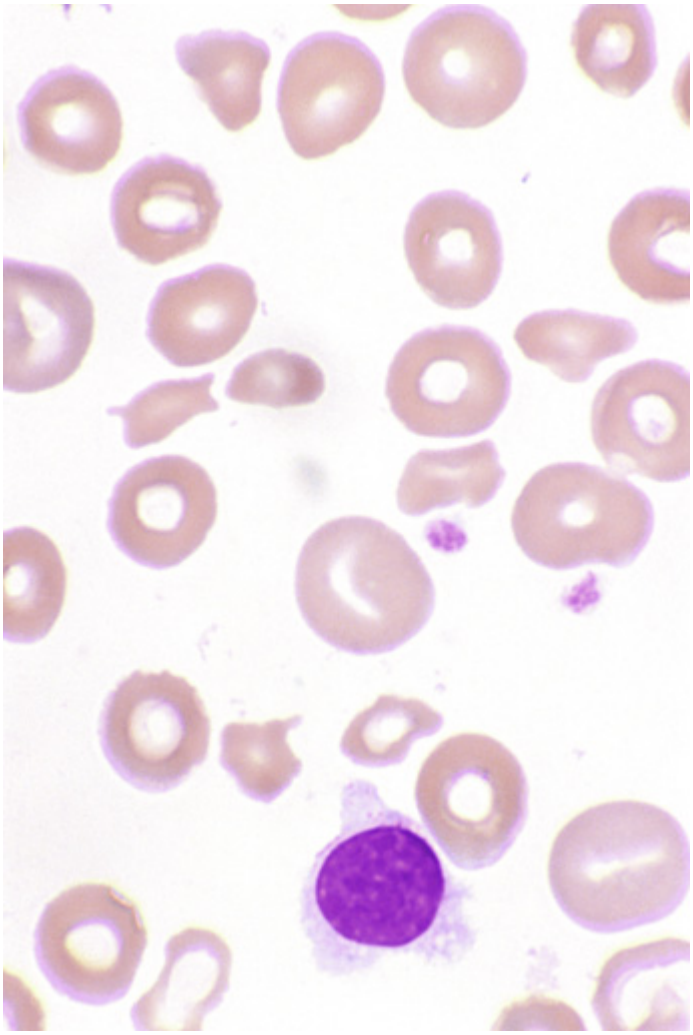

FIGURE 10-28 Fragmentation syndrome produced by a defective prosthetic aortic valve.

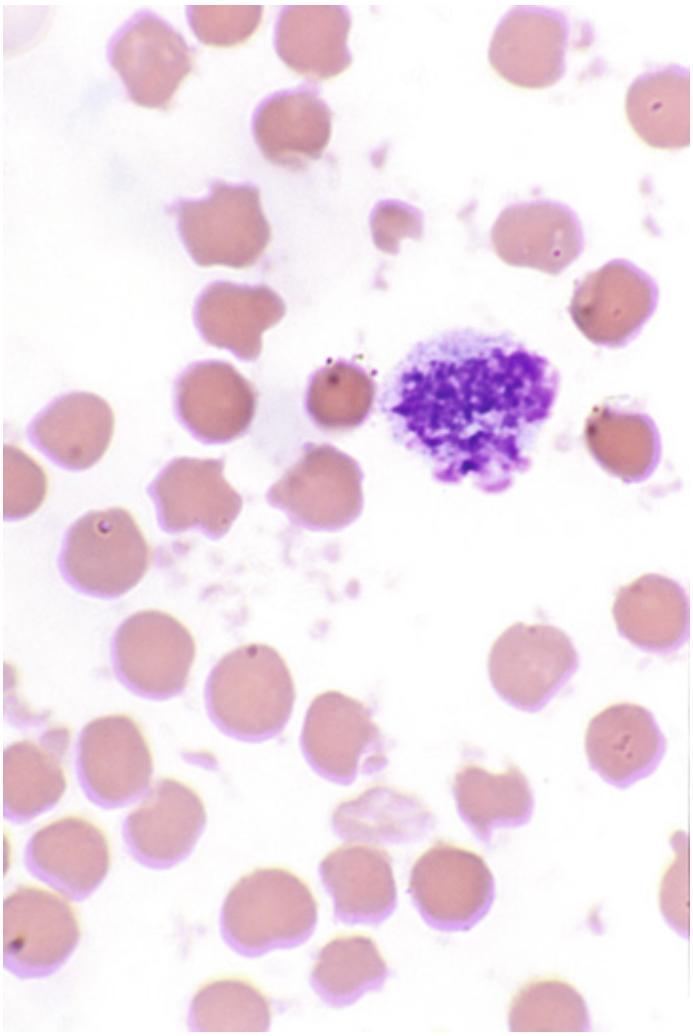

FIGURE 10-29 This blood smear was made from a specimen inadvertently exposed to high temperatures in a defective pneumatic tube system adjacent to a steam line. Numerous spherocytes, cytoplasmic red blood cell fragments, and a degenerating white blood cell are present.

Infection-Associated Hemolytic Anemia

Infection-associated hemolytic anemia is caused by organisms that parasitize or otherwise disrupt the RBCs, such as malaria (**Fig. 10-30**), babesiosis, and bartonellosis.

Macrocytic Anemia

Macrocytic anemia is defined as an MCV greater than 99 fL in adults and is dependent on age for infants and children. Because reticulocytes are larger than normal red cells, a mild degree of macrocytosis (MCV rarely >110 fL) may be seen after recent hemorrhage (>1 week), hemolytic anemia, or treated anemia with a brisk reticulocyte response. Secondary reticulocytosis is observed in a subset of patients with liver disease; the RBCs have increased membrane cholesterol and lecithin incorporation, producing thin macrocytes and target cells that have a shortened life span.[83] The increase in reticulocytes in all these processes is reflected by a high RDW. The remaining macrocytic anemias (**Table 10-6**) exhibit decreased or ineffective hematopoiesis, with low reticulocyte numbers and a frequently normal RDW.

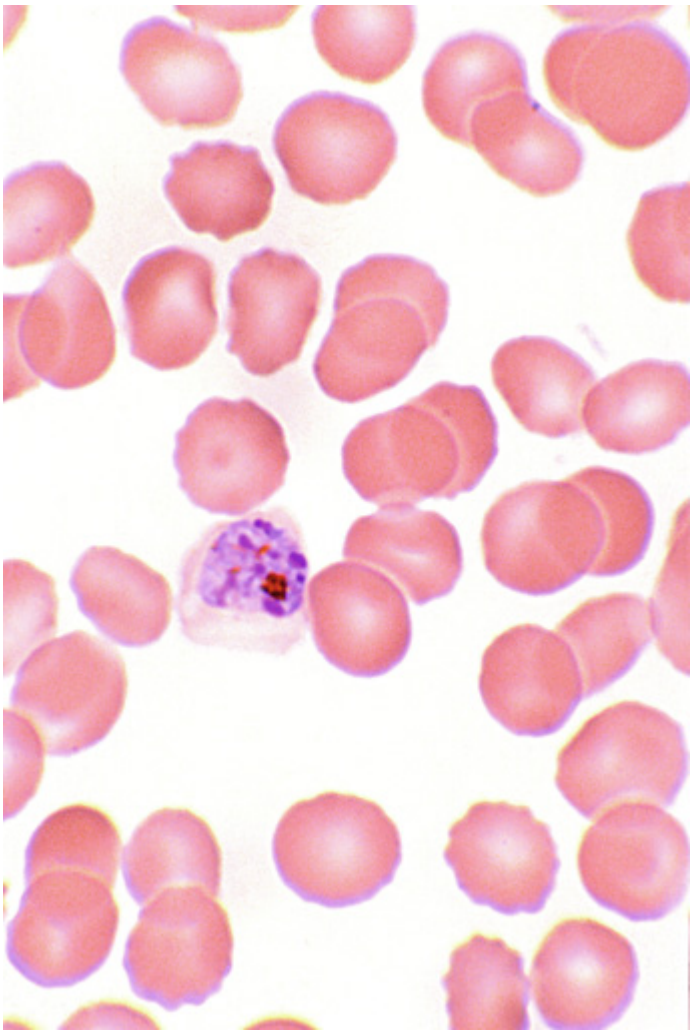

FIGURE 10-30 Mature schizont of *Plasmodium vivax*.

Megaloblastic Anemias

Megaloblastic anemias are the most common macrocytic anemias, particularly those caused by vitamin B_{12} (cobalamin) or folate deficiency (**Table 10-6**). Megaloblastic anemias are the consequence of ineffective erythropoiesis resulting from defects in DNA synthesis.[84,85] The coenzyme form of folate is an important cofactor in the rate-limiting step and many additional steps of DNA

(pyrimidine) synthesis; cobalamin plays an interdependent role involving methionine synthesis and the conversion of methylmalonyl CoA to succinyl CoA. Enlargement or "gigantism" of hematopoietic precursors is seen because cytoplasmic maturation proceeds while cell division is delayed by the lack of sufficient DNA to undergo mitosis. Increased intramedullary cell death ensues, with compensatory erythroid hyperplasia and the development of anemia characterized by oval macrocytes. Anemia is often a late event in folate or vitamin B_{12} deficiency; hypersegmentation of neutrophils usually appears earlier (**Figs. 10-31 to 10-34**). The hematologic findings in patients with megaloblastic anemia are readily identified (**Table 10-6**). Bone marrow examination is usually not required but may be performed for the evaluation of pancytopenia (which rarely can also occur in the presence of vitamin B_{12} deficiency) or when the typical peripheral blood findings are masked by concurrent iron-deficiency anemia or a constitutional microcytic anemia. It is extremely important to recognize that severe megaloblastic anemia may have sufficiently bizarre cells and increased pronormoblasts to be mistaken for MDS or acute erythroid leukemia. The absence of trilineage dysplasia or an increase in myeloblasts helps make this distinction. Abnormally low serum and red cell folate and serum vitamin B_{12} levels further support megaloblastic anemia.

Folate deficiency is most commonly nutritional in origin and is most prevalent in alcoholics, indigents, and the elderly. Mood disorders, particularly in elderly patients, may be attributed to undiagnosed folate deficiency. A normal diet contains a sufficient amount of vitamin B_{12}; thus total body stores of cobalamin are abundant. The most common cause of cobalamin deficiency in the

Western world is pernicious anemia. Under normal conditions, cobalamin complexes with intrinsic factor, a product of gastric parietal cells, binds to intrinsic factor receptors in the terminal ileum.[86] In pernicious anemia, parietal cells are destroyed through autoimmune mechanisms, and little or no cobalamin is absorbed. In contrast to folate deficiency, cobalamin deficiency also causes a demyelinating disorder with numerous neurologic manifestations. Controversy exists regarding the best diagnostic approach to identifying these vitamin deficiencies. The most commonly used indicators of deficiency are the red cell folate level and serum cobalamin; however, these tests are not entirely specific or sensitive. Serum cobalamin levels may be normal or only slightly reduced in some patients with vitamin B_{12} deficiency. Additional tests currently used include serum or plasma methylmalonic acid and plasma homocysteine levels, which better detect low tissue cobalamin stores among individuals with early deficiencies.[85,86] However, hyperhomocysteinemia may also be seen in folate deficiency. The measurement of serum holotranscobalamin II, the active form of cobalamin, is also a good marker of early vitamin B_{12} deficiency in patients with normal renal function.[84] Pernicious anemia is associated with several autoantibodies: measurement of parietal cell and intrinsic factor antibodies is diagnostically helpful in the absence of B_{12} absorption assays.[86] RBC folate levels correlate with long-term folate intake, whereas serum folate reflects recent folate intake. The U.S. Food and Drug Administration required the addition of folic acid to all breads, cereals, flours, corn meal, pasta products, rice, and other cereal grain products in the United States. National Health and Nutrition Examination Survey (NHANES) results showed marked

improvements in folate status, correlating with success of folate fortification. However, the prevalence of low RBC folate (<140 ng/mL) differed by sex, race, and ethnicity; low levels were most pronounced among non-Hispanic women of African descent compared with non-Hispanic White women and women of Mexican descent.[87] A retrospective review of Mayo Medical Laboratories' folate testing in a 10-year period (1999–2009) indicated that true folate deficiency is exceedingly rare in the current postfortification era[88]; furthermore, they concluded that routine ordering of RBC folate and serum folate together is unnecessary, because they provide equal diagnostic information in almost all situations.[89] On the other hand, testing must be undertaken judiciously based on the patient demographic served by each institution.[90]

Drugs that cause megaloblastic anemia are those that act primarily on DNA synthesis and include antifolates (e.g., methotrexate), purine analogues, pyrimidine analogues (e.g., zidovudine), and ribonucleotide reductase inhibitors (e.g., hydroxyurea). In addition, the metabolism of a number of anticonvulsant and antidepressant drugs is dependent on adequate folic acid for appropriate drug response.[85,91]

Table 10-6

AD, Autosomal dominant; *AR,* autosomal recessive; *CDA,* congenital dyserythropoietic anemia; *HEMPAS,* hereditary erythroblastic multinuclearity with positive acidified serum; *MK,* megakaryocyte; *XLR,* X-linked recessive.

Constitutional Causes

Constitutional causes of macrocytic anemia are much less common. DBA is a heterogeneous genetic disorder that usually presents within the first few months of life and by 1 year of age in 90% of cases (**Table 10-6**).[92] It is the first human disease found to be caused by mutations in a ribosomal structural protein (*RPS19* gene on chromosome 19q13.2).[93] Mutations of this gene are found in 25% of sporadic and familial cases. Additional genes that encode ribosomal proteins have been implicated (e.g., *RPS24*). Mutations in nonribosomal protein genes (i.e., *GATA1, TSR2, EPO, ARA2*), in association with a DBA-like phenotype, have also been described. To date, no mutation could be identified in 20% of patients with DBA.[93] The failure of erythroid production is hypothesized to be caused by faulty ribosome production, leading to apoptosis of erythroid precursors. Not surprisingly, the clinical manifestations of the disorder are heterogeneous. Affected family members may have dramatically different degrees of anemia, responses to therapy, and presence of congenital anomalies. Most commonly, the disease presents as a nonresolving severe macrocytic anemia with reticulocytopenia. Bone marrow specimens demonstrate few or no erythroid precursors (erythroblastopenia).[94] Some cases exhibit increased numbers of hematogones. Circulating red cells contain increased HbF (heterogeneous distribution) and have a fetal distribution of intracellular enzymes. In addition to the blood and marrow findings, increased erythropoietin, elevated red cell adenosine deaminase levels, and i antigen expression help support the diagnosis.[93]

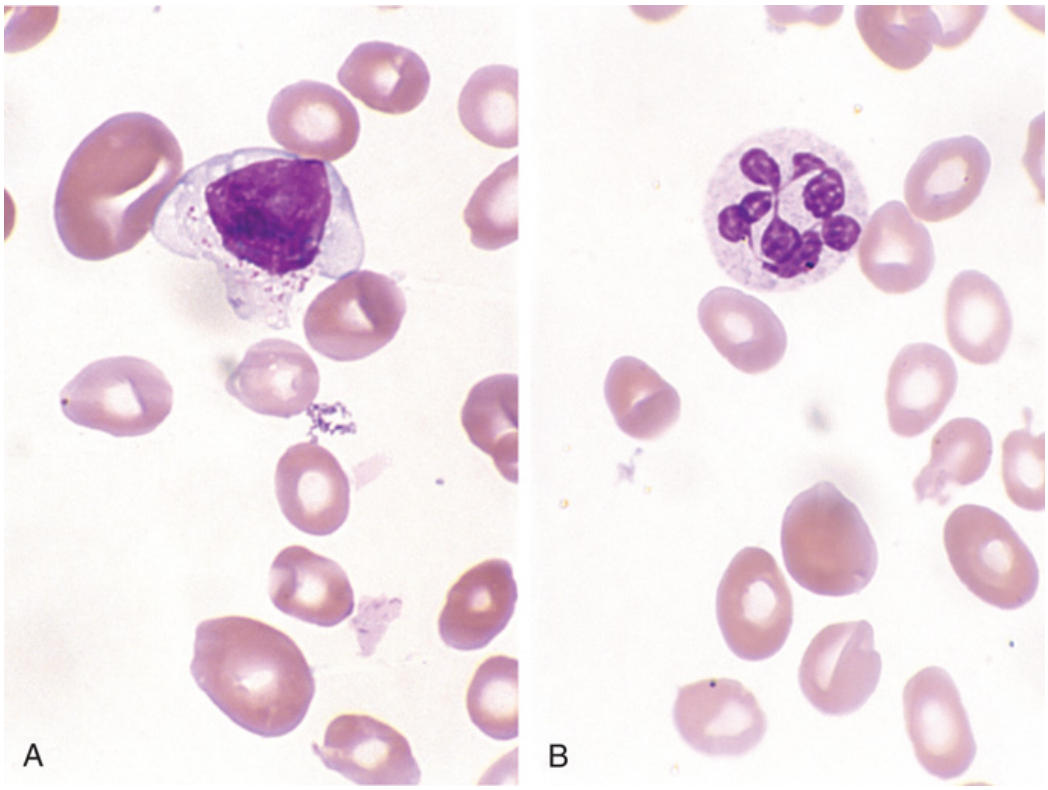

FIGURE 10-31 Macroovalocytes **(A)** and hypersegmented neutrophils **(B)** are typical features of megaloblastic anemia.

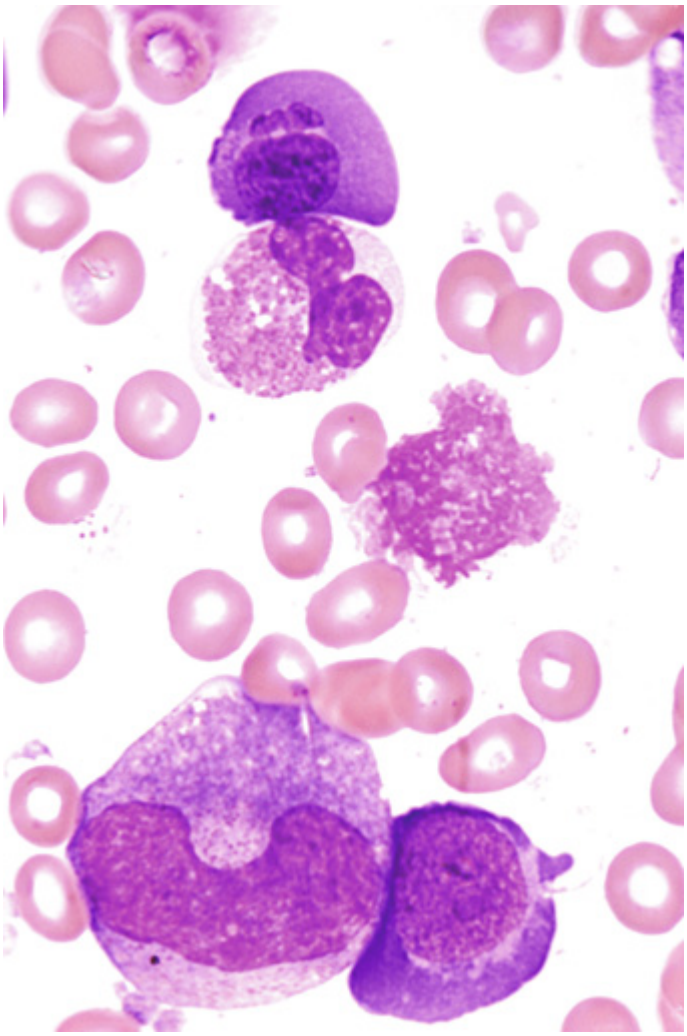

FIGURE 10-32 Bone marrow aspirate from a patient with cobalamin deficiency illustrates a giant C-shaped neutrophil band and megaloblastic normoblasts.

Congenital Dyserythropoietic Anemias

Congenital dyserythropoietic anemias (CDAs) are rare hereditary disorders characterized by abnormalities of erythropoiesis.[95] The three classically described forms, CDA I, II, and III, are defined by distinctive morphologic abnormalities of erythroblasts (**Table 10-**

6). Additional rare, unique types and variant forms are also recognized, some of which are present as a part of a syndrome. The morphologic hallmark of CDA is prominent erythroid hyperplasia and striking dyserythropoiesis, with normal myeloid and megakaryocytic lineages (**Figs. 10-35 to 10-37**). Erythropoiesis is ineffective, as manifested by reticulocytopenia, with variable degrees of anemia. Unlike CDA I, II, and III, CDA IV is characterized by a normal or slightly increased reticulocyte count with respect to the degree of anemia, along with generally severe hemolytic anemia and markedly elevated HbF.[95,96] Anisopoikilocytosis is common to all types. Circulating RBCs occasionally have basophilic stippling, cytoplasmic vacuolization, or Cabot rings. Patients with CDA II have strong expression of protein antigens i and I on their RBCs. In general, the clinical findings are those associated with a chronic hemolytic anemia, including increased lactate dehydrogenase and bilirubin levels, jaundice, splenomegaly, tendency to form gallstones, and iron overload. CDA II is the most common CDA and may be the most frequently misdiagnosed; the correct diagnosis is often not made until patients are teenagers, or even adults, despite the identification of a chronic hemolytic anemia earlier in life.[95] Unlike the other CDAs, CDA II may have associated microspherocytes and a positive osmotic fragility test, suggesting a diagnosis of HS.[95] This can be resolved by genetic testing, which has become a frontline method for evaluation. In the past, CDA II was also misdiagnosed as PNH as a result of a positive Ham acidified serum lysis test (*CDA II* has been called *HEMPAS,* or hereditary erythroblastic multinuclearity with positive acidified serum), but this is no longer an issue, as PNH is now diagnosed by flow cytometry.[97] The

presence of hypoglycosylated band 3 is a pathognomonic biochemical feature of the membrane proteins isolated from CDA II.[95] Treatment with interferon-α has been effective in a few patients with CDA I with *CDAN1* mutations.[95] Activin receptor ligand traps (e.g., luspatercept, sotatercept), which target ineffective erythropoiesis, are being studied as potential therapies for CDA II. Hematopoietic stem cell transplant is another option in severe cases.

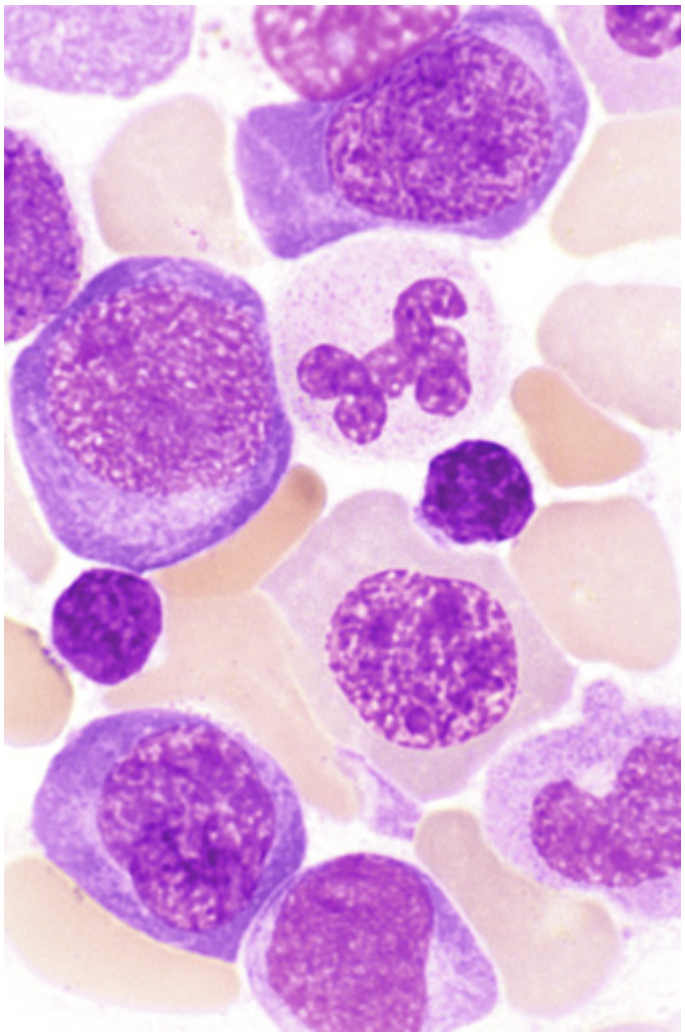

FIGURE 10-33 Bone marrow aspirate from a patient with pernicious anemia shows dyssynchrony of nuclear and cytoplasmic maturation in megaloblasts. Band neutrophils often have serpentine nuclear contours.

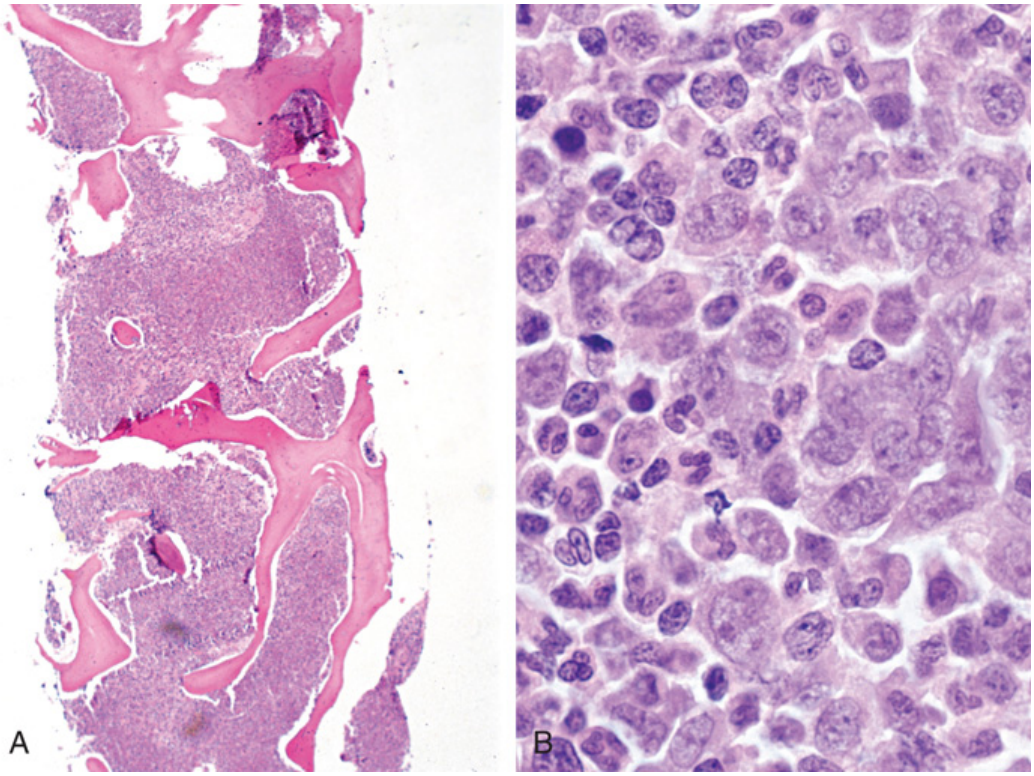

FIGURE 10-34 The trephine biopsy section of pernicious anemia is often markedly hypercellular **(A)** and contains clusters of large pronormoblasts **(B).** It is important to distinguish this picture from myelodysplastic syndromes and acute erythroid leukemia.

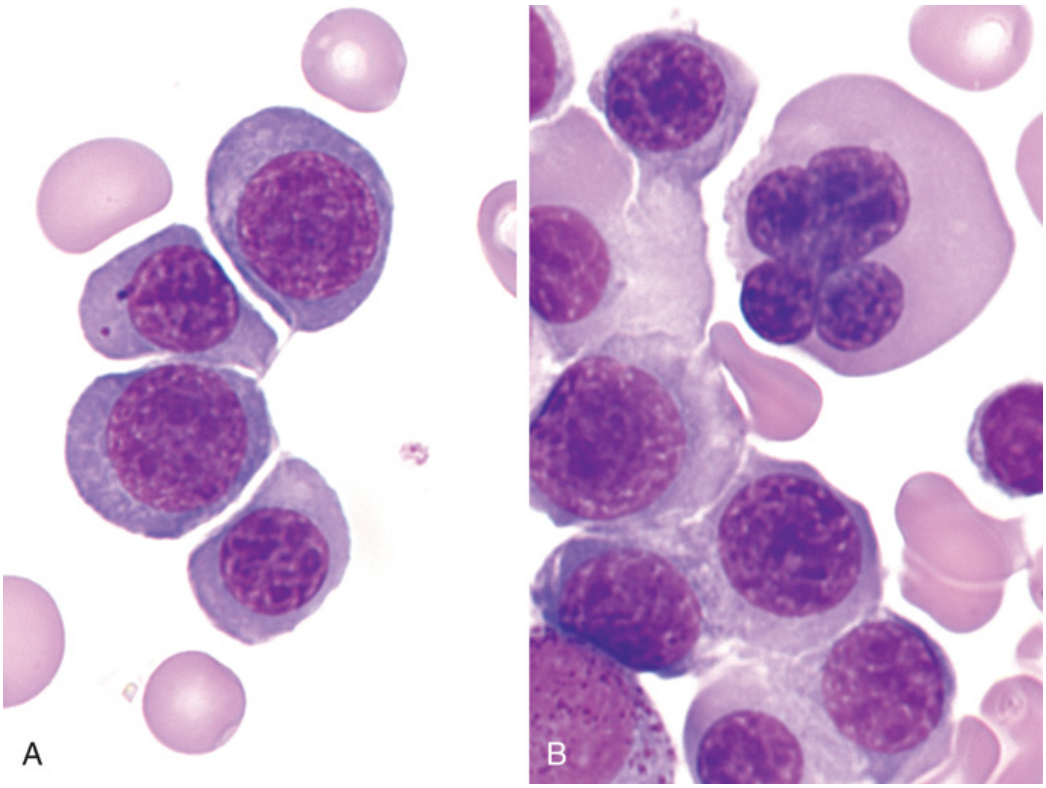

FIGURE 10-35 Bone marrow aspirate of congenital dyserythropoietic anemia type I shows megaloblastic maturation, intranuclear bridging by chromatin filaments **(A),** and multinucleation **(B).**

EVALUATION OF LEUKOPENIA

Neutropenia

Neutrophils are the most prevalent leukocyte in circulation before 1 week and after approximately 5 years of age. Neutropenia is therefore the most common cause for a decreased white blood cell count. Yet, it is notable that only 3% to 5% of all neutrophils are present in the peripheral blood, while the majority are in the bone marrow storage pool, ready to be mobilized when the need arises.[98,99] Thus, the adequacy of bone marrow reserve plays a large role in whether the neutropenic patient is at risk for adverse events, such as severe infection.

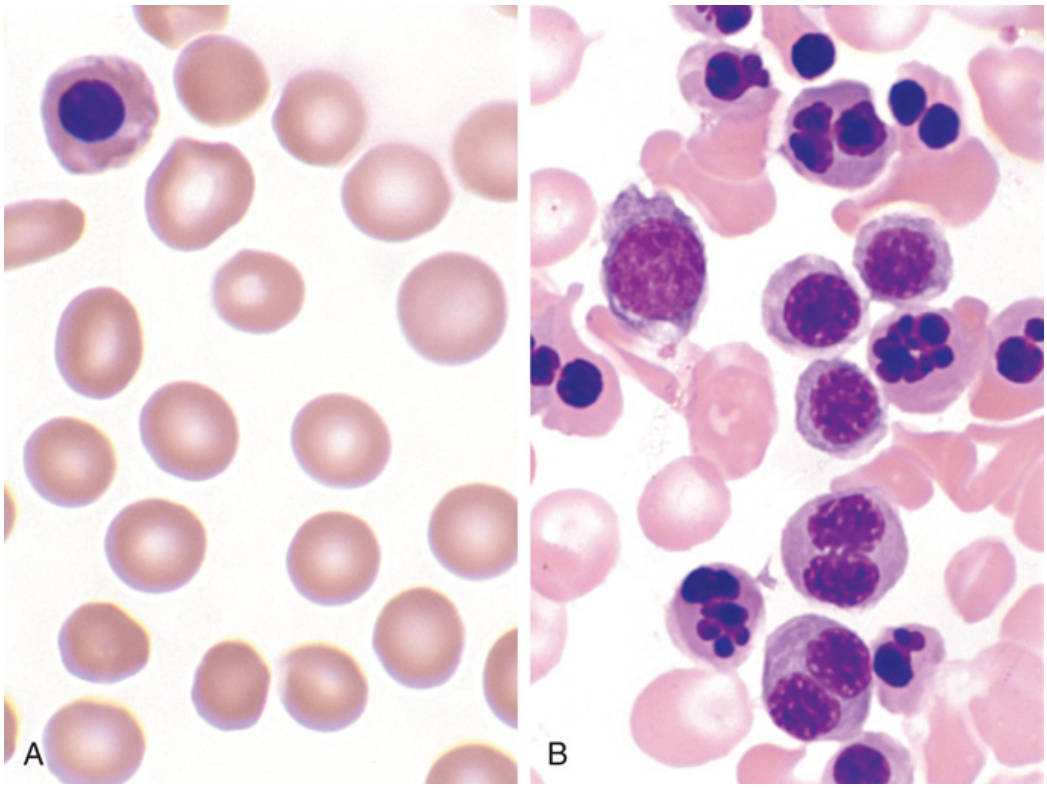

FIGURE 10-36 **A,** Peripheral blood smear from a 16-year-old girl with congenital dyserythropoietic anemia type II (hereditary erythroblastic multinuclearity with positive acidified serum [HEMPAS]) shows mild normochromic normocytic anemia and a normoblast. The patient underwent a bone marrow study for unrelated tumor staging. **B,** Numerous binucleated and multinucleated normoblasts were found. Her younger brother had similar changes. Both had a positive acidified serum test.

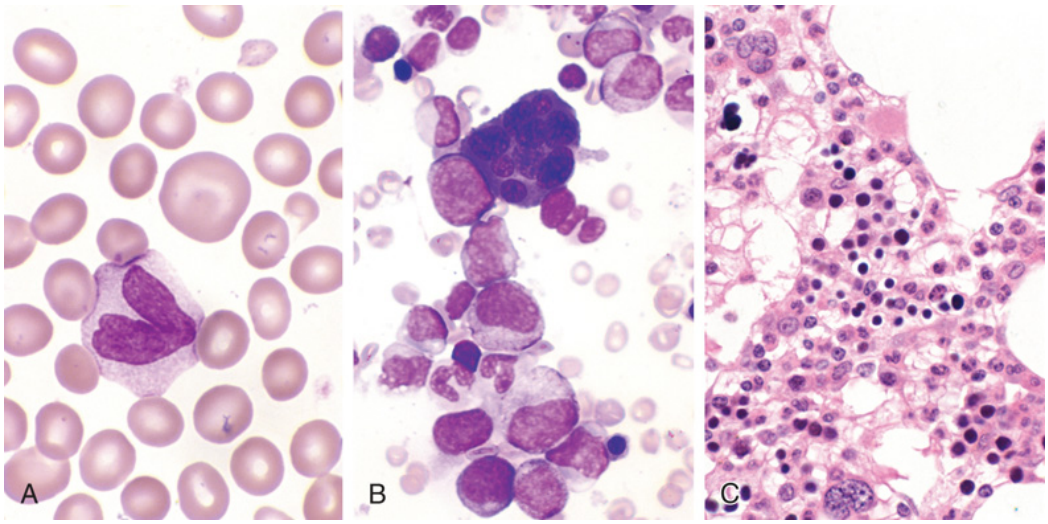

FIGURE 10-37 **A,** Peripheral blood smear of congenital dyserythropoietic anemia type III shows macrocytic red blood cells and a megaloblastic neutrophil band. **B,** The bone marrow smear contains a gigantoblast with eight nuclei. **C,** Occasional multinucleated erythroid precursors are seen in the trephine biopsy section.

Age, sex, and ethnic background affect neutrophil counts, and appropriate reference ranges must be considered. Without taking into account sex and ethnic differences, neutropenia is usually present if absolute neutrophil counts (ANCs) are less than 0.7×10^9/L in newborns, less than 2.5×10^9/L in infants, and less than 1.5×10^9/L in children and adults. Compared with Whites, Latinos have slightly higher neutrophil counts, and persons of African descent and some Middle Eastern ethnic groups have slightly lower neutrophil counts, owing to differences in myeloid production or regulation of neutrophil storage.[100] Among healthy individuals of African ancestry, 25% to 50% have ANCs of 1.0 to 1.5×10^9/L that are linked

to Duffy antigen receptor chemokine *(DARC)* gene polymorphisms. The *DARC*-null genotype plays a role in *Plasmodium vivax* malaria resistance and possibly other endemic infections.[101] This normal variant has been designated as "Duffy-null associated neutrophil count" (DANC) or "typical neutrophil count with Fy(a-b-) status." Thus, as an isolated laboratory finding in certain ethnic populations (including African Americans, Africans, Bedouin Arabs, Ethiopian and Yemenite Jews), ANCs at this level are clinically inconsequential and do not lead to increased risk of infection; instead, they are considered a **normal variant with ANC <1.5 × 10^9/L**—the terminology preferred to the previous designation of "benign ethnic neutropenia" or "benign familial neutropenia."[102,103] Any individual with severe neutropenia (<0.5 × 10^9/L) that persists for more than a few days has a significant risk for developing a life-threatening infection, particularly from endogenous bacteria. Neonates are particularly vulnerable, because they have qualitative neutrophil defects, a limited bone marrow neutrophil storage pool, and an inability to rapidly increase neutrophil production. Up to 38% of septic neonates become neutropenic.[104]

Several classifications for neutropenia exist. One relies on ANC levels to predict infection risk (i.e. mild, moderate, severe). Others classify based on congenital/constitutional versus acquired or primary versus secondary causes for neutropenia.[105] Another schema is based on normal/increased versus decreased bone marrow reserve, particularly helpful to the laboratorian who reviews bone marrow biopsies.[99] If the bone marrow biopsy displays normal/increased bone marrow reserve, then the neutropenia is likely caused by extrinsic factors from immune-mediated destruction

with decreased neutrophil survival, increased neutrophil utilization or neutrophil redistribution, or ineffective trafficking. Neutropenia with decreased bone marrow reserve could be caused by an intrinsic maturation or proliferation defect in myelopoiesis (i.e., through germline or somatic gene variants), increased apoptosis or secondary to conditions that suppress granulopoiesis by direct toxic effects by free radicals or metabolites, or immune-mediated destruction.

Yet another classification is an age-related schema, as some conditions are seen more commonly in infancy, childhood, or adulthood.[99,106] An age-related problem-solving approach combines more clinically based algorithms: exploring worrisome signs and symptoms of low bone marrow reserve, observing the pattern of historical and/or prospectively collected CBC data (i.e., Is the onset of neutropenia acute or chronic? Is neutropenia steady or cyclical?), and examining the blood smear for possible clues to the diagnosis (**Fig. 10-38**).[98,99,105-107] Laboratory testing would be geared toward suspicion of various etiologies: infection (i.e., microbiologic cultures, serologic studies, polymerase chain reaction [PCR], etc); autoimmune disease (e.g., antineutrophil antibodies, rheumatoid factor, C-reactive protein [CRP], erythrocyte sedimentation rate [ESR], etc.); neoplasms/malignancy (e.g., bone marrow biopsy, flow cytometry, etc.), nutritional deficiencies (e.g., B_{12}, folate, homocysteine, methylmalonic acid, copper, zinc); immunodeficiencies (e.g., immunoglobulins, immune evaluation for detection of cellular or humoral immunity); and congenital/constitutional disorders (e.g., molecular/genetic testing for bone marrow failure syndromes, etc.). Although specialized neutrophil antibody testing (e.g., granulocyte agglutination test,

granulocyte indirect immunofluorescence test) have been referenced in the past, these tests are available in very few clinical laboratories, and results are generally considered not helpful in the diagnosis and management of patients.[108-110]

In general, patients with ANC >1.0 × 10^9/L can be managed as outpatients, while febrile patients with severe neutropenia (ANC <0.5 × 10^9/L) are admitted for intravenous antibiotics. The latter are assumed to be at high risk for marrow hypoplasia and severe infection; presumptive management with parenteral antibiotics in these instances is prudent.

Neutropenia in the Neonatal Period, Infancy, and Childhood

Causes of neutropenia in neonates depend on maternal factors, genetics, immunologic factors, and postnatal infections, the latter being the most common cause of neutropenia in this age group. In infancy and childhood, neutropenia is often transient or chronic and self-resolving; causes are typically infectious or immunologic in nature (**Box 10-3**).

Neonatal Alloimmune Neutropenia

Neonatal alloimmune neutropenia is caused by transplacental passage of maternal IgG antibodies that are sensitized to paternally inherited human neutrophil antigens (HNAs) on fetal granulocytes.[111,112] The number of postpartum women with HNAs is significantly higher than the incidence of neutropenia, suggesting that many of the antibodies are clinically irrelevant. Neutropenia varies from relatively mild to severe; thus, an affected infant may be either asymptomatic or septic in extremely severe cases. The

neutropenia resolves spontaneously in 6 to 11 weeks after decay of maternal antibodies but may last as long as 6 months.[109] Severe neutropenia is ameliorated by administration of granulocyte colony-stimulating factor (G-CSF). A bone marrow examination, although not normally required, shows normal-to-increased cellularity with a decrease in mature neutrophils.

Primary Autoimmune Neutropenia

Primary autoimmune neutropenia (AIN), or AIN of childhood, is the most common cause of chronic neutropenia in infants and children when not associated with other pathology. This condition affects children younger than 38 months, with spontaneous resolution in 90% of cases by 2 to 3 years of age, with the remainder recovering by age 11.[113] Infectious complications are usually less severe than expected for the degree of neutropenia.[114] A bone marrow examination is usually not required, but if performed, the bone marrow is often normocellular or hypercellular with left-shifted myeloid hyperplasia. Neonates can also develop AIN secondary to placental transfer of autoantibodies when the mother has AIN.

A transient neutropenia of unknown mechanism can be seen in small-for-gestational-age newborns or neonates of hypertensive women.[112]

If older children develop chronic AIN, evaluation for a congenital immunologic disorder such as common variable immunodeficiency should be considered.

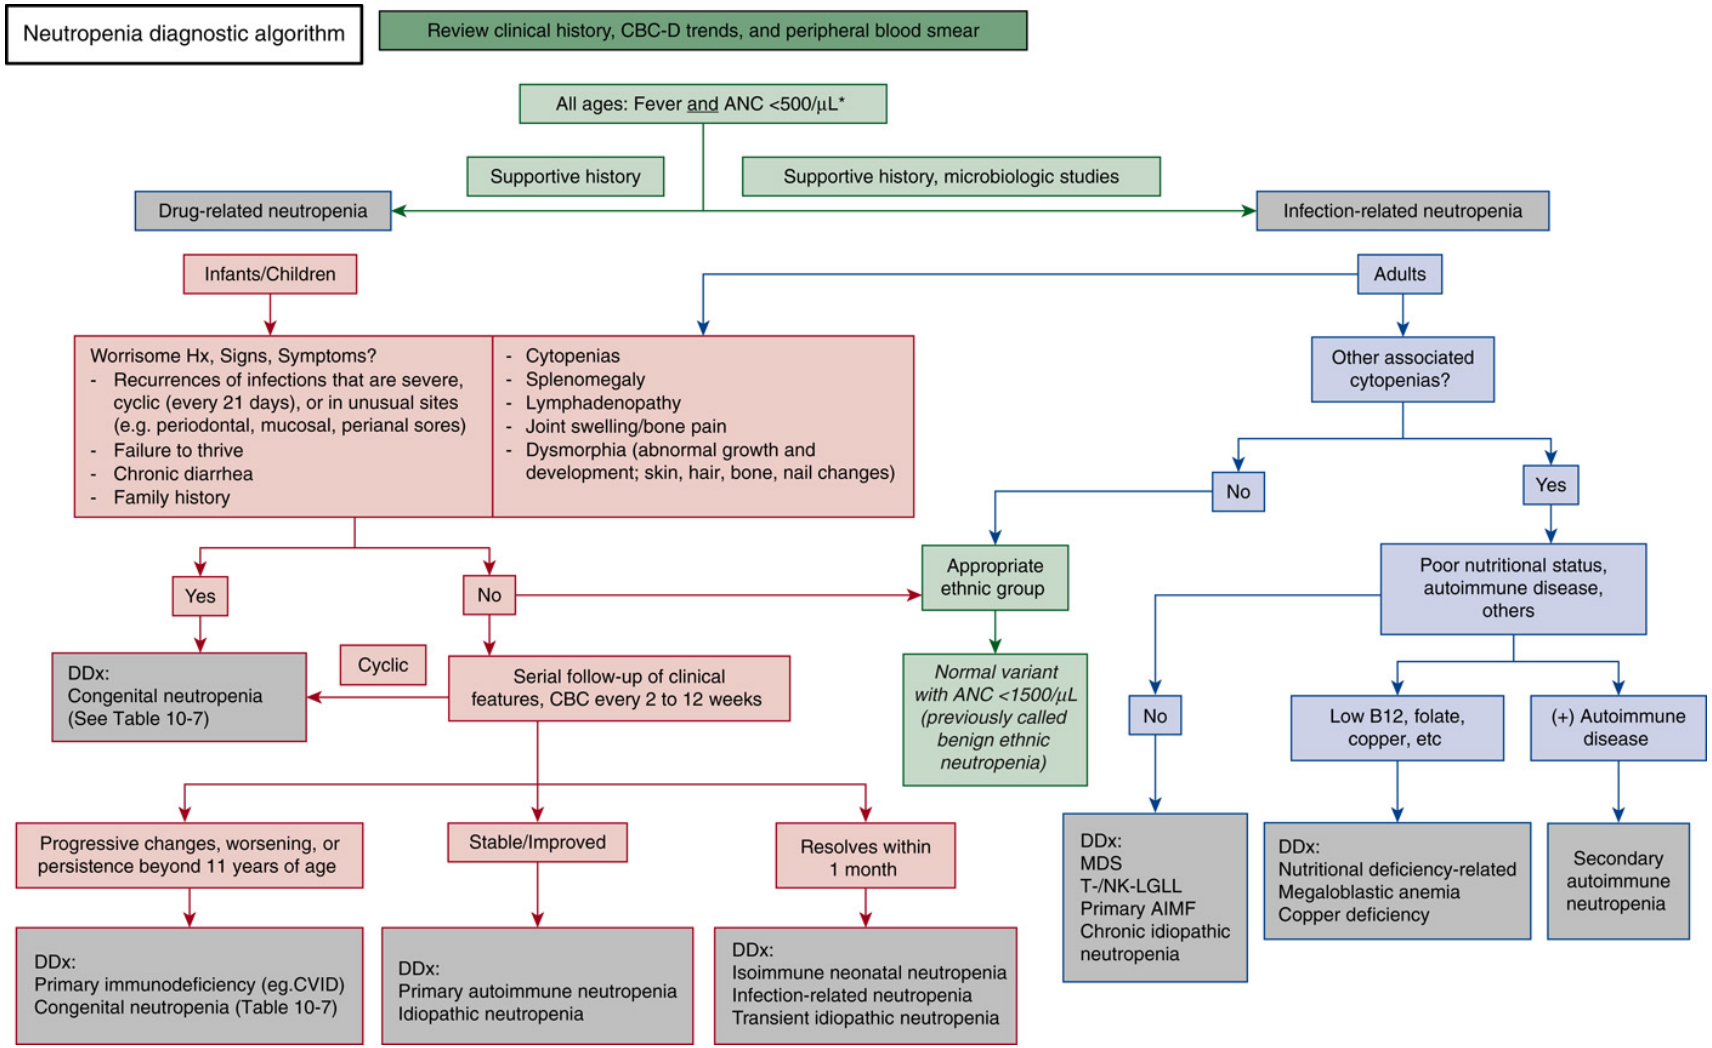
Infection-Related Neutropenia in Infancy/Childhood

Three days after birth, neutropenia is more commonly associated with necrotizing enterocolitis or nosocomial infection. Vertical

transmission of human immunodeficiency virus (HIV) infection should also be considered in newborns with unexplained neutropenia. Acute isolated neutropenia in children is most often the consequence of a recent viral infection. Neutropenia develops within 48 hours of infection and may persist for up to 6 days. In a cohort of immunocompetent hospitalized children with neutropenia (range, 0 to 16 years), more than 80% were age 3 years or younger. In addition, infectious etiologies were uncovered in 29% of cases, including brucellosis, rickettsiosis, respiratory syncytial viral infection, and others.[115] In addition to primary loss by extensive neutrophil infiltration into infected tissue, splenic sequestration or antineutrophil antibody formation (with Epstein-Barr virus [EBV] infection) may accelerate neutrophil destruction. Monitoring blood counts for evidence of recovery is usually all that is required.

Neutropenia in Adults

Neutropenia in adults has a large number of causes (**Box 10-3**), most of which are secondary to an associated condition (see Secondary Autoimmune Neutropenia section for further discussion). In contrast to the pediatric population, a bone marrow examination is often required in adults when the clinical history and physical examination do not elicit a likely neutropenic etiology, and particularly when other cell lineages are affected. The cause of neutropenia is often multifactorial.



Neutropenia diagnostic algorithm

FIGURE 10-38 Neutropenia algorithm.Drug-induced and infection-related are the most common etiologies for neutropenia for all age groups. *ANC,* Absolute neutrophil count; *BMBx,* bone marrow aspirate and biopsy; *CBC-D,* complete blood cell count with differential.

Drug-Induced Neutropenia

Drug-induced neutropenia is the most common cause of neutropenia in adults. Neutropenia secondary to chemotherapy or radiotherapy shows a dose-dependent relationship. An idiosyncratic drug reaction is the most common cause for an unexpected isolated neutropenia in an outpatient setting. Idiosyncratic drug-induced agranulocytosis (ANC $<0.5 \times 10^9$/L) is defined as an adverse reaction in an abnormally susceptible individual with previously normal neutrophil counts.[116] Individuals with mild-to-moderate neutropenia (ANC 0.5 to 1.5×10^9/L) are alternatively referred to as having *drug-induced neutropenia*. The onset of neutropenia is unpredictable in these processes but usually occurs 1 to 2 weeks after initial drug exposure or immediately after drug reexposure. Almost any drug can be involved.[116] Common offending drugs causing severe neutropenia are clozapine, methimazole, sulfasalazine, trimethoprim-sulfamethoxazole, and cocaine (levamisole-tainted).[117] Some of these medications, in addition to posttransplant immunosuppressive agents, also induce pseudo–Pelger-Huët changes, mimicking neutrophilic dysplasia[118] (**Fig. 10-39**).

Box 10-3 Causes of Acquired Neutropenia*

Drug Induced Causes That Overlap With Secondary Immune-Mediated Mechanisms

- Antibiotics (sulfasalazine), antifungals, antimalarials
- Anticonvulsants
- Anti-inflammatories
- Antipsychotics (clozapine)
- Antithyroid agents (thionamides)
- Antidepressants
- Sedatives
- Cardiovascular drugs
- Diuretics
- Other: levamisole, rituximab

Primary Immune Mediated

- Neonatal alloimmune neutropenia
- Autoimmune neutropenia of childhood
- Transfusion reaction

Secondary Immune Mediated

- Autoimmune disorders: rheumatoid arthritis, systemic lupus erythematosus, primary biliary cirrhosis, polyarteritis nodosa, scleroderma, Castleman disease, Sjögren syndrome
- Infection: *Helicobacter pylori,* HIV, parvovirus B19

- Neurologic diseases: multiple sclerosis
- Malignancy: Hodgkin lymphoma, T-cell large granular lymphocytic leukemia, Wilms' tumor
- Drug induced: rituximab, fludarabine, propylthiouracil
- Transplantation: stem cell, bone marrow, kidney
- Bone marrow injury: aplastic anemia, paroxysmal nocturnal hemoglobinuria

Other

- Chronic idiopathic neutropenia (likely immune mediated)
- Infection (most common cause)
  - Viral: human immunodeficiency virus; respiratory syncytial virus; cytomegalovirus; Epstein-Barr virus; hepatitis A, B, or C; influenza; measles; mumps; rubella; yellow fever; varicella; herpes simplex virus
  - Bacterial: rickettsia, typhoid, miliary tuberculosis, tularemia, brucellosis, streptococcus, staphylococcus, *Escherichia coli, Klebsiella* spp.
  - Protozoan: malaria, kala-azar, trypanosomiasis
  - Fungal: histoplasmosis, *Candida* spp.
- Nutritional deficiencies: vitamin B_{12} (cobalamin), folic acid, copper, severe caloric deprivation
- Bone marrow infiltration: carcinoma, leukemia, lymphoma, myeloma, granulomatous diseases, fibrotic processes
- Endocrine or metabolic disorders: Addison disease, hyperthyroidism, hypopituitarism, hyperglycemia, acidemia, tyrosinemia, glycogen storage disease type 1B

- Hypersplenism
- Radiation
- Toxins, alcohol
- Hemodialysis
- Maternal hypertension

* List is not all-inclusive and instead represents major causes.

Late-onset neutropenia is seen with the monoclonal antibody (mAb) anti-CD20 (rituximab)[119] and with the chimeric antigen receptor T-cell therapy (CAR-T), which may have other cytopenias.[120] Causative mechanisms differ depending on the drug involved and are often incompletely understood. Roles for immune-mediated (immune complex, hapten, or autoimmune) or nonimmune-mediated mechanisms, such as active drug metabolite toxicity to neutrophils or marrow stroma, have been described. The incidence of drug-induced neutropenia increases with age, likely reflecting the higher use of multiple medications in the elderly. Greater susceptibility of some individuals to idiosyncratic reactions is hypothesized to relate to increased myeloid precursor sensitivity to a normal drug concentration or to gene polymorphisms that alter drug metabolism or drug pharmacokinetics. If a severe, drug-related neutropenia is suspected, all nonessential drugs and over-the-counter medications should be discontinued, with substitution of essential medications. Drug-induced agranulocytosis may be fatal with continued exposure to the drug.

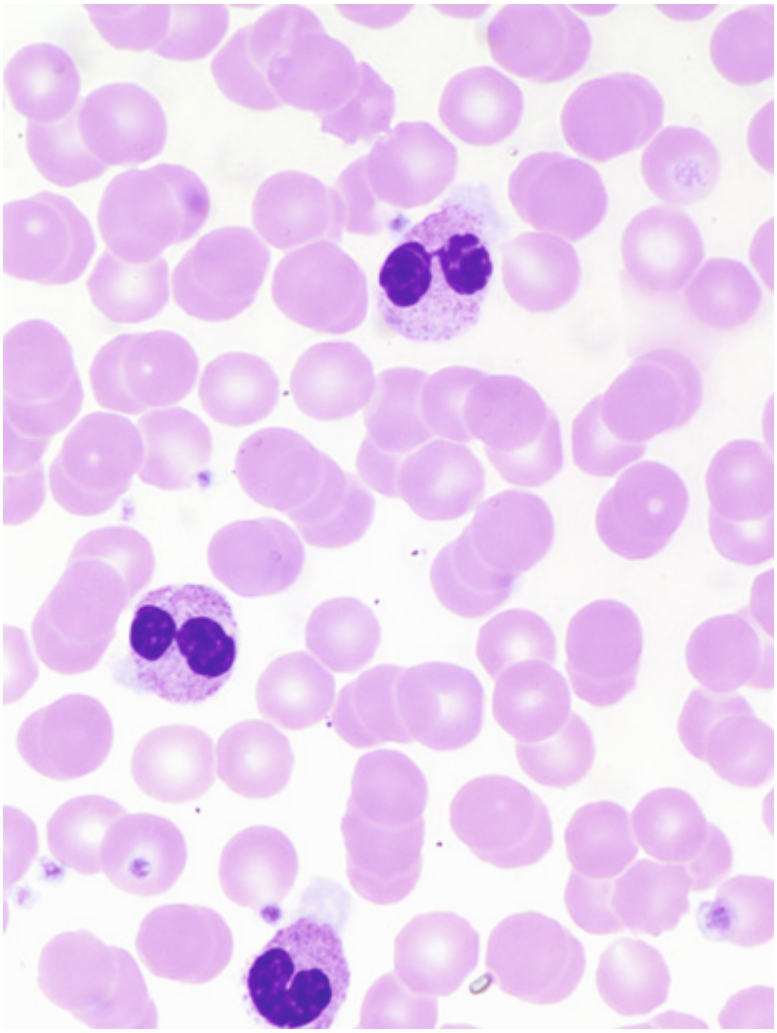

FIGURE 10-39 Peripheral blood smear of acquired pseudo–Pelger-Huët anomaly in a lung transplant recipient treated with mycophenolate mofetil.Two of the neutrophils feature symmetric bilobed nuclei with so-called “pince nez” morphology.

Secondary Autoimmune Neutropenia

Autoimmune neutropenia (AIN) is more often secondary rather than primary in adults. Secondary AIN is associated with systemic

autoimmune disorders, infectious diseases, neoplasms, neurologic disorders, organ transplants, and certain medications.[105] Concurrent thrombocytopenia or hemolytic anemia may be seen, and the neutropenia is often multifactorial in etiology. A bone marrow evaluation may be required to exclude a neoplastic process or aplasia. Physical findings and specific immunologic tests supporting an autoimmune disorder usually suffice to make the diagnosis.[103] Neutropenia associated with systemic autoimmune disorders (e.g., lupus, primary biliary cirrhosis, Sjögren syndrome) may track with disease activity and is rarely severe, except in association with Felty syndrome (i.e., triad of rheumatoid arthritis, neutropenia, and splenomegaly). Both Felty syndrome and T/natural killer (NK)-cell large granular lymphocytic (LGL) leukemia with rheumatoid arthritis have an inherited DR4 haplotype in a majority of cases and are part of the same disease process.[121] Neutropenia occurs in 70% to 80% of patients with LGL leukemia and is of multifactorial origin, with a role for antineutrophil autoantibodies, myelopoiesis inhibition by cytokines, soluble Fas ligand-mediated apoptosis (shed from LGLs), and splenic sequestration. In addition to morphologic evaluation, immunophenotyping for LGLs and identification of a TCR gene rearrangement confirms the diagnosis.

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia is defined as a persistent (>3 months), non-oscillating, and unexplained reduction in neutrophils.[122] This is essentially a diagnosis of exclusion after extensive evaluation for other causes. Middle-aged females are primarily affected, particularly those with an HLA-DRB1*1302

genetic predisposition who may have concurrent mild anemia, thrombocytopenia, osteopenia, or osteoporosis. Spontaneous remissions occur rarely among adults. The bone marrow is typically normocellular with a slightly decreased myeloid-to-erythroid ratio caused by mild T-cell and cytokine-mediated suppression of granulopoiesis.

Infection-Related Neutropenia

Infection-related neutropenia may be caused by a large number of infectious agents, including almost any type of viral infection (**Box 10-3**). Postinfectious neutropenia, although more common in children, is usually self-limited unless the patient is septic or has persistent neutropenia associated with EBV or HIV infections. A number of different mechanisms are involved in the pathogenesis, including infection of progenitor or endothelial cells, immunologically mediated bone marrow suppression (particularly viral infections), excessive cellular destruction (especially bacteremia with endotoxemia), increased neutrophil adherence to the endothelium, development of antineutrophil antibodies, and enhanced neutrophil utilization at the site of infection.[103,105]

Nutritional Deficiency–Related Neutropenia

The myeloid cells in the bone marrow generally show normal morphology in the majority of acquired neutropenias. Notable exceptions include megaloblastic anemia (**Table 10-6**) and copper deficiency. Neutropenia associated with vitamin B_{12} or folate deficiency rarely occurs without anemia and macrocytosis. Copper deficiency should be considered when cytoplasmic vacuoles are present in myeloid (particularly promyelocytes and myelocytes) and

erythroid precursors.[123] The bone marrow may be variably cellular with myeloid and erythroid dyspoiesis, ring sideroblasts, and increased hematogones. Patients have concurrent normocytic, macrocytic, or microcytic anemia, neurologic disorders, and rarely, thrombocytopenia. Copper deficiency occurs secondary to excess zinc intake (through supplements, medications, or denture fixatives), total parenteral nutrition, and gastrointestinal disorders (e.g., partial gastric resection). Mild neutropenia is also observed with severe caloric deprivation, as in anorexia nervosa.

Congenital Neutropenia

Congenital neutropenia refers to neutropenias with genetic mutations and not simply those that are present at birth. Many of these disorders have intrinsic defects that cause premature apoptosis of cells, ineffective neutrophil production, and recurrent infections. The Severe Chronic Neutropenia International Registry (SCNIR) and other national registries recommend identification of mutations in the more than 25 genes that affect the neutrophil differentiation program.[124] A subset of these is discussed here and summarized in **Table 10-7**.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) represents a heterogeneous group of disorders characterized by inherited mutations that result in severe neutropenia and a maturation arrest in neutrophilic myeloid production. Patients present with acute and life-threatening bacterial and fungal infections often involving the skin, oropharynx, and lung. Advancements in next-generation sequencing (NGS) technology have uncovered mutations associated with SCN, yet the genetic cause

is still unknown in more than 20% of cases.[124] Molecular classification in the remaining cases is important for risk stratification, treatment, and prognosis. The most frequent pathogenic alterations in patients with SCN are autosomal dominant, heterozygous *ELANE* mutations that present with severe pyogenic infections in early infancy; unless treated with G-CSF or hematopoietic stem cell transplantation, they are fatal by 3 years of age. More than 100 distinct *ELANE* mutations have been described in congenital neutropenias.[124] *ELANE* mutations produce a misfolded neutrophil elastase protein that activates the unfolded protein response mechanism, leading to neutrophil apoptosis. Mutations of *GFI-1* cause a rare autosomal dominant form of disease also associated with lymphopenia. Kostmann originally described an autosomal recessive form of SCN in 1956, classically known as Kostmann neutropenia. It is associated with *HAX1* mutations and is seen in Swedish, Turkish, and Middle Eastern populations, accounting for 15% of SCNs, second in frequency only to *ELANE* mutations.[124] Infants present in the first weeks of life with severe bacterial infections, and a subset develops neurologic symptoms (epilepsy, cognitive defects, mental retardation) caused by an additional *HAX1* isoform expressed in neurons. Autosomal recessive disease caused by mutations of *G6PC3* and *VPS45* are rare, as is X-linked disease.

SCN is considered a preleukemic condition, with one review describing a 21% cumulative incidence of transformation to MDS or acute myeloid leukemia (AML) after 15 years.[124] Clones with acquired *CSF3R* and subsequent *RUNX1* mutations have been identified in patients who progressed to MDS or AML[125,126] (**Fig.**

10-40). G-CSF is the treatment of choice in SCN and ameliorates neutropenia, reduces infection risk, and improves quality of life in more than 90% of patients with SCN through increased neutrophil survival.[124] However, progression to MDS or AML is more frequent in patients requiring high doses of G-CSF; the current hypothesis is that poor response to G-CSF therapy likely identifies an "at risk" group of SCN individuals that are likely to have adverse clinical outcomes with G-CSF.

Cyclic Neutropenia

Cyclic neutropenia is an autosomal dominant disorder caused by *ELANE* mutations associated with low propensity for leukemic progression and milder disease than SCN such that some patients are not diagnosed until adulthood.[124,127] Patients have neutrophil counts that oscillate at 21-day intervals (intervals vary from 14 to 36 days) between normal and almost absent levels. The marrow exhibits a myeloid maturation arrest before the period of severe peripheral neutropenia. Accelerated apoptosis of bone marrow progenitor cells is found in all stages of the cycle, with insufficient myeloid output.[124] The diagnosis is established by monitoring serial neutrophil counts over a 6-week to 8-week period. G-CSF provides effective therapy without a significant risk for MDS or leukemic transformation.[107,125] Symptoms often improve as an individual grows older.

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome (SDS) is a rare, autosomal recessive, multisystem disorder that usually presents in the first few years of life.[128,129] Affected infants invariably have malabsorption, steatorrhea, and failure to thrive, with ultimate growth retardation.

Increased infections are caused by neutropenia with impaired neutrophil chemotaxis and, commonly, T-cell and B-cell defects. The diagnosis is made based on identification of exocrine pancreatic dysfunction and intermittent or persistent neutropenia. Biallelic mutations of the Shwachman-Bodian-Diamond syndrome gene *(SBDS)* located on 7q11 are found in 90% of individuals, although some patients with clinical disease do not have these mutations. An additional three genes have been associated with an SDS-like phenotype: DnaJ heat shock protein family member C21 *(DNAJC21)*,[130,131] elongation factor-like 1 *(EFL1)*,[131,132] and signal recognition particle 54 *(SRP54)*.[133] All genes associated with SDS are involved in ribosome biogenesis, further advancing the concept that SDS is a ribosomopathy.[134] Disease phenotype and bone marrow findings vary with time in individuals and among patients, making the diagnosis challenging in some cases.[135] Symptoms include intermittent anemia and thrombocytopenia, neurocognitive deficits, skeletal abnormalities such as metaphyseal dysostosis, and hepatomegaly.

Table 10-7

AD, Autosomal dominant; *AML,* acute myeloid leukemia; *AR,* autosomal recessive; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *MDS,* myelodysplastic syndrome; *S,* somatic; *WHIM,* warts, hypogammaglobulinemia, infections, and myelokathexis; *XL,* X-linked.

About 15% to 20% of individuals are diagnosed with MDS or AML at SDS presentation.[136] However, cytogenetic changes are common

and not necessarily harbingers of malignancy, including isochromosome 7q and 20q11 deletion.[128,129] Thus, chromosomal abnormalities in isolation (in the absence of prominent or progressive morphologic features of dysplasia or persistently increased numbers of blasts) should not automatically lead to a diagnosis of MDS or AML. Children with SDS do advance to bone marrow failure with progressive cytopenias and aplastic anemia,[128,129] with malignant transformation reported in 5% to 36% of patients.[136] Lifelong periodic bone marrow assessment is essential to monitor for these changes.

Chédiak-Higashi Syndrome

Though the exact prevalence is unknown, Chédiak-Higashi syndrome (CHS) is a rare disorder, with fewer than 500 cases reported in the literature. It exhibits diverse clinical manifestations related to abnormally enlarged lysosomes or lysosome-related organelles in cells (**Fig. 10-41**).[137] More than 60 different *LYST* mutations on chromosome 1q42.1-q42.2 are described. The type of mutation commonly affects the phenotype.[138] Improper cellular regulation and function of lysozymes and related organelles lead to severe immunodeficiency, mild coagulation defects, variable oculocutaneous albinism, progressive neurologic dysfunction, periodontal disease, and defective plasma membrane repair. Faulty neutrophil chemotaxis and function lead to frequent and severe pyogenic infections that characterize this disorder, whereas a deficiency in platelet-dense bodies contributes to the tendency for easy bleeding. The classic (i.e., childhood-onset) form of CHS develops into the so-called “accelerated phase,” which is fulminant

hemophagocytic lymphohistiocytosis/hemophagocytic syndrome (HLH).[137] Without bone marrow transplantation for classic CHS, the disease is often fatal in the first decade of life.[139]

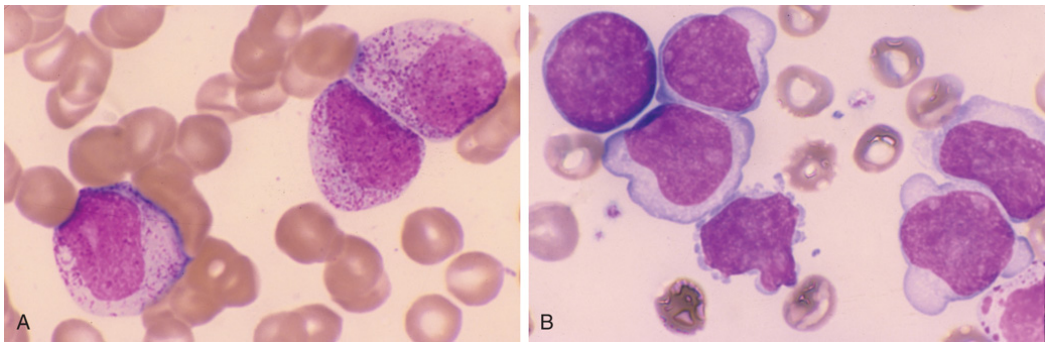

FIGURE 10-40 **A,** Bone marrow smear of severe congenital neutropenia in a 3-year-old boy illustrates a maturation arrest at the promyelocyte stage of development. **B,** Ten years later, after repeated poor response to therapy with high-dose granulocyte colony-stimulating factor (G-CSF), he developed acute myeloid leukemia. Point mutations in the G-CSF receptor gene were detected.

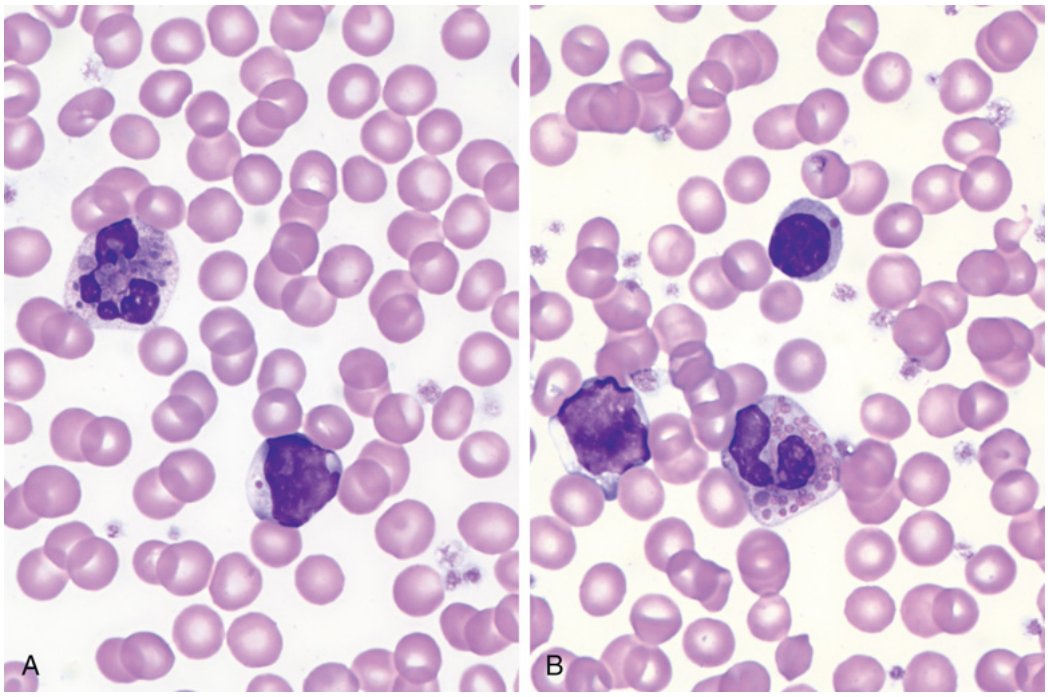

FIGURE 10-41 Giant neutrophil **(A)** and eosinophil **(B);** secondary granules are seen in this peripheral blood smear from a patient with Chédiak-Higashi syndrome. Note the abnormal large primary granules in the lymphocytes.

Myelokathexis

Myelokathexis is a histologic pattern of increased myeloid cells with excessive neutrophil apoptosis in the bone marrow. It is associated with the immunodeficiency disorder WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome.[140] Patients with WHIM have recurrent infections secondary to neutropenia, B-cell lymphopenia, and hypogammaglobulinemia. They are particularly susceptible to human papilloma virus infection and require careful surveillance. This is the first example of a disease mediated by a chemokine

receptor (CXCR4). *CXCR4* mutations on chromosome 2q21 are believed to increase intracellular signaling that allows for retention of neutrophils in bone marrow or tissue sites.[141]

Additional Disorders

Dyskeratosis congenita is a multisystem disorder that affects tissues with a high turnover rate, such as skin, mucous membranes, and blood. Neutropenia is often the presenting hematologic manifestation. As 80% to 90% of patients develop bone marrow failure, this disorder is more fully described later in this chapter in the section Evaluation of Specific Bone Marrow Failure Syndromes.

Neutropenia may also be a presenting feature of other congenital disorders including Fanconi anemia, reticular dysgenesis, cartilage-hair hypoplasia, Hermansky-Pudlak syndrome type 2, Griscelli syndrome type 2, *LAMTOR2* deficiency, Barth syndrome, AK2 deficiency, poikiloderma, CD40LG deficiency, Cohen syndrome, *GATA2* deficiency, Pearson marrow-pancreas syndrome, *STK4* deficiency, and glycogen storage disease type IB.[124]

Lymphopenia

Lymphopenia or lymphocytopenia is defined as an absolute lymphocyte count of less than 1.5×10^9/L in adults and less than 2.0×10^9/L in young children. It may occur in isolation or as part of pancytopenia. Lymphopenia can be further categorized as decreased B cells, T cells, NK cells, or their subsets. The causes of lymphopenia are extensive and include a variety of infectious, drug-related, autoimmune, and congenital processes (**Box 10-4**).

Infection-Related Lymphopenia

Lymphopenia is seen in a number of viral, fungal, bacterial, mycobacterial, and parasitic infections.[142] Reactive lymphocyte morphology in these disorders provides a clue to underlying infection. A decreased lymphocyte count is the hematologic hallmark of HIV infection. The destruction of $CD4^+$ memory T cells, followed by increased memory T-cell turnover and damage to the thymus and other lymphoid tissues, results in profound lymphopenia.[143]

Box 10-4 Causes of Lymphopenia*

HIV, Human immunodeficiency virus; *SARS,* severe acute respiratory syndrome.

Infections

- HIV
- SARS coronavirus, including coronavirus disease 2019 (COVID-19) caused by the novel SARS-coronavirus-2 (SARS-CoV-2)
- Influenza
- Respiratory syncytial virus
- Ebola
- Anaplasmosis (ehrlichiosis)
- *Legionella pneumophila*
- Tuberculosis
- Sepsis-induced immunosuppression

Therapy

- Steroids
- Rituximab
- Chemotherapy, especially purine analogues and alkylating agents
- Antibiotics
- Antithymocyte globulin
- Immunosuppressive therapy
- Radiation therapy

Autoimmune

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Crohn disease
- Vasculitis

Malignancy

- Carcinoma
- Hodgkin and non-Hodgkin lymphoma

Hematologic Disorders

- Aplastic anemia

Congenital

- Severe combined immunodeficiency
- DiGeorge syndrome (thymic aplasia)

- Wiskott-Aldrich syndrome
- Primary immunodeficiency syndromes

Other

- Physiologic stress
- Idiopathic CD4 lymphocytopenia

* List is not all-inclusive and instead represents major causes.

The emergence of the highly transmissible novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), in December 2019 led to a global pandemic with devastating morbidity and mortality, termed coronavirus disease 19 (COVID-19). As of August 2022, over 500 million cases had been reported worldwide, with the vast majority experiencing mild-to-moderate disease. Yet over the same period, severe infections have led to more than 6 million deaths caused by COVID-19.[144,145] In severe disease, not only is the respiratory system affected; there is marked inflammatory response, multiorgan dysfunction with renal, neurologic, and cardiovascular effects, and derangements in the coagulation and fibrinolytic pathways, leading to thromboembolic events.[146] The most notable CBC abnormalities are lymphopenia and neutrophilia at hospital admission, both of which are associated with increased odds of progression to severe disease and death.[147] Striking peripheral CD4 and CD8 T-lymphopenia in patients with severe COVID-19 is hypothesized to occur via diversion of T-cells into infected organs and activation-induced exhaustion, apoptosis, or pyroptosis.[148] A broad spectrum of peripheral blood smear findings

has been described in patients with COVID-19, including abnormalities in neutrophils, lymphocytes, monocytes, and platelets.[146,149] Several reports discuss the finding of circulating reactive "atypical" lymphocytes and/or lymphoplasmacytoid cells[150-152] (so-called "covidocytes"); some investigators report their association with better clinical outcomes (**Fig. 10-42**).[150]

Drug-Related Lymphopenia

Some therapeutic agents are associated with decreased lymphocyte counts. Within hours of administration, corticosteroids initiate lymphopenia, primarily of T cells, through a glucocorticoid receptor–associated apoptotic mechanism.[153] Chemotherapeutic agents, particularly alkylating agents and purine analogues, also induce lymphocyte depletion through several different apoptotic mechanisms. The CD4 T cells are especially sensitive, and lymphopenia a therapy may be prolonged.[154] The anti-CD20 mAb rituximab binds to B cells and produces cell death by complement-mediated lysis and apoptosis.[155]

Congenital Immunodeficiency Disorders

Lymphocytopenia in congenital immunodeficiency diseases and frequent viral, fungal, or protozoal infections suggest a T-cell disorder; on the other hand, abnormal serum immunoglobulin levels and recurrent infections with encapsulated bacteria point toward a B-cell disorder or antibody deficiency.[156,157] Severe combined immunodeficiencies (SCID) are rare disorders of humoral and cellular immunity, classified by the affected lymphocyte subsets (T-cell, B-cell, NK-cell).[157,158] They present as recurrent severe infections with unusual pathogens in young infants. Nearly half of

SCID cases are X-linked. Molecular defects in the following genes have been described in patients with SCID: *IL-2RG* (most prevalent), *JAK3, RAG1, RAG2, DCLRE1C, PRKDC, IL7R, CD3D, CD3E, CD247, PTPRC, CORO1A, ADA,* and *AK2*.[158] The most common chromosomal microdeletion disorder, 22q11.2 deletion syndrome (22q11.2DS), is a T-cell deficiency disorder. Initially dubbed "DiGeorge syndrome" in the 1960s for patients presenting with a clinical triad (immunodeficiency, congenital heart defects, and hypoparathyroidism), 22q11.2DS is much more heterogeneous than originally described. Its presentation may also include variable degrees of thymic hypoplasia, other congenital abnormalities (such as palatal, gastrointestinal, and renal), variable cognitive and developmental delays, neuropsychiatric illnesses, and predisposition to infections and autoimmune diseases.[159]

Reactive Lymphopenia

Stress lymphopenia is seen in the setting of myocardial infarction, major surgery, trauma, sickle cell crisis, acute stroke, and intense exercise.[160-162] Release of cortisol with subsequent apoptosis results in decreased lymphocyte numbers.[163] Idiopathic CD4 lymphopenia is a rare disease associated with persistent lymphopenia (CD4-positive cells $<0.3 \times 10^9$/L) in the absence of HIV infection or other recognized causes of low CD4 cell counts. The pathogenesis is unclear, but it is postulated to occur through redistribution into tissues (such as lymph nodes and spleen) or decreased CD4 T-cell production from disturbed thymic maturation, increased apoptosis via the Fas pathway, or defective interferon-γ production.[164]

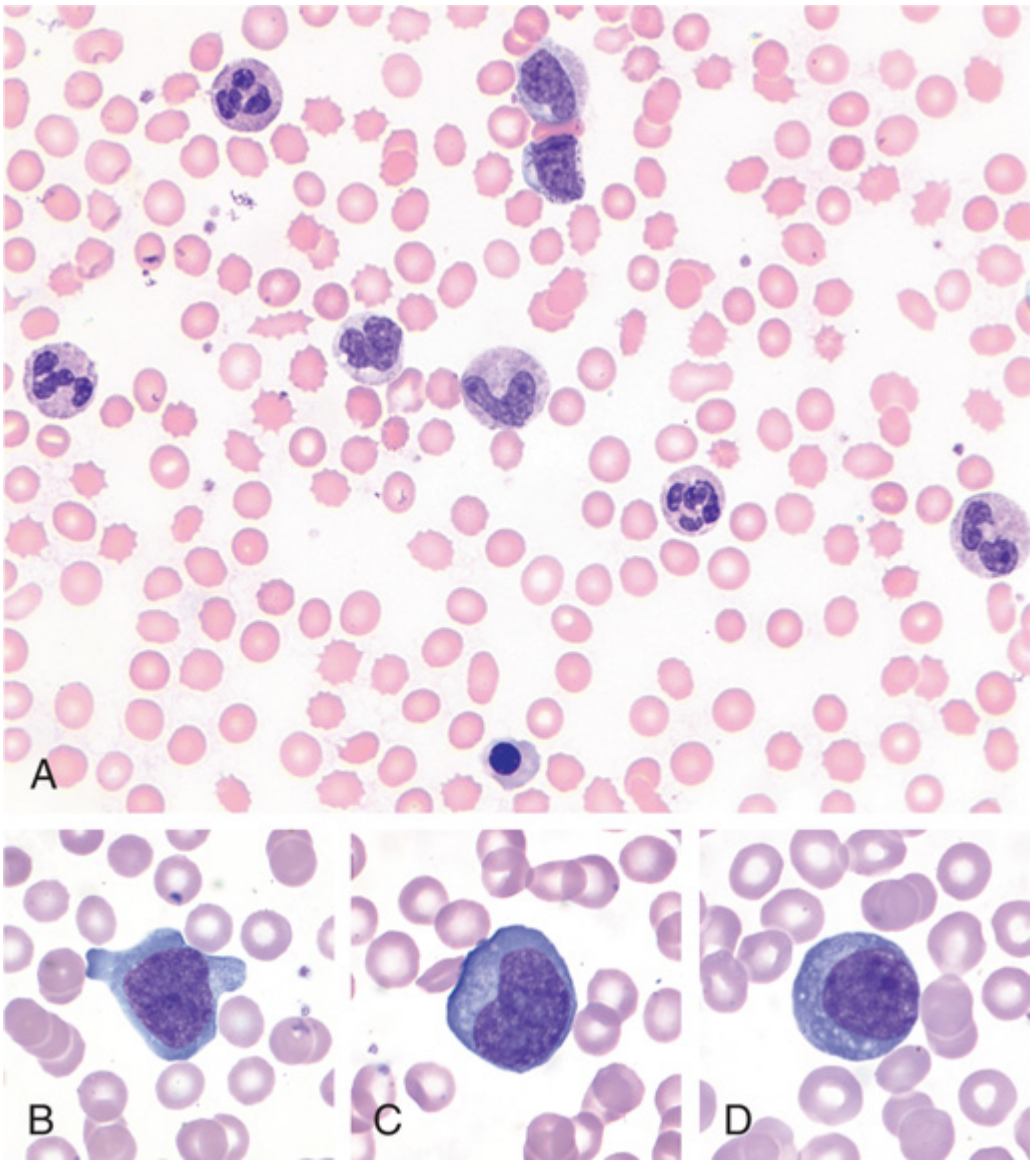

FIGURE 10-42 Peripheral blood smears from two patients with COVID-19.**A,** Left-shifted neutrophilia and marked lymphopenia are observed in the blood of an intubated 58-year-old man with severe pneumonitis who had not been vaccinated against SARS-CoV-2. **B-D,** Lymphoplasmacytoid cells (covidocytes) were

seen in the blood smear of a 25-year-old woman recovering from severe infection.

Lymphopenia Secondary to Autoimmune Disorders

Decreased lymphocyte count is a criterion for the diagnosis of systemic lupus erythematosus (SLE) (**Fig. 10-43**) and is encountered in other autoimmune diseases as well, particularly rheumatoid arthritis, Crohn's disease, and vasculitis.[165] Although the exact links between lymphopenia and autoimmune diseases have yet to be elucidated, key mechanisms for immune dysregulation have been proposed with a "double hit hypothesis."[166] The first hit is an autoimmune genetic propensity that, in lymphopenic states, leads to expansion of auto-reactive T cells via lymphopenia-induced proliferation (LIP). This is achieved with increased IL-7 availability signaling through the IL-7 receptor, Akt and JAK-STAT5 activation pathway, and BCL2 antiapoptotic pathway. The second hit is thought to occur when TGF-β signaling, which normally inhibits self-reactive T-cell proliferation, is suppressed in lymphopenic conditions.[167]

EVALUATION OF THROMBOCYTOPENIA

Thrombocytopenia is a decrease in the circulating platelet count to less than 150×10^9/L. It is encountered frequently in clinical practice, and when severe, is a common cause of hemorrhage. Thrombocytopenia is the result of decreased production, increased destruction or utilization, or abnormal distribution of platelets. Evaluation of megakaryocytes in patients with unexplained thrombocytopenia is one of the most common indications for a bone

marrow examination in clinical practice.[168] An important caveat before bone marrow evaluation is to confirm that the platelet count is not spuriously low as a result of in vitro platelet clumping. This phenomenon is most commonly caused by naturally occurring antibodies directed against a normally hidden platelet epitope (glycoprotein IIb/IIIa complex) that becomes exposed in the presence of ethylenediaminetetraacetic acid (EDTA). Blood collection in sodium citrate or an alternative anticoagulant may alleviate the problem.[169] Additional causes for platelet clumping include inadequate anticoagulant or improper mixing, cold agglutinin, and excessive trauma during venipuncture with release of thrombin. Review of the blood film before bone marrow evaluation is essential to look for platelet clumps and to evaluate for platelet rosetting around white blood cells (satellitism) and platelet–white blood cell aggregates.

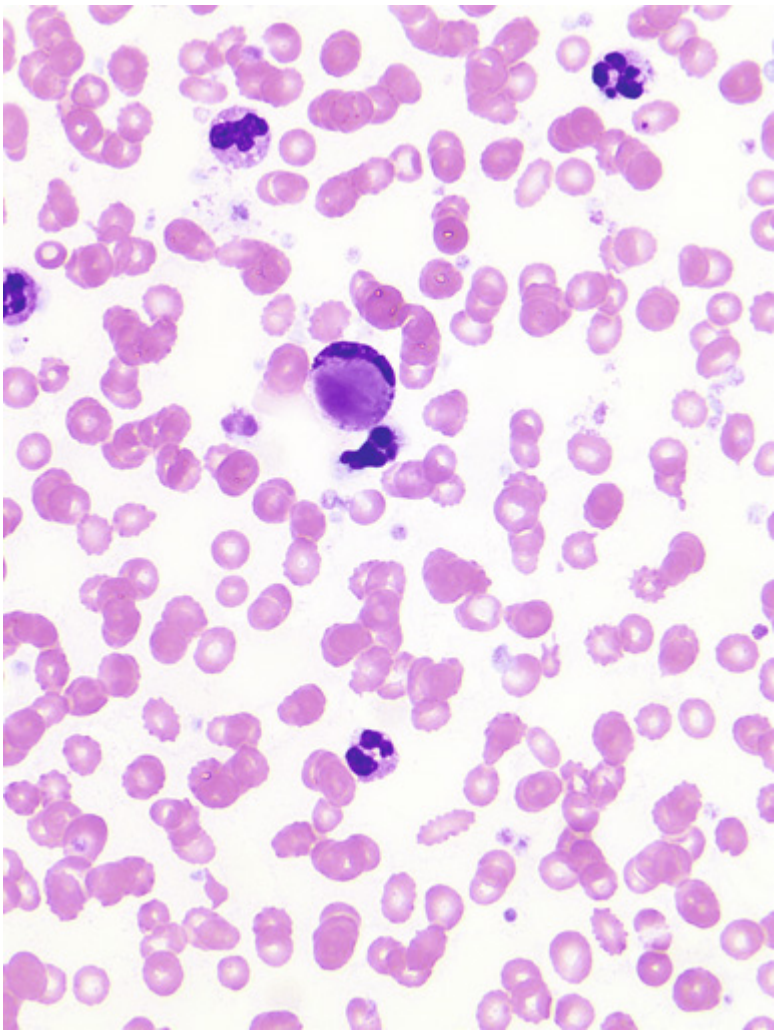

FIGURE 10-43 Peripheral smear from a patient with systemic lupus erythematosus (SLE).The lupus erythematosus (LE) cell contains phagocytized homogeneous purple nuclear material, which compresses the neutrophil nucleus.

Evaluation of bone marrow megakaryocytes is an important initial step in the workup for unexplained thrombocytopenia. Decreased megakaryocytes are indicative of decreased platelet production, whereas normal or increased megakaryocytes point toward

ineffective megakaryopoiesis (intramedullary cell death or excessive apoptosis) or loss of platelets from the circulation.

Table 10-8 lists the differential diagnoses for thrombocytopenia when megakaryocytes are absent or decreased. Age is an important consideration; an isolated loss of megakaryocytes (amegakaryopoiesis) suggests a congenital or, rarely, an autoimmune process with anti-megakaryocyte or anti-thrombopoietin antibodies. Identifying the cause of an underlying bone marrow failure disorder or other process (e.g., Fanconi anemia, acute leukemia) may be a challenge when isolated thrombocytopenia is the presenting finding. Evaluation for subtle dysplasia, viral effects, or abnormal cellular infiltrates is required. Cytogenetic evaluation, chromosome breakage studies (Fanconi anemia), and expanded molecular analysis with NGS for genes associated with bone marrow failure syndromes are warranted, as clinically indicated. Chemotherapy, toxin exposure, or prolonged use of certain drugs can selectively affect the megakaryocytes in some patients. Chronic platelet destruction or consumption may rarely induce amegakaryopoiesis.

Causes of acquired and congenital thrombocytopenia when the bone marrow megakaryocytes are normal or increased in number are listed in Tables **10-9 and 10-10**, respectively. A compensatory increase with greater numbers of immature and/or earlier forms of megakaryocytes (“left shift”) is often present during times of increased platelet destruction or utilization (**Fig. 10-44**). Younger megakaryocytes are often smaller and exhibit less nuclear lobation than mature forms. Platelets produced from these younger megakaryocytes are larger than the typical platelet diameter of 4 μm to 7 μm. In this setting, platelet accumulation in bone marrow

sinuses also suggests increased platelet consumption when bone marrow artifacts or a myeloproliferative neoplasm are excluded.

Acquired Thrombocytopenia

Immune-Mediated Thrombocytopenia

Immune thrombocytopenia (also called *immune thrombocytopenic purpura* or *ITP*) is the most frequent cause for platelet destruction. The 2011 American Society of Hematology guidelines for ITP (which largely adopted the International Working Group's recommendations for standardizing terminology and definitions)[170] were updated in 2019[171] with a focus on various management approaches, though most of the 2011 nomenclature was retained. The disease may be primary or secondary and is classified by phase: newly diagnosed (0 to 3 months), persistent (3 to 12 months), chronic (>12 months), or refractory (failure to respond to splenectomy or relapse after).[170] Disease severity is based on bleeding symptoms, not platelet count. Platelet antibody testing is not recommended because of poor sensitivity and specificity. Glucocorticoids are used as first-line therapy; however, if disease relapses soon after glucocorticoid therapy, then thrombopoietin receptor agonists (TPO-RA) (eltrombopag or romiplostim), rituximab, and/or splenectomy may be considered.[172] A small number of patients has been reported to develop moderate-to-severe marrow reticulin and/or collagen fibrosis with TPO-RA therapy, with reversal after drug discontinuation.[173-176] On the other hand, a Danish national patient registry reported moderate-to-severe fibrosis in a similar small number of chronic patients with ITP who had not undergone treatment with TPO-RA,[177] suggesting development of

fibrosis in chronic ITP may be part of the spectrum of autoimmune myelofibrosis (**Chapter 11**).

Primary Immune Thrombocytopenia

Primary ITP is defined as an acquired isolated thrombocytopenia with no identifiable associated medical condition. The pathogenesis is primarily IgG autoantibody–mediated platelet destruction, with complement-mediated opsonization or cell lysis, defects in T-cell regulation, and plasma effects on megakaryocyte production contributing to the decrease in platelets.[178] Increased T- and NK-large granular lymphocytes (T/NK-LGLs) are seen in patients with chronic ITP. Approximately 30% of children have a chronic form more similar to adult ITP.[179] These children usually present without a viral prodrome, and constitutional platelet disorders need to be excluded. Testing for *Helicobacter pylori* infection, antiphospholipid antibodies, and antinuclear antibodies (ANA) is advocated.[171]

* See **Table 10-11** for additional information.

† See **Table 10-7** for additional information.

Secondary Immune Thrombocytopenia

Secondary ITP is associated with a wide range of primary diseases, and terminology to describe the disease association is recommended in the diagnosis (e.g., secondary ITP [specific disease or drug-associated]). Some conditions linked to secondary ITP include rheumatologic disorders (e.g., antiphospholipid syndrome, SLE), medications, immunodeficiencies (e.g., common variable immunodeficiency, autoimmune lymphoproliferative syndrome), and infections (*H. pylori, Rickettsia,* viral).[180,181] Despite the extensive list of drugs known to be implicated, the diagnosis is frequently difficult and often becomes one of exclusion. The immune mechanisms involved are also varied and drug dependent, but they act primarily to increase peripheral platelet clearance, with some drugs also causing marrow suppression.[181]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia may be immune or nonimmune mediated. The latter is caused by platelet activation developing within days of heparin exposure that often resolves during continued therapy. Immune-mediated heparin-induced thrombocytopenia (HIT) occurs in 0.5% to 5% of individuals after receiving unfractionated or, less frequently, low–molecular-weight heparin for at least 4 days (**Table 10-9**).[182] Surgical patients are at greater risk than patients receiving heparin for medical interventions; HIT is rare in pediatric and obstetric patients. Antibodies against heparin/platelet factor 4 (heparin-PF4) immune complexes engage with platelet and monocyte Fc receptors, causing cellular activation, procoagulant microparticle release, and thrombin generation.[183] Venous or arterial thrombosis occurs in 17% to 53% of patients with

isolated HIT. Clinical scoring systems have been developed to determine the likelihood of HIT given the significant mortality that is associated with misdiagnosis and overdiagnosis in patients receiving heparin.[184] The 4Ts score for evaluating the pretest risk of HIT assigns points in four parameters (i.e., **t**hrombocytopenia, **t**iming of platelet count fall, **t**hrombosis or other sequelae, and other causes of **t**hrombocytopenia) and has been shown to have a very high negative predictive value for HIT when the 4Ts score is less than 4. However, positive predictive values for high or intermediate 4Ts scores are unsatisfactory; thus, this system performs best to exclude HIT. Testing with immunoassay for heparin-PF4 complex antibodies has high sensitivity (>90%) and low specificity, necessitating functional assay testing in some individuals with intermediate clinical findings. Bone marrow examination is required only when platelet counts do not normalize after discontinuation of heparin. Thrombocytopenia in HIT is typically less severe than that seen in classic drug-induced immune thrombocytopenia (DITP). The median nadir platelet counts are less than 20×10^9/L, translating into a high risk of hemorrhagic events in DITP.[185]

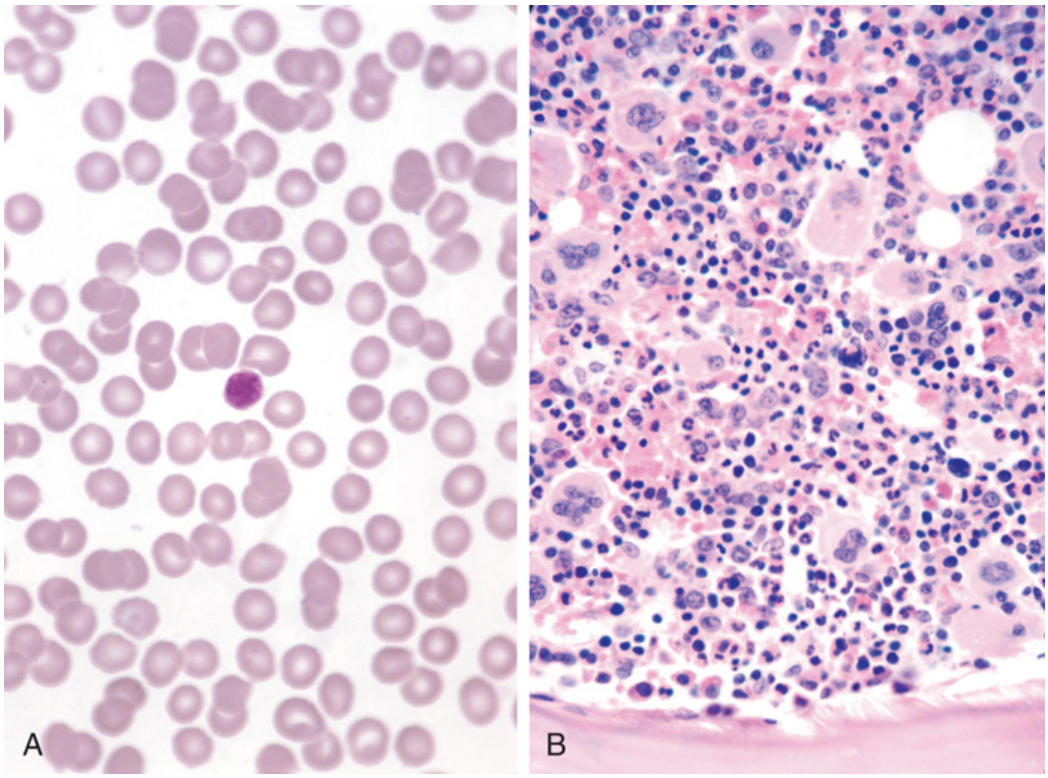

FIGURE 10-44 **A,** Peripheral blood smear of immune thrombocytopenic purpura. A single large platelet is seen at the center. Large platelets reflect early release from the bone marrow. **B,** The bone marrow trephine biopsy section contains increased numbers of megakaryocytes.

Infection-Associated Thrombocytopenia

Infection, especially viral infection, is a frequent cause of thrombocytopenia through direct infection of megakaryocytes, the toxic effects of organism proteins or cytokines, secondary hemophagocytosis, or immune-mediated destruction from antiplatelet antibodies. HIV-associated thrombocytopenia was reported in 5% to 30% of infected individuals before the advent of highly active antiretroviral therapy (HAART), though this has

significantly decreased in the post-HAART era.[186] HIV-associated thrombocytopenia involves multiple mechanisms. Immune-mediated platelet destruction occurs after specific or non-specific binding of anti-HIV antibodies or immune complexes to platelets (e.g., glycoprotein IIb/III). The virus directly infects megakaryocytes through CD4 and CXCR4 receptors, which causes ineffective platelet production. Megakaryocytes also undergo increased intramedullary apoptosis[187] and appear pyknotic, with near-naked hyperchromatic nuclei that have scant associated cytoplasm (**Fig. 10-45**).[188,189]

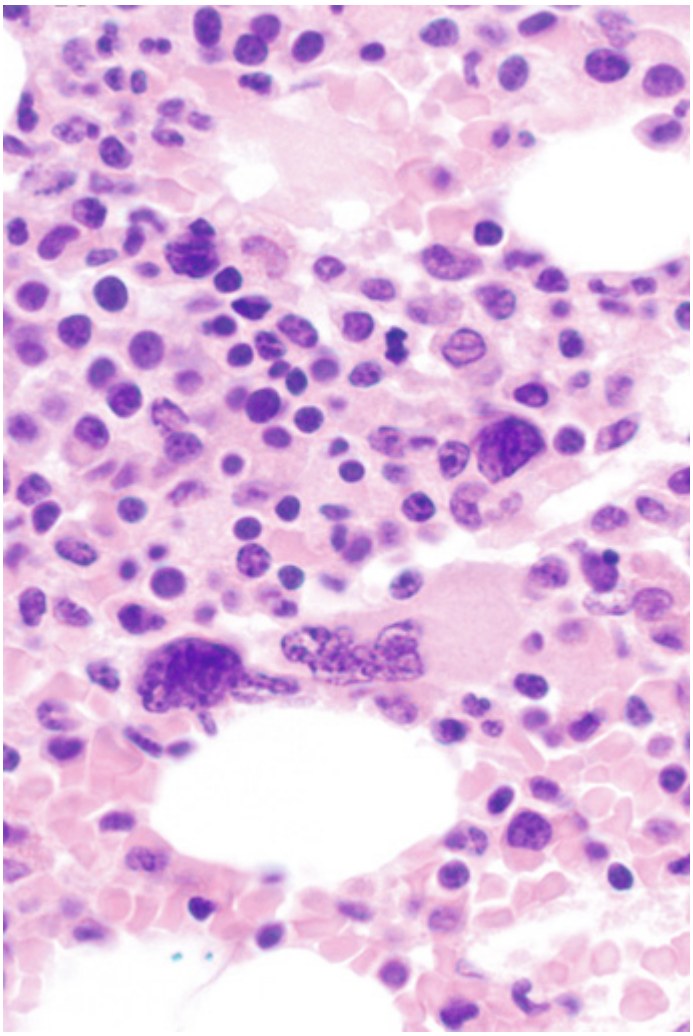

FIGURE 10-45 Several apoptotic megakaryocytes with high nuclear-to-cytoplasmic ratios are seen in this bone marrow biopsy section from a patient with HIV-associated thrombocytopenia.

H. pylori infection is associated with ITP. Some patients have secondary ITP (*H. pylori* associated), whereas others have primary ITP with a coincidental *H. pylori* infection.[190] The prior explains improvement in platelet counts among thrombocytopenic adults after *H. pylori* eradication programs in some regions of the world,

such as Italy and Japan, but not the United States. One trigger initiating the antiplatelet autoantibody response is modulation of the Fcγ receptor balance of monocytes/macrophages through inhibition of the immunosuppressive FcγRIIB signal.

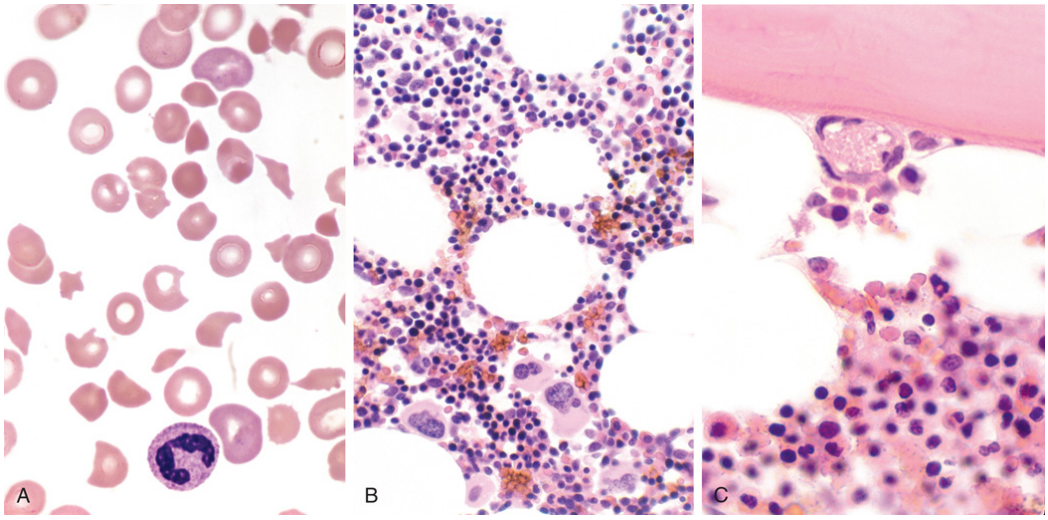

FIGURE 10-46 **A,** Peripheral blood smear of thrombotic thrombocytopenic purpura. Numerous red cell fragments (schistocytes) are present. No platelets are seen in this field. **B,** The bone marrow trephine biopsy section shows increased numbers of megakaryocytes. **C,** A platelet thrombus is seen in a small vein of the trephine biopsy section.

Neonatal Thrombocytopenia

In newborns, thrombocytopenia caused by perinatal complications such as infection or asphyxia rarely requires bone marrow evaluation before platelet counts resolve. Severe platelet reductions in the first month of life are usually caused by alloimmunization with platelet-

specific antigens that are incompatible between mother and child. This diagnosis of neonatal alloimmune thrombocytopenia (NAIT) is best made by examination for platelet antibodies in conjunction with parental and fetal platelet genotyping demonstrating incompatibility.[191]

Thrombocytopenia Secondary to Microangiopathic Processes

Microangiopathic processes are associated with thrombocytopenia, but the anemia and red cell fragmentation (i.e., schistocytes) may not be evident until a few days after the initial clinical presentation (**Fig. 10-46**). Mechanical fragmentation of erythrocytes occurs during flow through partially occluded high-shear microvessels. The partial arteriolar and capillary occlusion results from excessive platelet deposition or the formation of thrombi in disorders such as thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS, including atypical HUS).[192,193] Although disseminated intravascular coagulation (DIC) is typically discussed alongside thrombotic microangiopathies (TMAs)—because of their similarities in causing microvascular thrombosis in association with thrombocytopenia, hemorrhagic risk, and organ failure—only DIC exhibits activation of multiple systems (i.e., coagulation cascade, fibrinolytic pathway, and platelets); only marked platelet activation is seen in TMAs.[194]

Circulating autoantibodies that inhibit ADAMTS13 or increase its clearance cause immune-mediated TTP (iTTP). The metalloproteinase ADAMTS13 regulates von Willebrand factor (vWF) multimers by cleaving ultralarge forms released by the

endothelium that induce vessel wall platelet aggregation. Severe ADAMTS13 deficiency (<10%) is characteristic of hereditary TTP, but evaluation of levels is often insensitive for treatment purposes. Any patient with microangiopathic hemolytic anemia and thrombocytopenia without apparent alternative etiology is usually treated with plasma exchange and immunosuppression, because iTTP has a 90% fatality rate without appropriate therapy.[195] Immunosuppression with corticosteroids and rituximab are initiated early in the acute stage of disease. A humanized, bivalent variable-domain-only immunoglobulin fragment of vWF (caplacizumab) has transformed acute therapy for iTTP with its ability to rapidly normalize platelet counts, lower TTP-associated mortality, and decrease the rate of recurrent TTP.[196] Caplacizumab's mechanism of action is inhibition of the interaction between the vWF multimers and platelet GPIb, thereby reducing platelet consumption and thrombus formation.

Children with HUS present with a history of bloody diarrhea secondary to Shiga toxin-producing organisms, most commonly enterotoxigenic *Escherichia coli* (O157:H7 or O104:H4) or *Shigella*. Atypical HUS is usually not associated with diarrhea, and a majority of patients have alternative complement pathway or coagulation pathway mutations.[192,193] Secondary HUS may be seen in a number of disorders (malignant hypertension, autoimmune disorders, chemotherapy, pregnancy) and should be considered part of the primary disease.

Bone marrow examination for a microangiopathic process is usually reserved for questionable diagnoses or for evaluations of an underlying immune disorder such as SLE.

Splenic Sequestration

Splenic pooling of platelets causes their displacement from peripheral circulation; the platelets are not destroyed and remain exchangeable with the peripheral pool. Therefore, megakaryocytes may not increase in number. This condition is most often seen in patients with chronic liver disease with portal hypertension and splenomegaly,[197] and it may explain in part the loss of circulating platelets in some patients with Wiskott-Aldrich syndrome.[198]

Constitutional Thrombocytopenia

Mild forms of inherited thrombocytopenia (IT) may be inconspicuous, and adults are at risk for a misdiagnosis of ITP unless blood films or previous records that show subnormal platelet counts are reviewed. An appropriate diagnosis of IT avoids unnecessary procedures and treatments, and in more severe forms of IT, can provide access to appropriate therapeutic options. With the aid of NGS studies (including whole exome sequencing and RNA profiling), investigations have identified at least 40 novel disorders affecting platelet production and/or function.[199,200] These include varying clinical presentations of disease that involve one gene (e.g., *MYH9, GP1BB, WAS*); gene mutations that increase the risk for aplastic anemia/bone marrow failure syndromes (e.g., *MPL, THPO, HOXA11*) and/or predispose to myeloid or lymphoid malignancies *(RUNX1, ANKRD26, ETV6)*[201] (see **Chapter 45** for further discussion); mutations associated with additional clinically relevant congenital defects (e.g., *GATA1, FLI1, RBM8a*); and others that present solely with thrombocytopenia (e.g., *NBEAL2, GP9, ACTN1, TUBB1, CYCS*).[200] The discovery of new mutations has debunked

long-held beliefs and led to paradigm shifts about ITs: they are more frequent; most have mild-to-moderate thrombocytopenia; and most patients will have little-to-no bleeding tendency. In an Italian cohort, the six most common ITs (namely, Bernard Soulier syndrome [BSS], *MYH9*-related disease [*MYH9*-RD], *ANKDR26*-related thrombocytopenia [*ANKDR26*-RT], *ACTN1*-RT, *TUBB1*-RT, *CYCS*-RT) account for 75% of ITs and are not associated with severe bleeding diatheses.[200]

Review of the blood film for platelet size, compared with RBCs, helps in the diagnosis.[202] Giant platelets are seen in *MYH9*-RD (**Fig. 10-47**) and BSS (biallelic forms) (**Fig. 10-48**). Large platelets are found in *NBEAL2*-mutated gray platelet syndrome (**Fig. 10-49**), BSS (monoallelic forms), Paris-Trousseau syndrome, and multiple rare ITs with varying mutations (i.e., *TUBB1, FLNA, GFI1b, ITBA2B/B3, ACTN1, GATA1*).[203,204] Normal-sized platelets are present in congenital amegakaryocytic thrombocytopenia (CAMT), thrombocytopenia with absent radii (TAR), and radioulnar synostosis with amegakaryocytic thrombocytopenia. Smaller-than-normal platelets are associated with Wiskott-Aldrich syndrome and congenital autosomal recessive small platelet-thrombocytopenia (CARST) (**Table 10-8**).[199,203,204] Only a minor subset of the ever-growing list of ITs with normal-to-increased megakaryocytes is included in **Table 10-10**. Four disorders previously thought to be distinct (May-Hegglin anomaly, Sebastian, Fechtner, and Epstein syndromes) are now collectively termed *MYH9*-RD, as it became apparent that these different clinical manifestations represent the same disease.[205] Neutrophil inclusions with clumps of MYH9 protein (round or spindle shaped) help identify this disorder (**Fig.**

10-47). Additional abnormalities seen on blood films include pale, agranular platelets in gray platelet syndrome; vacuolated platelets and red cell anisocytosis in *GATA1*-related diseases; and stomatocytosis in sitosterolemia (i.e., hypercholesterolemia caused by aberrant accumulation of plant sterols, leading to premature atherosclerosis) with *ABCG5* or *ABCG8* mutations. A number of congenital platelet disorders (e.g., Glanzmann thrombasthenia) are caused by qualitative defects in platelets in the absence of thrombocytopenia.[204]

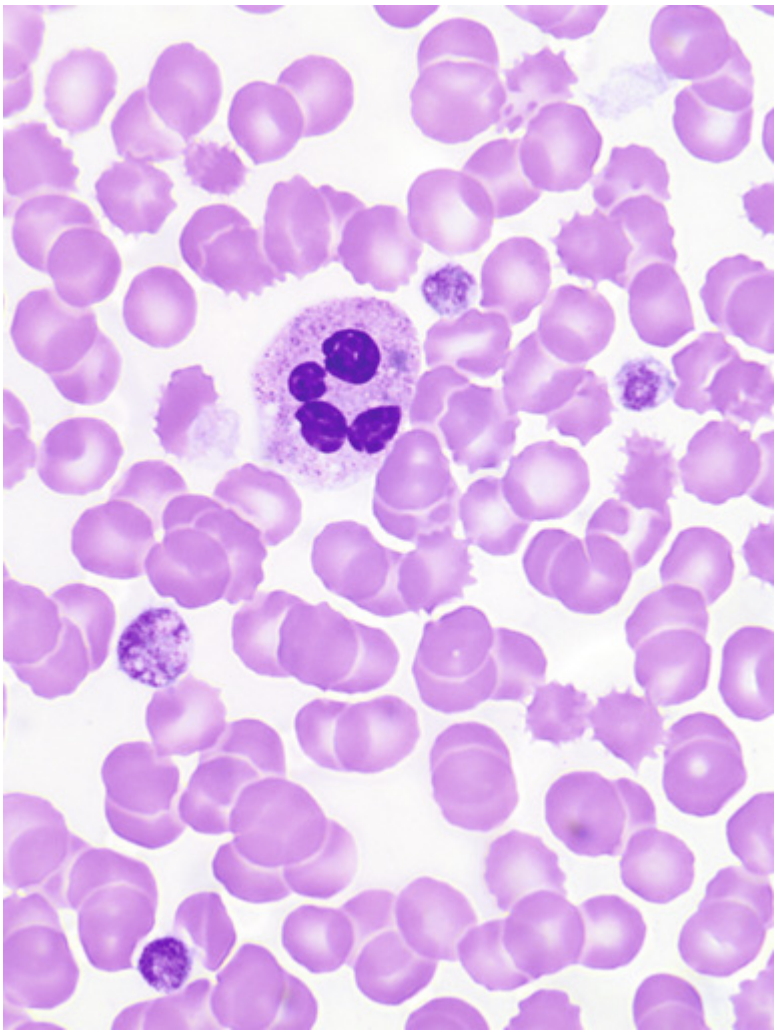

FIGURE 10-47 *MYH9*-related disease is characterized by large platelets and blue, round or crescent-shaped cytoplasmic deposits of MYH9 protein (May-Hegglin anomaly).Superficially, they resemble Dohle bodies seen in infection.

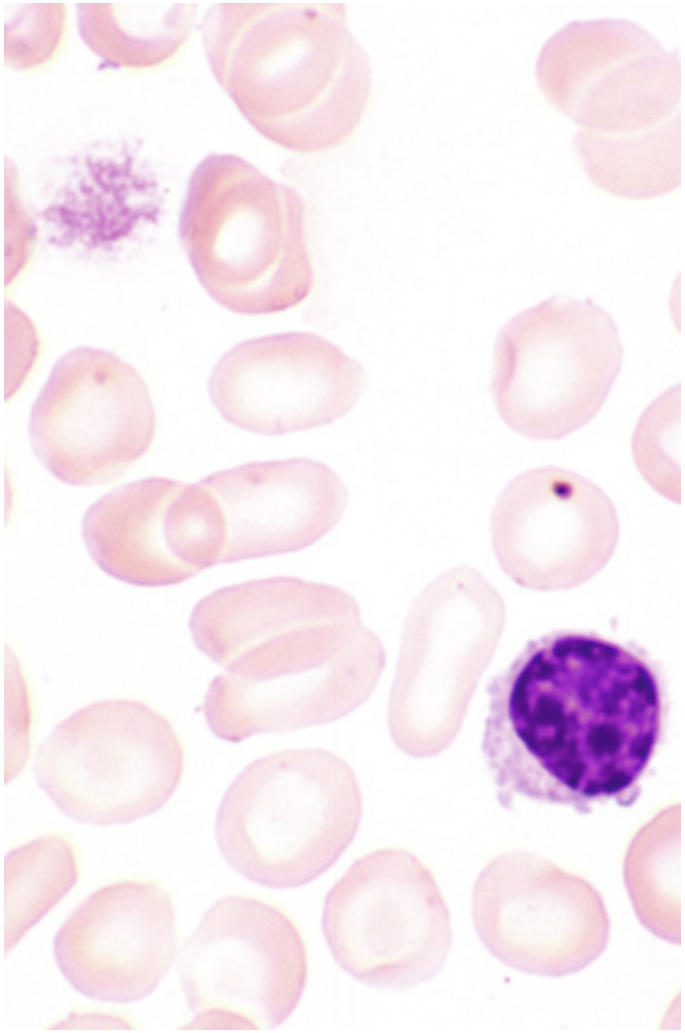

FIGURE 10-48 Peripheral blood smear of Bernard-Soulier syndrome.The large platelets in this disorder have absent or dysfunctional glycoprotein Ib-IX-V receptors. The patient also has β-thalassemia minor.

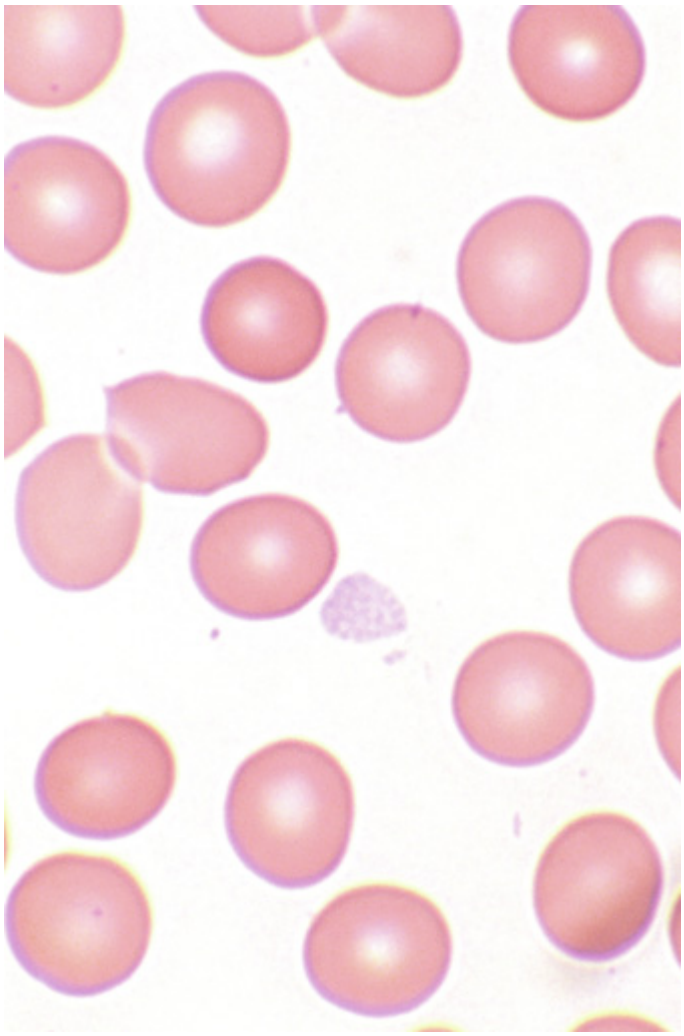

FIGURE 10-49 Peripheral blood smear of gray platelet syndrome.The large platelet is agranular as a result of the absence of α granules.

EVALUATION OF SPECIFIC BONE MARROW FAILURE SYNDROMES

Bone marrow hypoplasia involving more than one lineage, also termed *bone marrow failure,* is discussed in this section and includes congenital disorders, acquired aplastic anemia (AA) and PNH (**Table 10-11**). Acquired multilineage cytopenias may also be

caused by nutritional deficiencies (copper, vitamin B_{12}, folate), drug reactions, toxic effects (alcohol), and infections (especially viral); these are discussed in other sections of this chapter.

Select Acquired and Constitutional Bone Marrow Failure Syndromes

Paroxysmal Nocturnal Hemoglobinuria

PNH is a disease of hematopoietic stem cells that have acquired a somatic mutation in the phosphatidylinositol glycan class A *(PIG-A)* gene.[206] These cells have a growth or survival advantage over normal hematopoietic stem cells during immune-mediated bone marrow injury, with further genetic or epigenetic events enhancing their clonal proliferation. The progeny of PNH stem cells have reduced or absent glycosylphosphatidylinositol-anchored proteins (GPI-AP). More than 20 GPI-APs are expressed by hematopoietic cells and include important complement regulatory proteins such as CD55 and CD59 on erythrocytes. Flow cytometric analysis to detect the loss of these GPI-APs or a fluorescein-labeled proaerolysin variant (FLAER) that binds to the GPI anchor is diagnostic (**Fig. 10-50**).[207] The International PNH Interest Group subcategorized the disorder based on the size of the mutant clone and clinical findings into: (1) classical PNH (hemolysis and/or thrombosis), (2) PNH associated with AA or MDS, and (3) subclinical PNH with no clinical or laboratory evidence of hemolysis or thrombosis (PNH clone usually <1%).[208] The anticomplement 5 (C5) mAbs eculizumab and ravulizumab are approved to treat classical PNH.[209]

Aplastic Anemia

AA is an acquired immune-mediated disorder of variable severity with predisposing genetic and environmental factors that trigger disease.[210] Acquired AA is multifactorial in etiology but is most commonly idiopathic. Patients present with symptoms of anemia or with bleeding and are found to be pancytopenic with hypocellular bone marrows. Severe AA is characterized by a markedly hypocellular bone marrow (<25% of normal for age or 25% to 50% of normal with <30% hematopoietic cells) accompanied by two of the following: neutrophils $<0.5 \times 10^9$/L; platelets $<20 \times 10^9$/L; or reticulocyte count $<20 \times 10^9$/L (**Fig. 10-51**).[211] Very serious disease is particularly ominous and further defined by neutrophils $<0.2 \times 10^9$/L with low bone marrow myeloid reserves; consequently, infection is the major cause of death in these patients.[212] AA is thought to be caused by diminished self-renewal and repopulation capacity of hematopoietic stem cells.[213] T-cell–targeted apoptosis of CD34-positive stem cells and aberrant T-cell activation likely play a role through cytokine-mediated suppression and triggering of immune response pathways. Telomere length may be decreased as a result of increased mitotic demand on a limited pool of stem cells.[213]

AA is considered a non-neoplastic hematologic disorder, yet somatic mutations are common, with clonal hematopoiesis observed in more than 70% of patients.[210] Mutations typically are seen within 6 months of immunosuppressive therapy but can also be present at diagnosis. The most common somatic mutations are found in *PIG-A* and *HLA*. Other mutations are frequently seen in *BCOR, BCORL, DNMT3A,* and *ASXL1*. These findings may create diagnostic uncertainty and raise the possibility of refractory cytopenia of childhood (RCC) and hypoplastic MDS (hMDS) in all ages.[214,215]

Although morphologic criteria have been proposed to distinguish AA from myeloid neoplasia (or to predict risk of malignant transformation in AA) in adults[216] and pediatric patients,[215,217] subsequent studies demonstrate interobserver variability and the challenge in distinguishing these entities[218,219] (**Chapter 44** and **Chapter 45**). Megakaryocytic or granulocytic dysplasia, an increase in blasts, and MDS-defining cytogenetic abnormalities (such as monosomy 7) are not characteristic of AA and may be helpful in differentiating between AA and hMDS.[210,214,215] Given that 15% to 20% of patients with AA develop MDS/AML by 10 years of follow-up, periodic bone marrow surveillance (for dysplasia, increased CD34-positive cells, or progressive karyotypic abnormalities) is essential. Increased disease duration, older age, relapsed/refractory disease, accelerated telomere attrition, and certain genetic alterations have been associated with increased risk of progression to MDS or AML.[210]

Severe AA requires immunosuppressive therapy or hematopoietic cell transplantation to stop the immune-mediated destruction. Small PNH clones in 50% to 60% of patients with AA have been associated with better responsiveness to immunosuppressive therapy in some studies. An erythrocyte PNH clone size of 3% to 5% and a granulocyte PNH clone size of 20% to 25% best predict development of clinical PNH in these patients.[220]

Table 10-11

AA, Aplastic anemia; *AD,* autosomal dominant; *AML,* acute myeloid leukemia; *AR,* autosomal recessive; *FA,* Fanconi anemia; *GPI-AP,* glycosylphosphatidylinositol-anchored protein; *MDS,* myelodysplastic syndrome/neoplasm; *PMN,* polymorphonuclear neutrophil; *PNH,* paroxysmal nocturnal hemoglobinuria; *RBC,* red blood cell; *XL,* X-linked.

Approximately 25% of children and up to 10% of adults with AA have inherited bone marrow failure syndromes. Pancytopenia is the usual presentation for patients with Fanconi anemia or dyskeratosis congenita. The other congenital syndromes more commonly present with anemia (DBA), neutropenia (SCN, Kostmann syndrome, SDS), or thrombocytopenia (thrombocytopenia with absent radii, congenital amegakaryocytic thrombocytopenia), and they tend to remain single-lineage disorders (Tables **10-6** to **10-8 and 10-10**).

In addition to Fanconi anemia and dyskeratosis congenita, patients with SDS and CAMT develop secondary AA; these patients have an increased risk for progression to MDS or AML.

Fanconi Anemia

Fanconi anemia is the most prevalent of the constitutional syndromes and presents as AA in the first decade of life in 90% of cases.[221] Up to 25% of young patients diagnosed with Fanconi anemia have no discernible physical abnormalities.[222] Chromosome fragility testing of blood lymphocytes remains a useful diagnostic test, alongside sequencing for Fanconi anemia genes. Chromosomal fragility testing quantifies chromosomal breakage in Fanconi anemia cells with increased hypersensitivity to DNA cross-linking agents

(e.g., diepoxybutane, mitomycin). The hypersensitivity results in frequent chromosomal abnormalities, which may wax and wane, and difficulty tolerating therapeutic alkylating agents.[223] Excessive cellular apoptosis and consequent malfunction of stem cells lead to progressive bone marrow failure.[224] It has been speculated that *MYC* overexpression impairs stem cell function and contributes to bone marrow exhaustion.[225] Mutations in 22 different genes of the Fanconi anemia pathway have been identified.[226] This pathway functions as a DNA damage sensor and repair initiator and regulates oxidative stress. Stem cell transplantation has raised the life expectancy for patients with Fanconi anemia; however, the timing of transplantation is critical, as the development of solid tumors remains a significant problem.[227]

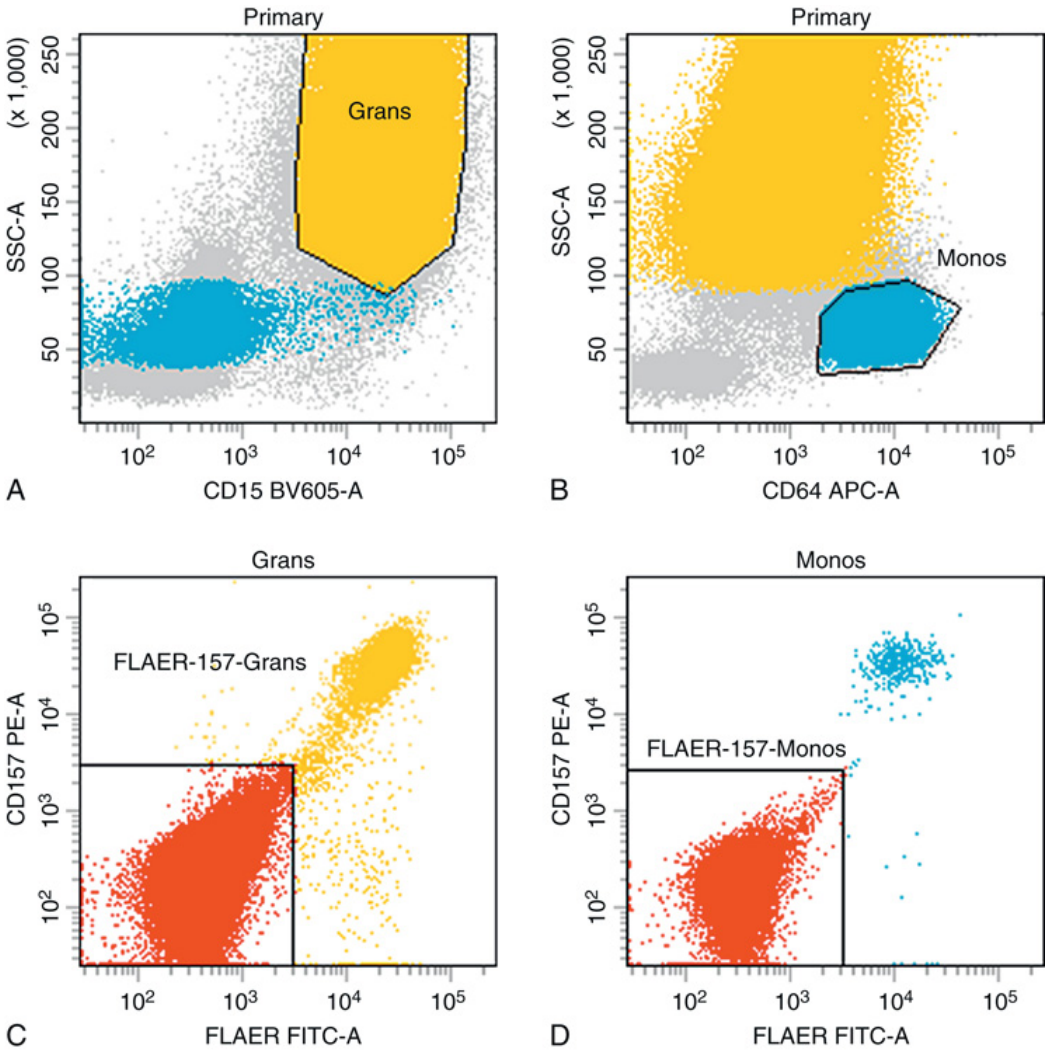

FIGURE 10-50 **A** and **B,** Granulocytes *(yellow)* and monocytes *(blue)* are identified by gating with CD15 and CD64, respectively. **C** and **D,** In paroxysmal nocturnal hemoglobinuria, they fail to stain with fluorescein-labeled proaerolysin variant (FLAER) and glycosylphosphatidylinositol-anchored CD157 *(red populations)*. Significant numbers of normally expressing granulocytes and monocytes

(yellow and blue populations, respectively) are also present.

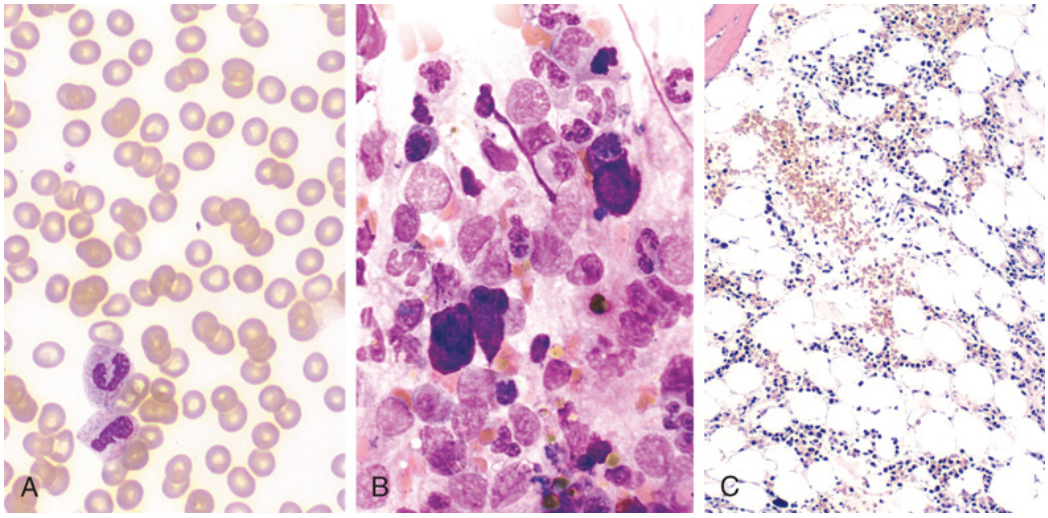

FIGURE 10-51 **A,** Pancytopenia in measles-associated aplastic anemia. Note the toxic granulation in the neutrophils. The hypocellular bone marrow smear contains numerous mast cells **(B),** and the trephine biopsy reflects subtotal aplasia **(C).**

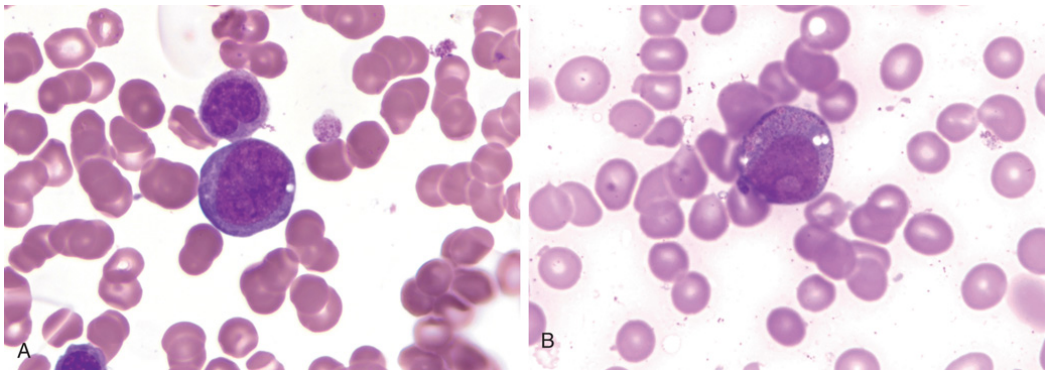

FIGURE 10-52 Bone marrow aspirate smear in VEXAS syndrome.Sharply punched-out cytoplasmic vacuoles are seen in an erythroblast **(A)** and promyelocyte **(B)**.

Dyskeratosis Congenita

Dyskeratosis congenita is a genetically heterogeneous telomere maintenance disorder.[228] Low telomerase activity leads to accelerated telomere shortening, decreased proliferative capacity among affected hematopoietic progenitors, and features of a premature aging syndrome. The age of onset, severity, and clinical manifestations vary.[228] Individuals with the classic X-linked form of disease (*DKC1* mutation) present with lacy reticular pigmentation, dysplastic nails, and oral leukoplakia. Severe childhood variants, such as Hoyeraal-Hreidarsson and Revesz syndromes, have associated cerebellar hypoplasia and developmental dysfunction. Some patients with minimal physical findings reach adulthood before diagnosis. The initial clinical presentation may be bone marrow failure, especially in patients with *TERC, TERT,* or *TIN2* mutations, and screening for short telomeres is indicated in these patients. Most boys with X-linked disease develop bone marrow

failure by 20 years of age. The estimated cumulative incidence of marrow failure is 80% by 30 years of age.

VEXAS Syndrome

VEXAS (vacuoles, E1 enzyme, X-linked autoinflammatory, somatic) syndrome is a newly recognized adult-onset, treatment-refractory, rheumatologic/bone marrow failure disorder caused by mutations of the X-linked *UBA1* gene. Patients present with a variety of progressive autoinflammatory and hematologic manifestations, including chondritis, fevers, cytopenias (especially macrocytic anemia, lymphopenia, and monocytopenia), neutrophilic dermatoses, lung involvement, thrombosis, vasculitis, and dysplastic marrow containing hallmark cytoplasmic vacuoles in myeloid and erythroid precursors.[229] A significant proportion of patients present with or develop MDS (30-50%), multiple myeloma/monoclonal gammopathy of undetermined significance (MGUS) (25%), or monoclonal B-cell lymphocytosis[230] (see **Chapter 45**).

Mutations in the ubiquitin activating enzyme-1 *(UBA1)* gene, which encodes a key ubiquitylation pathway enzyme, are found in hematopoietic myeloid and lymphoid progenitors but not in mature lymphocytes or fibroblasts.[231] Many of the autoinflammatory symptoms likely result from dysregulation of inflammation pathways disrupted by mutated myeloid cells. The disorder is rare, and its incidence has been estimated at 1/4200 men aged 50 years or older.[232]

Macrocytosis is seen in nearly all patients, and left-shifted neutrophils are found in half of all cases. The immature neutrophils often contain sharply punched-out vacuoles, and segmented

neutrophils show hypogranular and/or hypolobated (pseudo–Pelger-Huët) changes. Lymphopenia, monocytopenia, and mild-to-moderate thrombocytopenia are often present.[230]

Bone marrow aspirate smears show vacuolation in myeloid and erythroid precursors, including myeloblasts (**Fig. 10-52**). Vacuoles are not seen in lymphocytes. Megakaryocytes generally lack vacuoles, but along with myeloid and erythroid precursors show dysplastic changes. Biopsies are hypercellular with granulocytic hyperplasia and erythroid hypoplasia. Dysplastic changes in more than 10% of any cell line are only found in cases meeting the WHO MDS criteria.[230] Half of patients with MDS exhibit abnormal cytogenetics and/or molecular genetic abnormalities, including mutations in *DNM3A, GNA11, CSF1R,* and *EZH2*.[230] Cases with plasma cell dyscrasias show morphology typical for multiple myeloma or MGUS.

A limited number of disorders demonstrate prominent cytoplasmic vacuoles. These include copper, folate, and vitamin B_{12} deficiencies, acute alcohol toxicity, antibiotic therapy, MDS, and smears prepared from old EDTA-anticoagulated specimens. The constellation of autoinflammatory manifestations, macrocytic anemia, and/or myelodysplasia with associated vacuolated myeloid and erythroid precursors should prompt *UBA1* mutation analysis.

Pearls and Pitfalls

- Most isolated acquired anemias can be diagnosed based on peripheral blood smears, clinical history, physical examination, and laboratory findings.

- RBC size is extremely helpful in narrowing the differential diagnosis for hypoproliferative anemias (i.e., inadequate reticulocyte response).
- Schistocytes associated with microangiopathic processes may not be evident until a few days after the initial clinical presentation. In particular, the absence of increased schistocytes does not exclude the possibility of disseminated intravascular coagulation.
- Patients with acquired red cell aplasia need to be evaluated for parvovirus infection, recent or remote thymoma, underlying neoplasm, or lymphoproliferative disorders (particularly T-cell large granular lymphocytic leukemia).
- Iron stores may appear adequate in iron-deficient individuals who have recently received parenteral iron therapy or red cell transfusions.
- Children who develop profound pure red cell aplasia from parvovirus B19 infection should be evaluated for an underlying congenital hemolytic disorder, such as hereditary spherocytosis.
- Patients with intravascular hemolysis or cytopenias and bone marrow hypocellularity should be screened for paroxysmal nocturnal hemoglobinuria.
- Evaluation for T-cell large granular lymphocytic leukemia is recommended in cases of idiopathic red cell aplasia or in patients with autoimmune disorders who have unexplained chronic cytopenias.

- Nutritional deficiencies (cobalamin, folate, copper) may mimic myeloid neoplasms.
- Congenital disorders causing ineffective or reduced hematopoiesis are more likely to present in infancy or childhood but may not be identified until adulthood in some patients.
- Congenital dyserythropoietic anemia type II may be misdiagnosed as chronic hemolytic anemia with microspherocytes and a positive osmotic fragility test. Bone marrow evaluation is required to make the correct diagnosis.
- Only 3% to 5% of all neutrophils are present in the peripheral blood. The majority are in the bone marrow storage pool, ready to be mobilized when the need arises; thus, the adequacy and functionality of the bone marrow myeloid reserve determines the risk of infection in a neutropenic patient.
- Absolute neutrophil counts below 1500/μL (1.5×10^9/L) are a normal variation in persons of African descent and other specific ethnic groups.
- The most common form of neutropenia in adults is drug induced.
- Neonates often become neutropenic when septic; infection-related neutropenia is a common etiology of neutropenia in childhood.
- Peripheral smear evaluation for platelet clumps or satellitism is required to exclude pseudothrombocytopenia.

- Mild thrombocytopenia may be seen during pregnancy and usually resolves after delivery.
- Congenital platelet disorders should be considered in thrombocytopenic patients with increased large platelets on smear review and no hematologic findings suggestive of an associated myeloid neoplasm.
- Large platelets may be inaccurately gated and undercounted by automated hematology analyzers using an impedance method.
- Leukemic cytoplasmic tags, cryoglobulin deposits, and microspherocytic and/or red cell fragments can spuriously elevate platelet counts in automated hematology analyzers using an impedance method. Laboratory protocols (such as manual peripheral blood smear review, manual hemocytometer platelet counts, fluorescence platelet counts) should be in place to confirm automated platelet counts.
- Megakaryocytes may not be increased in individuals with thrombocytopenia secondary to splenic pooling of platelets.
- Iron should be evaluated in aspirate smears or touch preparations instead of biopsies, as acid decalcifying agents cause iron chelation.
- Clonal hematopoiesis is common in aplastic anemia and, in isolation, should not be considered evidence of myeloid neoplasia. Bone marrow features of aplastic anemia overlap those of hypocellular myelodysplastic syndrome (in all ages) and refractory cytopenia of childhood.
- Children and young adults with idiopathic aplastic anemia should be evaluated for an inherited bone marrow failure

syndrome, particularly Fanconi anemia and dyskeratosis congenita.

- Fanconi anemia may not be associated with identifiable physical abnormalities in 25% of cases.

Chapter 11: Bone Marrow Findings in Inflammatory, Infectious, and Metabolic Disorders

Giovanni Insuasti-Beltran, and Nancy S. Rosenthal

OUTLINE

REACTIVE NEUTROPHILIA

REACTIVE LYMPHOCYTOSIS

REACTIVE EOSINOPHILIA

REACTIVE BASOPHILIA

REACTIVE MONOCYTOSIS

BONE MARROW IN INFECTIOUS DISORDERS

- **Bacterial Infection**
- **Rickettsial Infection**
- **Parasitic Infection**
- **Viral Infection**

Fungal Infection

Bone Marrow Necrosis

Fever of Unknown Origin

BONE MARROW IN NON-INFECTIOUS SYSTEMIC AND INFLAMMATORY DISORDERS

Non-infectious Granuloma

Systemic Rheumatic Disease

Sarcoidosis

Alcohol Abuse

Hepatic Disease

Renal Disease

Hypothyroidism

Hyperthyroidism

CONCLUSION

This chapter addresses the peripheral blood and bone marrow response to a variety of non-malignant conditions. In inflammatory or metabolic disorders, the bone marrow findings may be consistent with the underlying disease, suggestive of a complication of the disease, or related to treatment. Although performed less commonly now because of more advanced imaging studies, a bone marrow examination may be performed to evaluate a fever of unknown origin, looking for a specific infectious cause.[1]

Reactive proliferations of leukocytes (i.e., leukocytosis) and their associated differential diagnoses are discussed first, followed by specific findings in infectious, inflammatory, and metabolic disorders.

REACTIVE NEUTROPHILIA

Neutrophilic hyperplasia is usually caused by the endogenous secretion of granulocyte-macrophage colony-stimulating factor or granulocyte colony-stimulating factor in response to inflammation. Common causes are infection, systemic rheumatic disease, and malignancy (**Box 11-1**).[2] Demargination of neutrophils into the circulating pool, and subsequent doubling of the neutrophil count, can be seen after acute stress or epinephrine administration. Corticosteroid therapy increases neutrophils in the peripheral blood because of their early release from marrow stores. Exogenous growth factor therapy may also cause a rise in the neutrophil count. It may be difficult in some cases to distinguish between reactive neutrophilic hyperplasia and a myeloproliferative process (typically chronic myeloid leukemia).[3] Morphologic findings such as a basophilia, abnormal megakaryocytes, and marrow fibrosis may be helpful, but genetic analysis may be needed to determine the diagnosis.[4]

In reactive neutrophilia, examination of the peripheral blood smear shows an increase in the absolute neutrophil count. The white blood count rarely exceeds 50×10^9/L. Circulating immature neutrophils, termed a *left shift,* are often present,[5] and morphologic abnormalities such as toxic granulation, cytoplasmic vacuolization, and Döhle bodies are seen (**Fig. 11-1**). Marrow aspirate smears show

an increased myeloid-to-erythroid ratio and, in some cases, a relative increase in myelocytes and promyelocytes. Increased cytoplasmic granularity may be noted. Marrow tissue sections may show increased cellularity, with an increased myeloid-to-erythroid ratio. Early granulocytic precursors are typically seen in paratrabecular areas. In some cases, this proliferation is so exuberant that it can be mistaken for a neoplastic process and can even mimic metastatic carcinoma (**Fig. 11-2**).

REACTIVE LYMPHOCYTOSIS

An increase in lymphoid cells in the peripheral blood is associated with a variety of underlying conditions, most commonly related to viral infections (Epstein-Barr virus [EBV], cytomegalovirus [CMV], hepatitis, human herpesvirus 6, human immunodeficiency virus [HIV]) or drug reactions,[6] but it may also be seen in stress conditions.[7,8] The latter conditions may be related to endogenous epinephrine release.[9] Rare cases of polyclonal T-cell lymphocytosis have been described in patients with thymomas.[10] The peripheral lymphocytosis secondary to infection is predominantly a T-cell reaction.[11] An increase in large granular lymphocytes may be seen after bone marrow transplantation.[12]

- Acute stress
- Obesity
- Drugs
- Epinephrine administration
- Corticosteroid therapy
- Lithium
- Smoking

Reactive marrow lymphocytosis is characterized by an increase in benign-appearing lymphocytes. The increase may or may not be associated with a peripheral lymphocytosis and may be caused by either an interstitial increase in lymphoid cells or an increase in lymphoid aggregates. Increased precursor B-lymphoid cells (hematogones) may be seen in a variety of conditions, especially in children, but they are common after chemotherapy in both adults and children (**Fig. 11-3**). These cells may be morphologically similar to lymphoblasts in B-lymphoblastic leukemia (see **Chapter 42**). Flow cytometric or immunohistochemical evaluation is helpful in distinguishing the two. The patient's age is important in determining whether lymphoid cells are increased because children normally have more lymphocytes (up to 35%) in the bone marrow.[13] In adults, the normal value for lymphocytes on the aspirate smear is approximately 6% to 25%.[14]

Persistent polyclonal B-cell lymphocytosis is a rare disorder seen primarily in young women who are often cigarette smokers (**Box 11-2**).[15,16] Patients are typically asymptomatic and rarely have lymphadenopathy or splenomegaly.[17] There is an association with human leukocyte antigen-DR7 (HLA-DR7).[18] EBV has been found in

the peripheral blood cells of rare patients, and the cells appear to have a defective CD40 activation pathway.[19,20] Increased polyclonal immunoglobulin M (IgM) is found in the serum.

The peripheral blood shows increased lymphocytes with moderate amounts of cytoplasm and bilobed nuclei (**Fig. 11-4**). These cells may be seen in the bone marrow aspirate smear and biopsy, typically in an intrasinusoidal or intravascular pattern.[21] Immunophenotypic evaluation shows a polyclonal proliferation of B cells that are often CD19-positive, CD20-positive, FMC7, IgD-positive, and CD27-positive; multiple *IGH*::*BCL2* rearrangements have been detected.[15,22] Isochromosome i(3q) with a *MECOM* gene amplification is present in some cases.[23-25] The lymphoid proliferation may persist for many years without any clinical evidence of the development of malignancy.

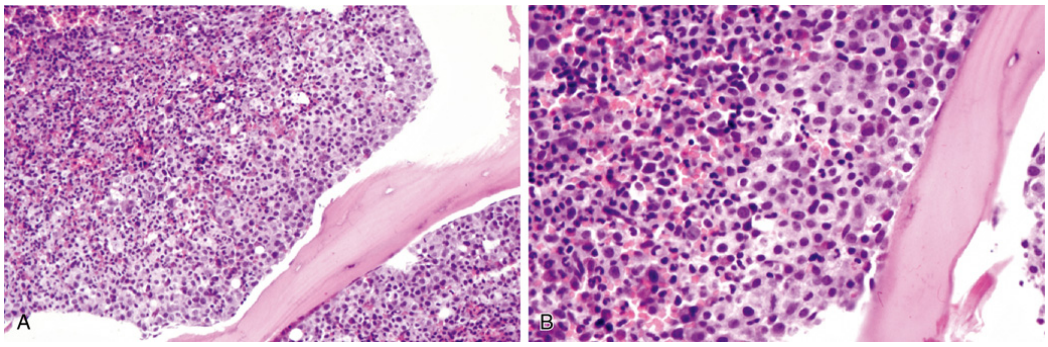

FIGURE 11-2 Paratrabecular myeloid precursors in bone marrow biopsy at low power **(A)** and high power **(B),** resembling metastatic carcinoma.

REACTIVE EOSINOPHILIA

Reactive eosinophilia is caused by a wide variety of underlying conditions (**Box 11-3**).[26-47] Mild elevations in the eosinophil count are usually because of allergic conditions; moderate eosinophilia is more common in lymphomas, rheumatoid arthritis (RA), and non-hematologic malignancies; and severe elevations are seen in parasitic infections, pulmonary eosinophilia, and clonal eosinophilic disorders.[48,49] Rarely, reactive eosinophilia has been reported as a constitutional abnormality; two of the reported patients had a chromosomal abnormality—a pericentric inversion of chromosome 10.[47]

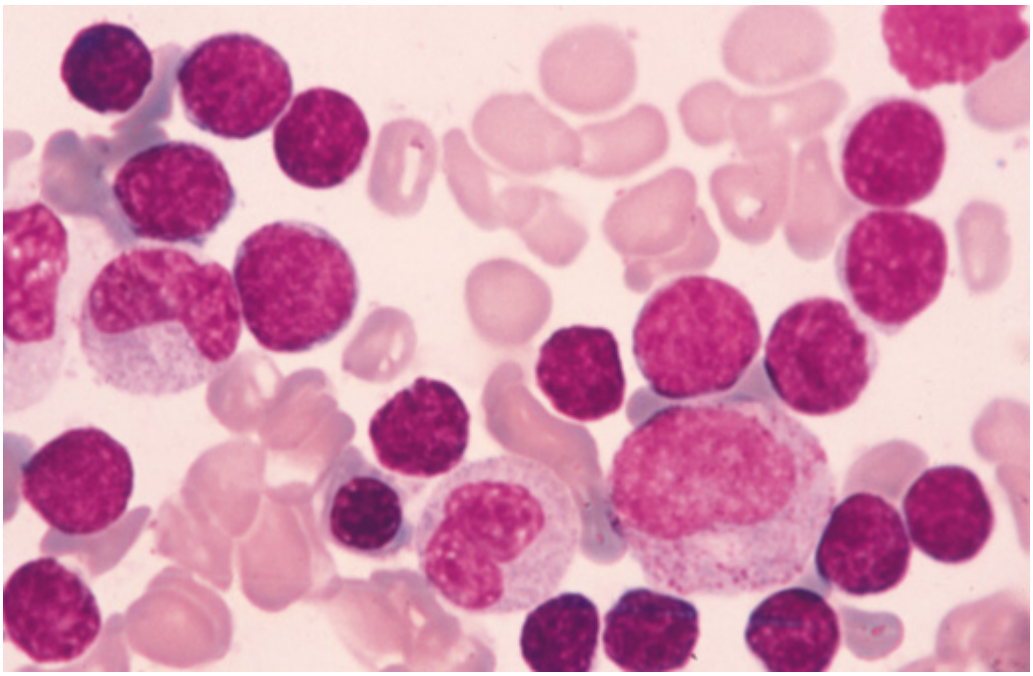

FIGURE 11-3 Precursor B cells (hematogones) in the bone marrow aspirate from a child with neutropenia.The cells have a high nuclear-to-cytoplasmic ratio, with condensed chromatin and no nucleoli.

Box 11-2 Characteristics of Persistent Polyclonal B-Cell Lymphocytosis

Clinical Findings

- Female predominance
- Age 20–40 years
- Asymptomatic
- Cigarette smoker

Laboratory Findings

- Peripheral lymphocytosis
- Bilobed lymphocytes
- Increase in polyclonal serum immunoglobulin M
- Multiple *IGH*::*BCL2* gene rearrangements
- Polyclonal immunophenotype—memory B cells
- Increased frequency of human leukocyte antigen-DR7
- Isochromosome i(3q)

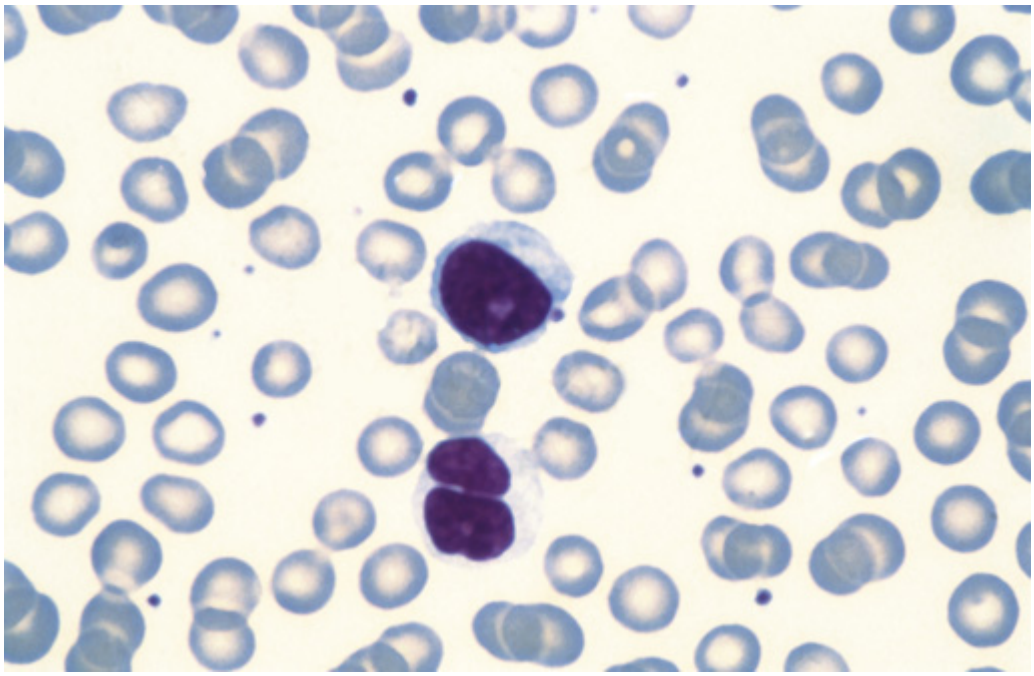

FIGURE 11-4 Polyclonal B-cell lymphocytosis in a peripheral blood smear.Atypical bilobed lymphocytes are seen. Courtesy Linda Sandhaus, MD.

In cases of reactive eosinophilia, the marrow aspirate smears show increased eosinophils and precursors, usually greater than 5% of the bone marrow nucleated cells.[50] Eosinophilic myelocytes frequently show small basophilic granules. Such myelocytes represent a normal stage of eosinophil development, and the basophilic granules likely represent eosinophil primary granules.[51] In tissue sections of the bone marrow, there is often a diffuse increase in eosinophils and precursors, but focal eosinophilia may be seen surrounding the lesions of marrow involvement by Hodgkin lymphoma, malignant lymphoma, benign lymphoid aggregates, systemic mast cell disease, and Langerhans cell histiocytosis (**Fig. 11-5**).[52,53] In these cases,

increased eosinophils may not be seen in the peripheral blood or in the aspirate smear.

A more detailed discussion of the evaluation of patients with non-neoplastic and neoplastic eosinophilia can be found in **Chapter 50**.

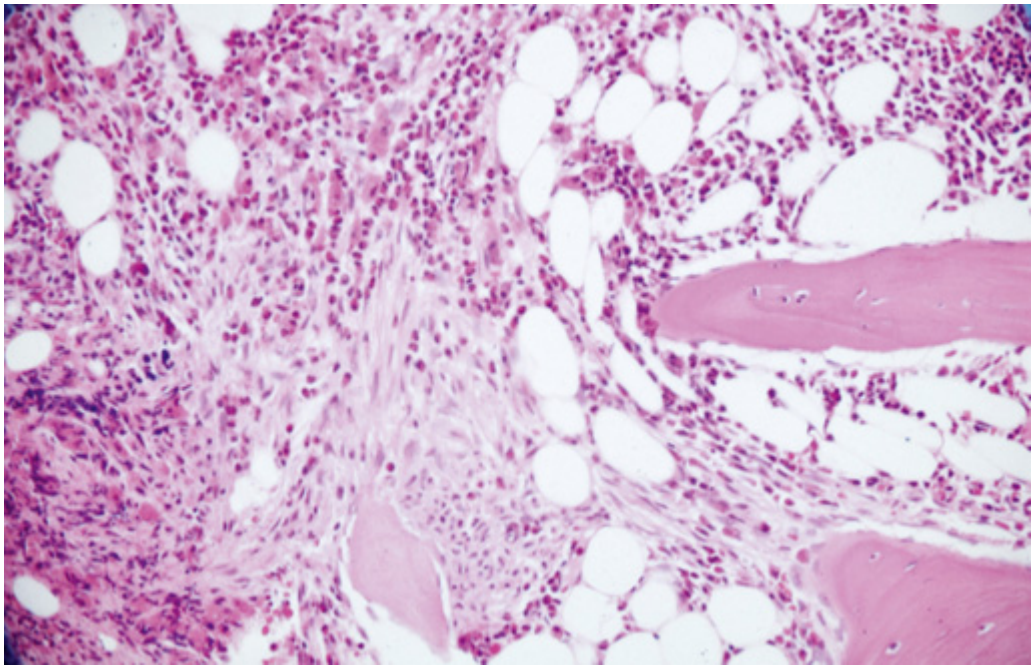

FIGURE 11-5 Increased eosinophils are seen surrounding a bone marrow lesion of systemic mastocytosis.

Box 11-3 Causes of Reactive Eosinophilia

- Atopic disorders: allergy, asthma, eczema[26-28]

- Acute myocardial infarction
- Autoimmune disorders
- Carcinoma
- Hodgkin lymphoma
- Hypothyroidism
- Neutropenia

- Splenectomy

REACTIVE BASOPHILIA

Reactive basophilia is not a common finding. In some cases, it may be seen with a reactive eosinophil proliferation. Peripheral blood findings show an absolute basophil count greater than 0.2×10^9/L. Bone marrow aspirate smears show an increase in basophils and precursors, accounting for more than 2% of cells.

Commonly associated conditions are allergies, carcinoma, chronic inflammation, malignant lymphoma, plasma cell myeloma, radiation, and renal failure.[54,55]

REACTIVE MONOCYTOSIS

A peripheral blood monocytosis is defined as a monocyte count greater than 1×10^9/L; an increased monocyte level in a bone marrow aspirate smear is often defined as greater than 3% of the differential count.[14] Associated conditions include acute and chronic inflammation, autoimmune disorders, acute myocardial infarction,[56] carcinoma,[57] hypothyroidism,[58] and splenectomy[59] (**Box 11-4**). Monocytes are also commonly increased in the presence of neutropenia after chemotherapy or because of a congenital deficiency.[60]

BONE MARROW IN INFECTIOUS DISORDERS

Bacterial Infection

Bacterial infections often cause an increase in neutrophils in the peripheral blood, with an increase in immature myeloid cells, or a left shift. Exceptions are seen in neonates and in older adult or debilitated patients who cannot mount a neutrophilic response. Morphologic changes associated with bacterial infection include toxic granulation, Döhle bodies, and cytoplasmic vacuolization. In rare cases, bacteria may be seen within neutrophils and monocytes. An increase in circulating neutrophils results in a subsequent increase in myeloid precursors in the bone marrow.

Rare bacterial infections such as pertussis may cause a lymphocytosis in the peripheral blood, which consists of predominantly CD4-positive cells (**Fig. 11-6**).[61] In children, these lymphocytes often have irregularly shaped, often clefted (i.e., cleaved) nuclei, similar to the cells seen in peripheralization of follicular lymphoma. Neutropenia may be seen with *Salmonella* or *Brucella* infections. Uncomplicated tuberculosis infection does not typically cause a change in the neutrophil count.

Red cell abnormalities are rarely seen in bacterial infections. *Mycoplasma* pneumonia can lead to the development of a cold agglutinin. Severe hemolysis can be seen in *Clostridium* infection owing to the presence of a hemolysin, phospholipase C.[62]

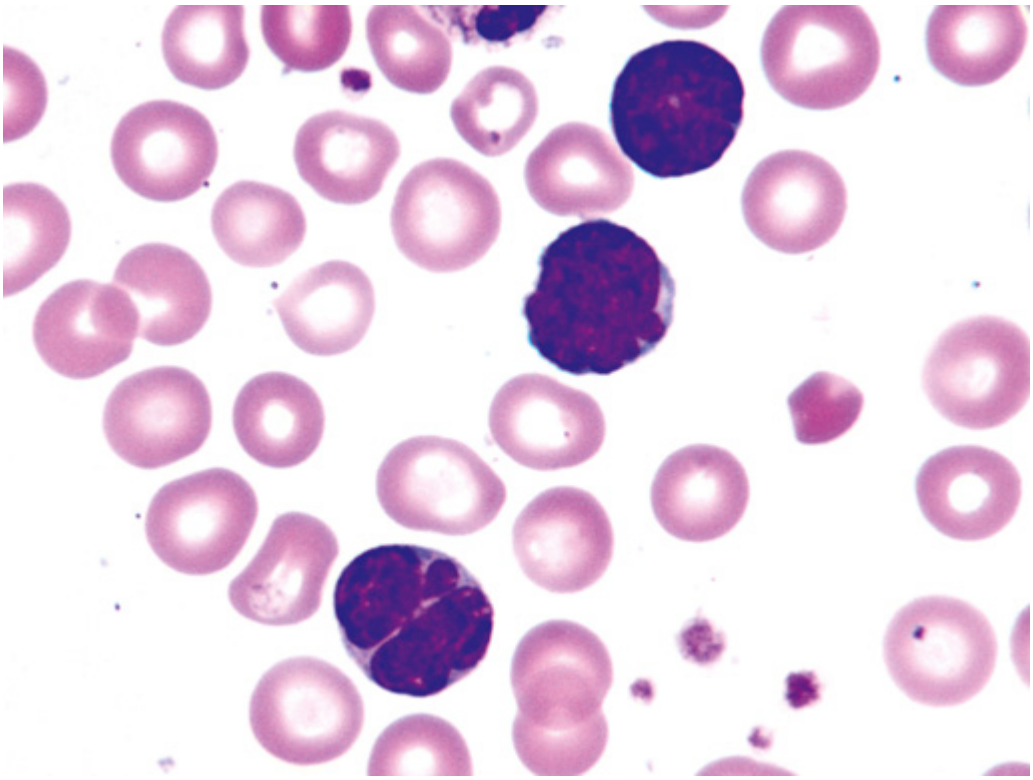

FIGURE 11-6 Small-clefted lymphocytes in the peripheral blood smear from a child with pertussis infection.

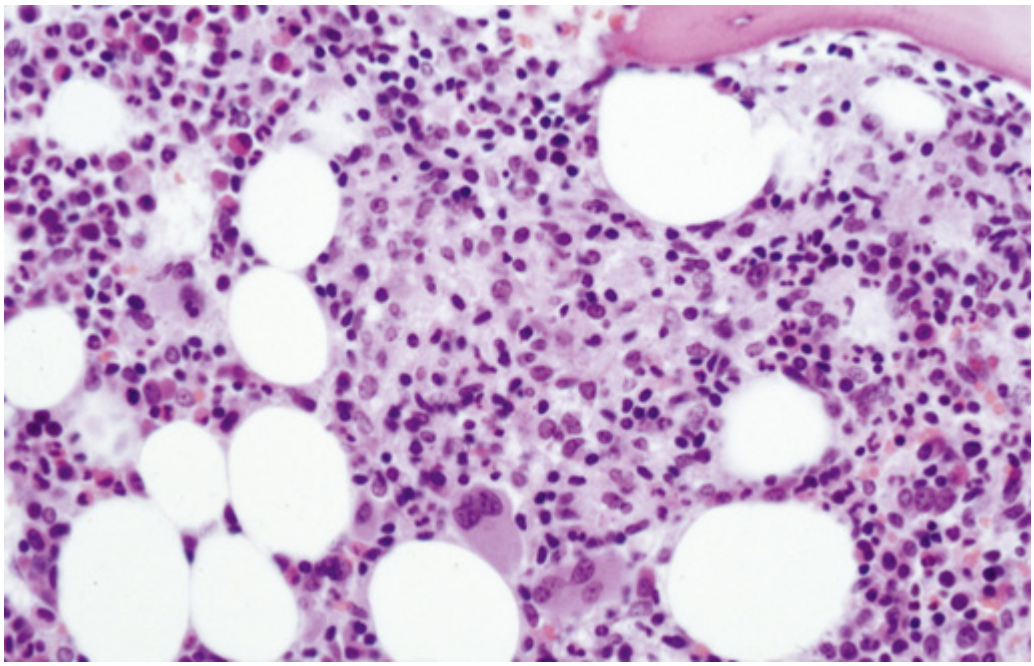

FIGURE 11-7 Non-caseating granuloma in a bone marrow core biopsy from a patient with brucellosis.

The only bacterial infections diagnosed with any frequency within the bone marrow are those caused by mycobacteria. Rare cases of infection with *Tropheryma whipplei* , the causative agent of Whipple disease, have been described.[63] Periodic acid–Schiff–positive, diastase-resistant organisms are seen within marrow macrophages. Confirmation can be accomplished by polymerase chain reaction (PCR). *Salmonella typhi* infection has been associated with pancytopenia caused by hemophagocytosis,[64,65] granulomas, ring granulomas, or bone marrow necrosis.[66] *Salmonella* organisms may be seen within neutrophils and monocytes. Bone marrow involvement by lepromatous leprosy is characterized by a proliferation of foamy histiocytes that contain the bacilli or by the presence of bacilli lying free in the marrow interstitium.[67]

Brucellosis can cause marrow granulomas, hemophagocytosis, and peripheral pancytopenia (**Fig. 11-7**).[68]

Mycobacterial infection of the bone marrow is most commonly caused by *Mycobacterium tuberculosis* or *Mycobacterium avium* complex. The incidence of the latter infection, mostly seen in severely immunosuppressed individuals, is significantly decreased with effective antiretroviral therapy for HIV infection. Rare cases of infection with other mycobacteria have been described.[69] Patients with pulmonary tuberculosis may have thrombocytosis, leukocytosis, or monocytosis.[70,71] Peripheral blood abnormalities in miliary tuberculosis include the anemia of chronic inflammation, leukopenia, thrombocytopenia, and pancytopenia. Peripheral lymphopenia or thrombocytopenia suggests marrow involvement by granulomas in *M. tuberculosis*.[72] Patients with *M. avium* complex infection may have peripheral blood abnormalities associated with an underlying HIV infection. Negatively stained linear inclusions may be seen within histiocytes on Wright-stained preparations in *M. avium* complex infection (**Fig. 11-8A–B**).[73] Granulomas can rarely be found on an aspirate smear but are typically detected on the clot section or core biopsy. Caseation within marrow granulomas is rare, but when present it is highly suggestive of infection with *M. tuberculosis*. In *M. avium* complex infection, the granulomas may not be well formed, or there may be diffuse infiltration by histiocytes. Special stains for acid-fast bacilli show rare organisms in *M. tuberculosis* (**Fig. 11-8C**); the bacilli are more easily found in cases of *M. avium* complex infection and may be numerous. Blood cultures are a more sensitive technique for detecting mycobacteria, especially in the setting of HIV infection,[74] and it has been argued that bone

marrow examination has limited value in this setting.[75] Detecting the organism with an acid-fast bacilli stain can significantly shorten the time it takes to make a diagnosis, which may have a positive clinical effect.[76] Rarely, granulomas and organisms can be found in culture-negative patients.[77]

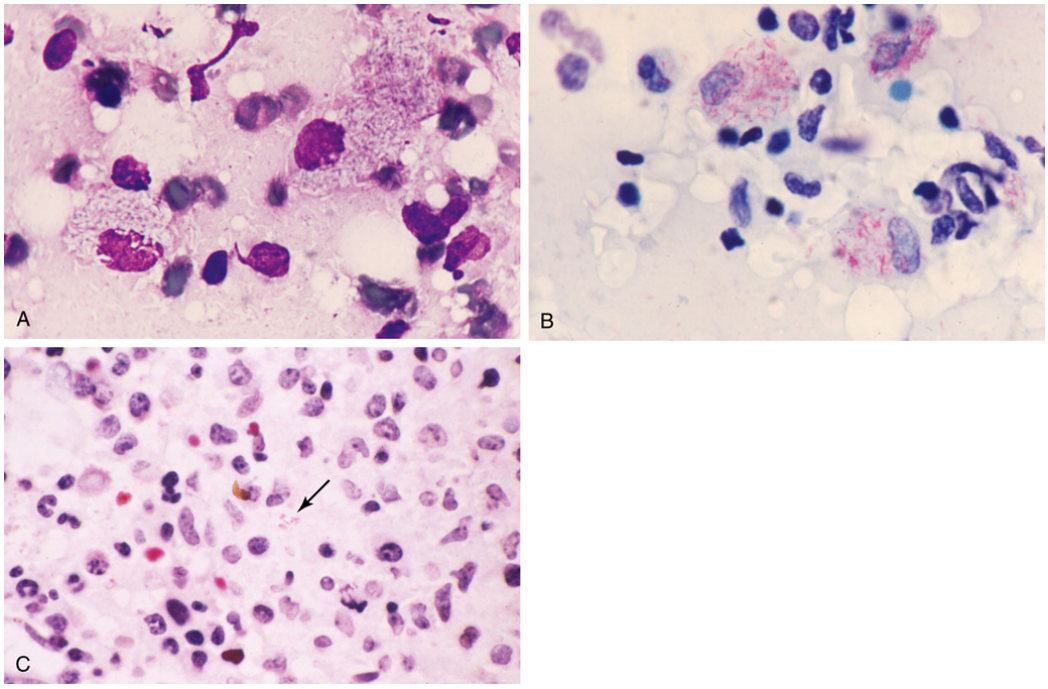

FIGURE 11-8 **A,** Touch preparation of bone marrow from an HIV patient with *Mycobacterium avium* complex infection. The histiocytes show linear, negatively stained inclusions on Wright-Giemsa stain. **B,** The inclusions in **A** are seen to be mycobacteria on the acid-fast stain. **C,** Rare *Mycobacterium tuberculosis* organisms are identified on this acid-fast stain in a granuloma from a different patient *(arrow)*.

Rickettsial Infection

Rickettsial infections, including Q fever, ehrlichiosis, and anaplasmosis are diseases caused by bacteria spread by ticks and mites. They have been diagnosed in the bone marrow and blood. Infection with *Coxiella burnetii* causes Q fever, which leads to a characteristic donut or ring granuloma in bone marrow clot sections or core biopsies. The granuloma consists of a ring of epithelioid histiocytes and neutrophils surrounding a central vacuole with an outer fibrin ring (**Fig. 11-9**).[78,79] These granulomas are not specific for Q fever and have been seen in CMV infection, Hodgkin lymphoma, EBV infection, and typhoid fever.[80]

Human ehrlichiosis and anaplasmosis are caused by infection with *Ehrlichia chaffeensis, Anaplasma phagocytophilum,* or, less commonly, *Ehrlichia ewingii*.[81] The first organism infects monocytes, and the other two infect granulocytes. Any of these infections can cause leukopenia, with a left shift, and thrombocytopenia.[82] A white blood count greater than 11×10^9/L and a platelet count greater than 300×10^9/L are associated with an extremely low yield for anaplasmosis based on PCR testing.[83] Fever and elevated hepatic transaminases may also be seen. The organisms can be identified in the peripheral blood smear, in which small clusters of darkly stained bacteria may be found rarely in monocytes or more commonly in neutrophils.[84] Bone marrow pathology has been better studied in monocytic ehrlichiosis. Granulocytic hyperplasia is common; organisms may be seen within histiocytes in the aspirate, and 67% of patients have granulomas on biopsy sections (**Fig. 11-10**).[85] The bone marrow in patients infected with *Anaplasma* is either normocellular or hypercellular, with rare

infected cells present.[86] Lymphoid aggregates, plasmacytosis, and erythrophagocytosis may be seen.[87] PCR testing of peripheral blood will confirm the diagnosis.[88]

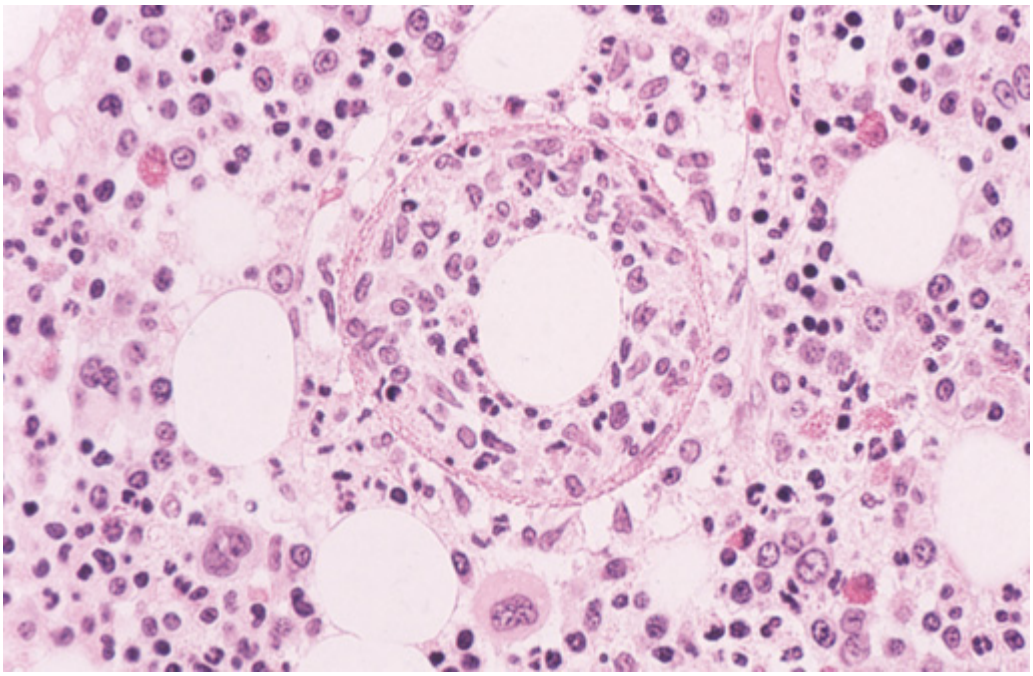

FIGURE 11-9 Fibrin ring granuloma on a bone marrow core biopsy from a patient with Q fever.

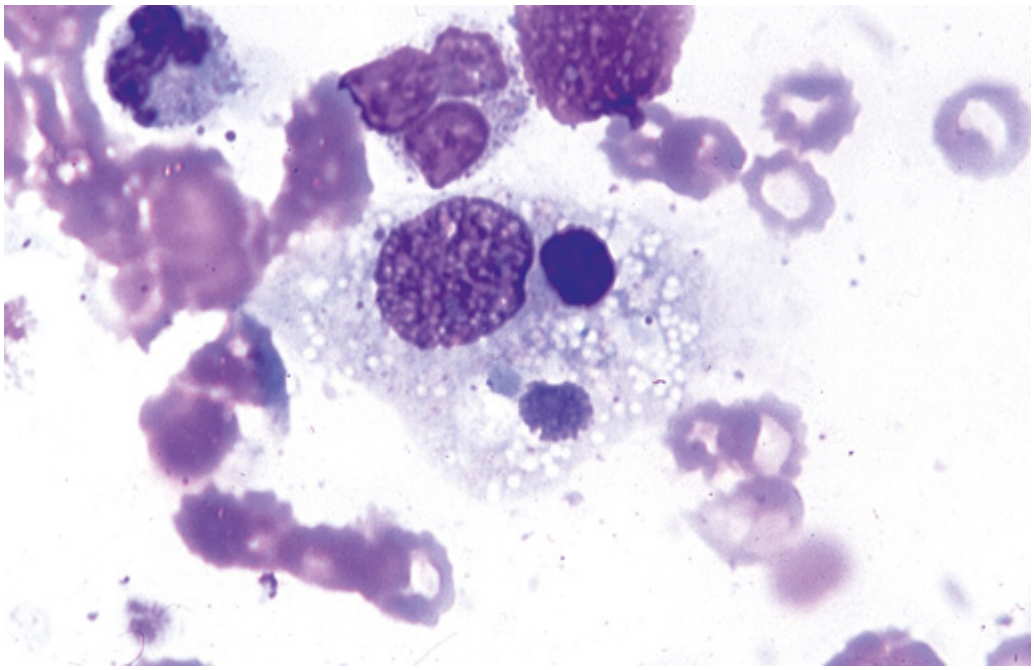

FIGURE 11-10 Bone marrow aspirate smear showing ehrlichiosis.The organisms are contained within histiocytes.

Parasitic Infection

Infections with tissue-invasive parasites result in an increased eosinophil count in the peripheral blood and bone marrow. *Toxoplasma gondii* pseudocysts have been seen in association with bone marrow necrosis in patients with HIV infection.[89]

Leishmaniasis is a severe disease caused by *Leishmania* species found in endemic areas, but it is also an opportunistic infection in immunocompromised individuals, including those with HIV infection or organ transplantation.[90,91] Clinical findings include fever, hepatosplenomegaly, and pancytopenia. A reactive increase in plasma cells is seen on the aspirate smear. Leishman-Donovan bodies can be seen within macrophages in patients with

leishmaniasis. Granulomas may be seen on the core biopsy or clot section. The amastigotes are typically visible within histiocytes. The cytoplasm of the amastigote stains blue, with a red nucleus and a rod-shaped kinetoplast.[92]

Viral Infection

Cytomegalovirus

CMV is a DNA virus that is a member of the herpes family. Acute CMV infection may be associated with a proliferation of reactive lymphocytes in the peripheral blood, similar to those seen with infectious mononucleosis caused by EBV infection (**Fig. 11-11**).[93] In rare cases, CMV-infected cells with abundant cytoplasm and nuclear inclusions may be seen in the peripheral blood.[94] These cells are most easily seen in the feathered edge of the blood smear. Other peripheral blood findings include hemolysis, neutropenia, and thrombocytopenia.[95-97]

Bone marrow biopsy abnormalities include granulomas or ring granulomas.[98] Rarely, large intranuclear inclusions can be seen in endothelial cells (**Fig. 11-12**). A myeloid maturation arrest leading to neutropenia can also be seen on the aspirate smear. CMV is one of the causes of hemophagocytic syndrome.

In infants, either congenital or acquired CMV infection can mimic some or most of the clinical features of juvenile myelomonocytic leukemia (JMML).[99] Genetic evaluation for RAS pathway, NF1 or PTPN11 mutations, or monosomy 7 may be required for a definitive final diagnosis of JMML.[100] CMV infection has also been reported to mimic myelodysplasia in adults who present with thrombocytopenia.[101] CMV infections can be seen in patients

infected with HIV. Rare intranuclear inclusions may be present, but no other specific findings can be attributed to CMV infection. CMV infection after stem cell transplantation can lead to delayed engraftment, especially with respect to recovery of platelet counts.[102] Similar bone marrow suppression can be seen with human herpesvirus 6 infection.[103]

Epstein-Barr Virus

EBV infection causes peripheral blood and bone marrow abnormalities. The most characteristic finding in the peripheral blood in patients with infectious mononucleosis is an absolute lymphocytosis with many reactive appearing lymphocytes. These are usually larger than normal and a proportion of them may display one or more prominent nucleoli and abundant deeply basophilic cytoplasm. Older patients often have fewer reactive lymphocytes in the peripheral blood.[104] Immunophenotypically, the circulating lymphoid cells are predominantly CD8-positive T cells.[105] Apoptosis of lymphoid cells is also a frequent finding (**Fig. 11-13A–C**).[106] In addition to exhibiting lymphocytosis, patients may be anemic or thrombocytopenic. In rare patients with EBV infection, hemolytic anemia develops because of a cold agglutinin. If the patient develops hemophagocytic syndrome or bone marrow suppression secondary to EBV, pancytopenia may be present. Rare cases of atypical myelomonocytic proliferations have been seen secondary to EBV infection; this in young children may be clinically confused with JMML.[107] Aplastic anemia has also been described as a sequela of EBV infection.[108,109]

EBV is associated with malignant lymphoid proliferations, including Burkitt lymphoma, lymphomatoid granulomatosis, and immunodeficiency lymphoproliferative disorders, which are discussed in other chapters.

Studies to determine whether a patient has EBV infection should be performed on the peripheral blood. A monospot test for the detection of heterophil antibodies that become positive during the second week of illness, may be used to confirm the diagnosis. This test is more likely to be negative in young children and older adults, owing to the limited production of heterophil antibodies in these age ranges. If the monospot test is negative and the clinical picture is consistent with mononucleosis, additional tests for specific viral antibodies directed against viral capsid antigen, early antigen, and Epstein-Barr nuclear antigen should be performed.

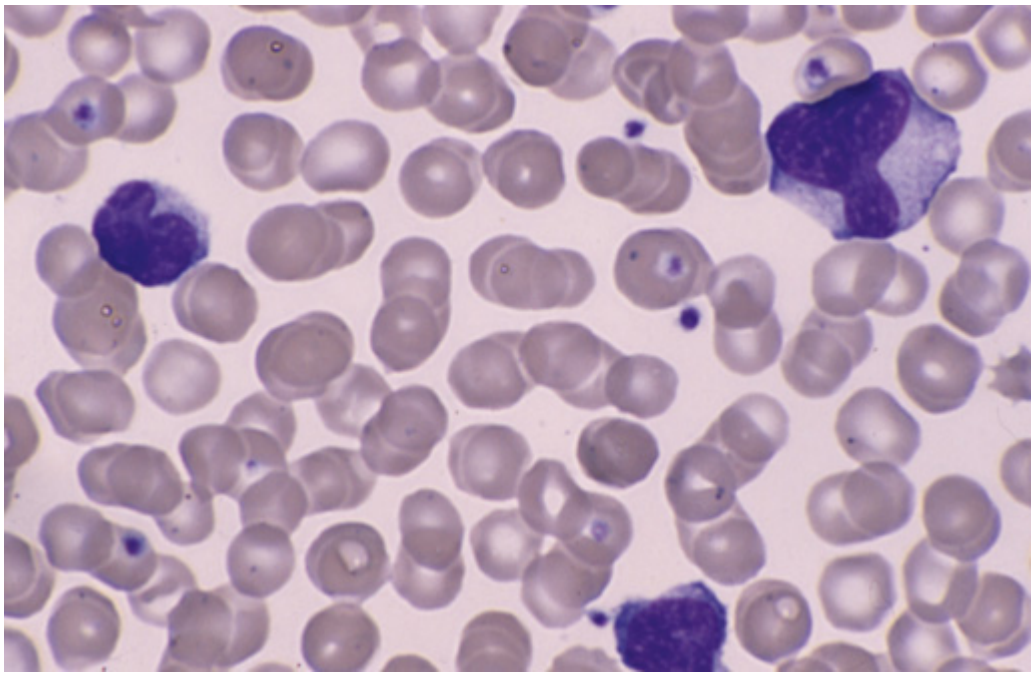

FIGURE 11-11 Peripheral blood smear showing reactive lymphocytes from a patient with cytomegalovirus infection.

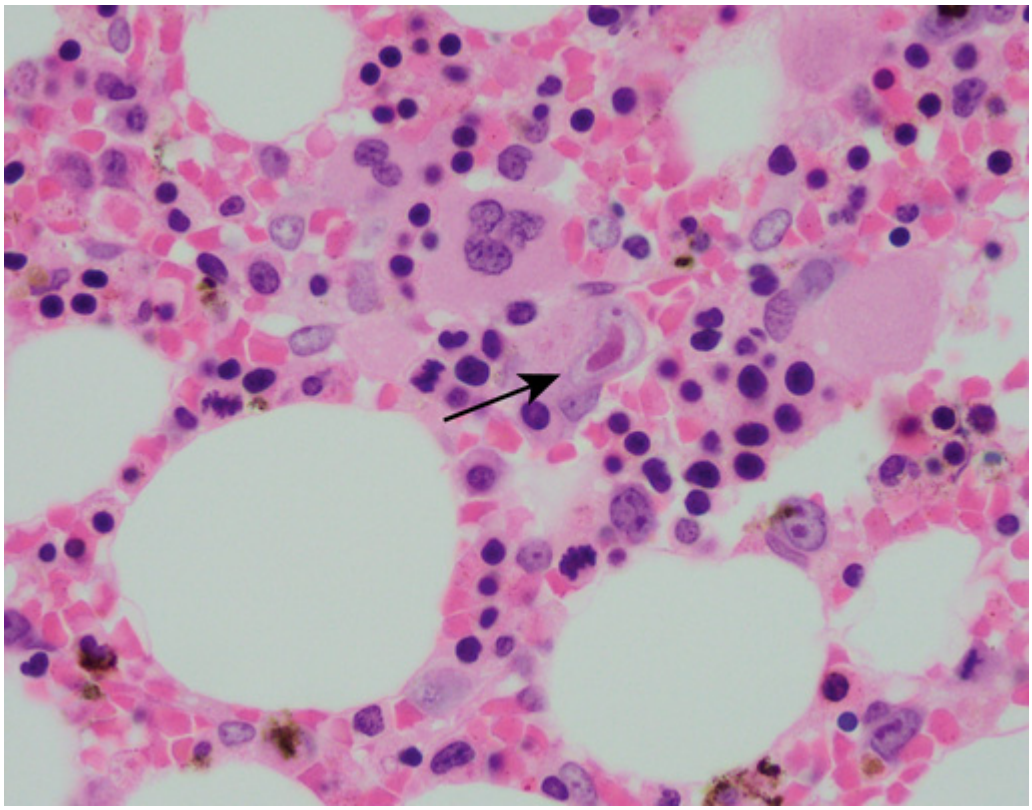

FIGURE 11-12 Bone marrow core biopsy showing a large eosinophilic cytomegalovirus inclusion *(arrow)*.

Bone marrow examinations are generally not done in patients with infectious mononucleosis; however, when bone marrow biopsies have been performed, benign lymphoid aggregates and non-caseating granulomas without giant cells have been described.[110] In situ hybridization studies for EBV-encoded RNA (EBER) may be performed on biopsy tissue to substantiate the diagnosis (see **Fig. 11-13D–E**). Marrow aplasia and hemophagocytic histiocytes are seen if aplastic anemia or hemophagocytic syndrome complicates acute EBV infection.

Human Immunodeficiency Virus

Numerous hematologic abnormalities have been described in patients with HIV infection including anemia, granulocytopenia, lymphopenia, and thrombocytopenia.[111] These abnormalities have been lessened with the advent of highly active retroviral therapy (HAART).[112] The anemia is typically caused by chronic disease but may also be caused by infection, nutritional deficiency, medication, or malignancy.[113] Thrombocytopenia can be because of medications, thrombotic microangiopathy, or immune causes. The degree of neutropenia is related to the severity of the disease. Circulating reactive lymphocytes may be seen at any time during the course of the disease.

Bone marrow features include hypercellularity, serous fat atrophy, lymphoid aggregates, reactive plasmacytosis, eosinophilia, megakaryocytic abnormalities including increased megakaryocyte apoptosis (manifested as naked nuclei), and increased iron stores (**Fig. 11-14**). Giant pronormoblasts may be seen in parvovirus B19 infection. Granulomas and involvement by lymphoma may also be seen. Stains for acid-fast bacilli and fungi should be performed in all patients regardless of the presence of granulomas; however, the presence of infection has decreased substantially.[114]

Hepatitis

Acute viral hepatitis may be associated with reactive lymphocytosis in the peripheral blood. Hepatitis A, B, C, D, E, and G have been associated with the development of aplastic anemia.[115] Patients with hepatitis C develop a variety of hematologic complications, including monoclonal gammopathies and cryoglobulinemia; they also have an increased risk for low-grade lymphoproliferative disorders.[116] Type

II mixed cryoglobulinemia has been associated with atypical lymphoid aggregates in the bone marrow. These aggregates often consist of monomorphic small lymphocytes and may be paratrabecular in location (**Fig. 11-15**).[117] Immunophenotyping reveals the cells to be B cells that express BCL2, and they may show light chain restriction. Molecular analysis shows an oligoclonal expansion of B cells in many cases. Care should be taken in diagnosing lymphomatous involvement in the bone marrow in the absence of other clinical or molecular evidence of lymphoma.[118]

Hantavirus

Hantavirus pulmonary syndrome was first described in 1993 in the southwestern United States. The infection is caused by Sin Nombre virus.[119] In the prodromal phase, thrombocytopenia is the only finding.[120] The peripheral blood findings that accompany the pulmonary leak syndrome are thrombocytopenia, hemoconcentration, leukocytosis with a left shift, and lymphopenia with more than 10% immunoblasts. Immunoblasts may also be seen in the bone marrow.[121]

Parvovirus B19

The bone marrow findings associated with parvovirus B19 are found in Chapter 11.

COVID-19

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is the causative organism of the coronavirus disease 2019 (COVID-19) pandemic, a disease with a broad spectrum of clinical presentations and severity.[122] Aside from the well-known pulmonary

manifestations, a variety of hematologic findings have been described in patients affected by COVID-19, including increased risk for thrombotic events (at both major and micro vascular levels) and changes in CBC parameters.[123] The latter include thrombocytopenia, apoptosis-mediated lymphopenia, and neutrophilia.[124] These quantitative alterations are more commonly seen in severely affected patients. Important morphologic changes described range from increased monocyte vacuolization and expansion of atypical lymphocytes in initial stages or mild disease; more severe or advanced disease has been associated with loss of these changes in the setting of increased neutrophilia and left-shifted maturation.[125]

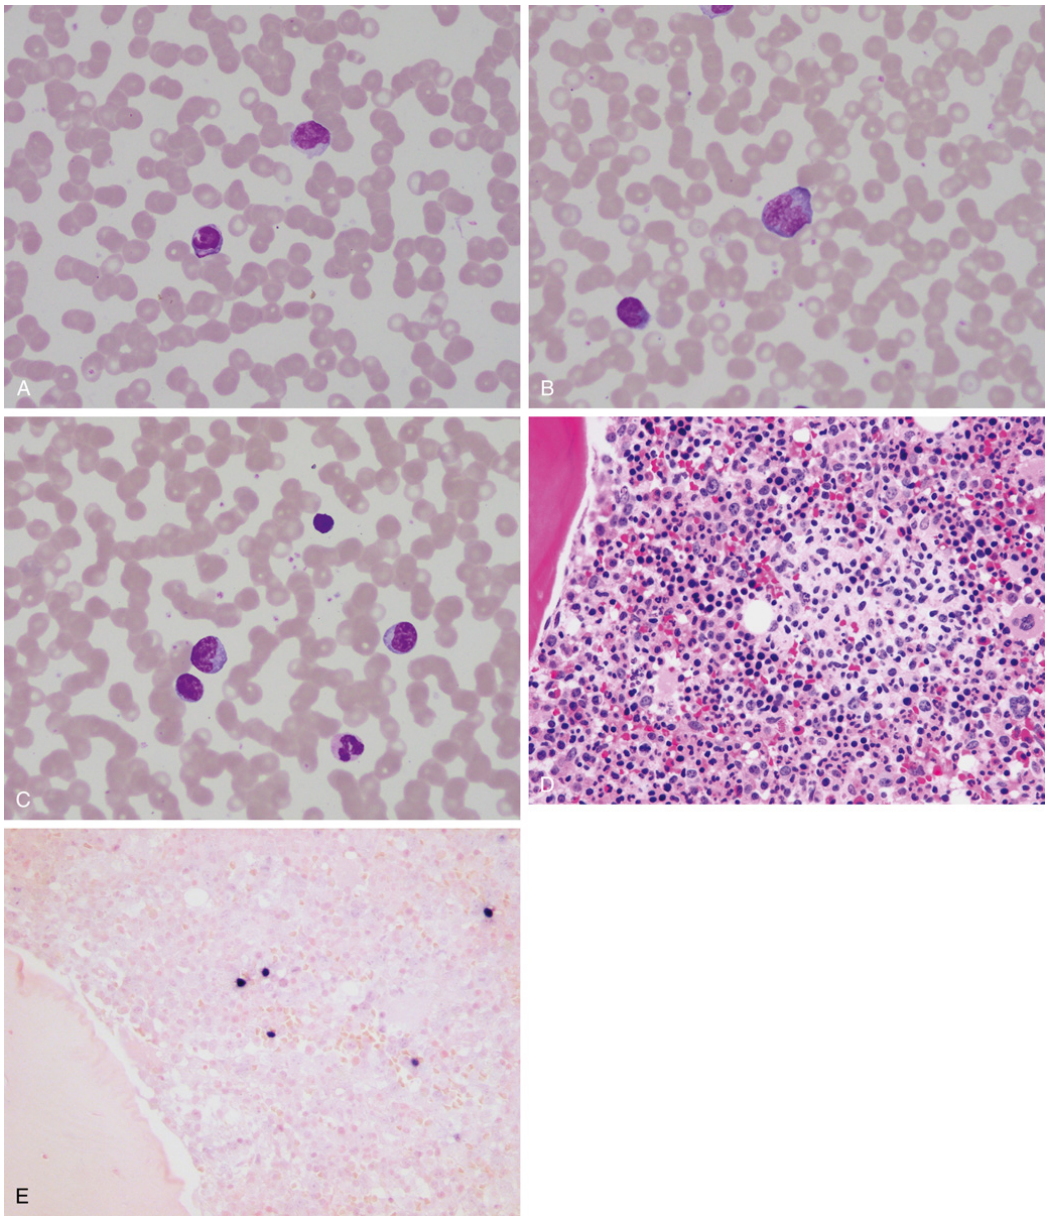

FIGURE 11-13 **A–C,** Peripheral blood smear showing reactive lymphocytes and apoptotic cells from a patient with infectious mononucleosis caused by Epstein-Barr virus infection. **D** and **E,** Bone marrow from the same patient shows small, ill-defined histiocytic-lymphocytic aggregates. In

situ hybridization for EBER1 shows several scattered hybridization signals.

Fungal Infection

Fungal infections of the bone marrow are most often caused by *Histoplasma* or *Cryptococcus*[126] and are most common in patients with underlying immunodeficiencies.[127] Other fungal infections such as coccidioidomycosis, blastomycosis, and aspergillus have rarely been described. In patients with histoplasmosis, peripheral blood findings may include anemia, thrombocytopenia, and leukopenia. In disseminated infection, fungemia may be present, and *Histoplasma* organisms can be seen in circulating monocytes or neutrophils (**Fig. 11-16A**). Hemophagocytic syndrome has been described in HIV patients with disseminated histoplasmosis[128] and in rare patients with cryptococcal meningitis.[129]

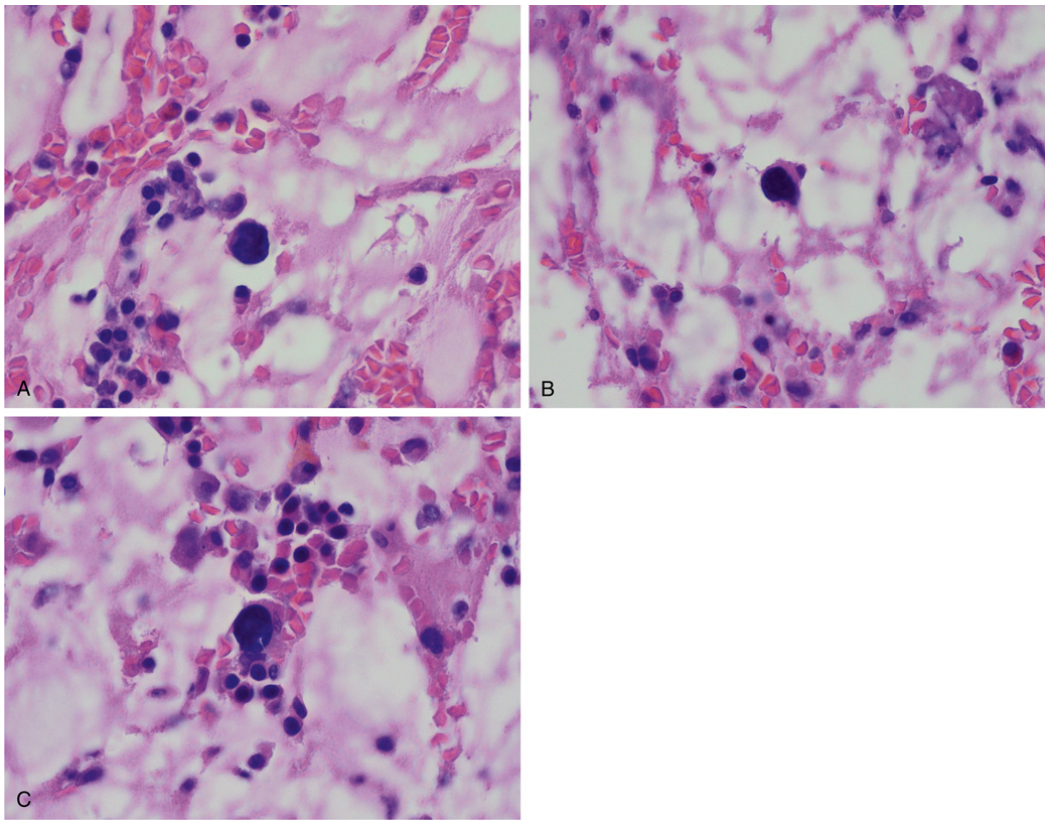

FIGURE 11-14 **A–C,** Dysplastic megakaryocytes with naked nuclei characteristically seen in the bone marrow in HIV infection.

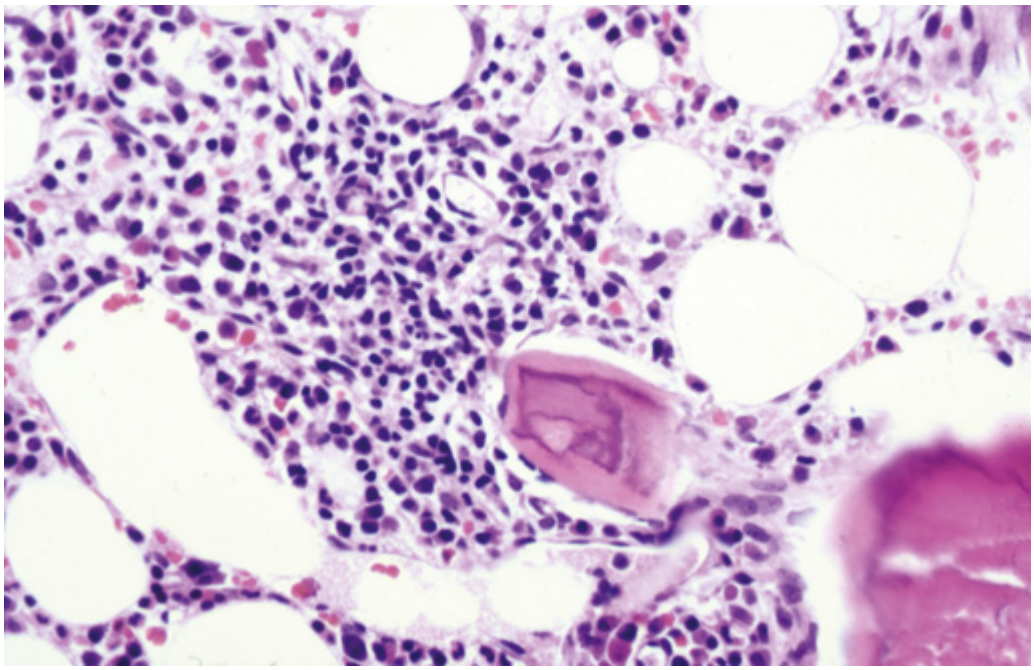

FIGURE 11-15 Bone marrow core biopsy showing atypical lymphoid aggregates from a patient with hepatitis C infection.

Bone marrow examination is often useful for the evaluation of disseminated histoplasmosis, particularly in the setting of HIV infection, in which case the marrow is involved in up to 80% of patients.[123] Wright stain can identify organisms in the aspirate smear in many cases (see **Fig. 11-16B**).[130] Rarely the organisms are confined to the megakaryocytes owing to emperipolesis.[131] Granulomas may be seen on the clot section or core biopsy. *Histoplasma* organisms are positive for both periodic acid–Schiff and Gomori methenamine silver. Cryptococcal organisms can also be recognized on Wright-stained aspirate smear material as variably sized budding yeasts (**Fig. 11-17**). Granulomas can be seen on histologic sections, and a Gomori methenamine silver or mucin stain can be used to stain the organism. Confirmation by antigen testing

can be done on a urine specimen for histoplasmosis or on serum for *Cryptococcus*. Coccidioidomycosis is also a rare cause of granulomas within the bone marrow.

Bone Marrow Necrosis

Bone marrow necrosis is defined as necrosis of hematopoietic tissue and marrow stroma without necrosis of the adjacent bone. An increase in interleukins with increased apoptosis is postulated as the mechanism. It can be seen in severe infections, hemoglobinopathies, and in disseminated intravascular coagulation, although it is more commonly documented with malignancies.[132,133] The most common malignancies are hematologic, including B-lymphoblastic leukemia, acute myeloid leukemia, and lymphoma. Necrosis because of carcinoma is less common but has been described with lung, stomach, breast, and prostate carcinomas. In many cases, the site of the primary tumor is not identified.[134] Severe bone pain is the most common symptom. Other findings associated with the patient's underlying disease, such as fever, weight loss, malaise, and night sweats, are also common. Bone tenderness may be evident on physical examination. The prognosis depends on the underlying disorder.

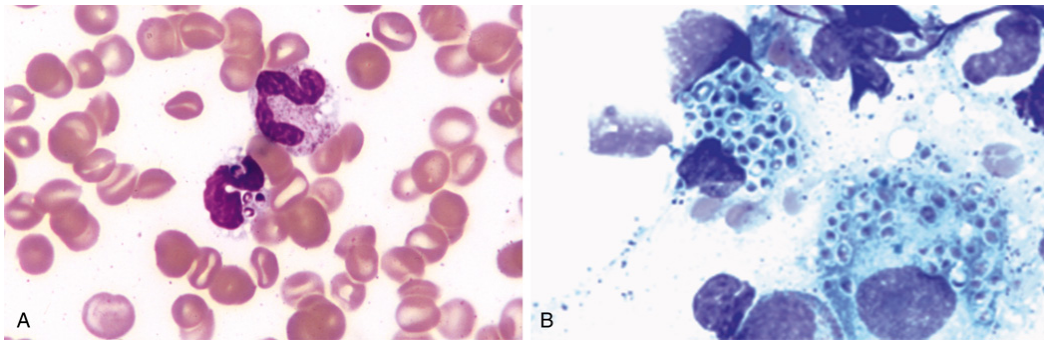

FIGURE 11-16 **A,** Peripheral blood neutrophils that have phagocytized *Histoplasma* organisms. **B,** Histiocytes in the bone marrow stuffed with the same organism.

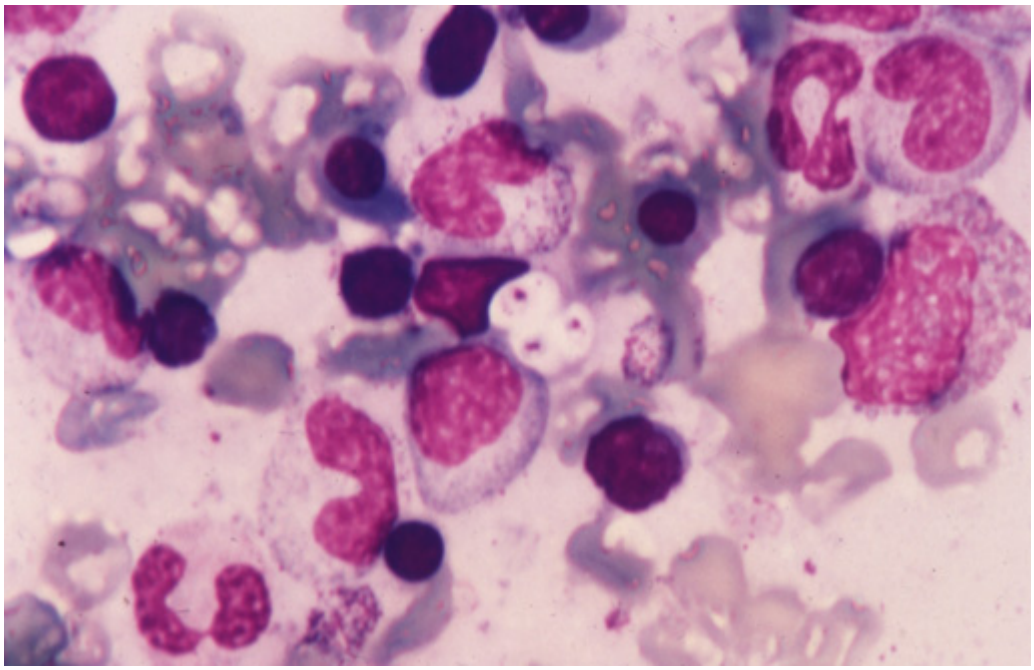

FIGURE 11-17 Bone marrow touch preparation from a patient with underlying chronic lymphocytic leukemia and *Cryptococcus* infection. Several encapsulated yeasts are seen.

The most common peripheral blood findings are anemia, thrombocytopenia, and a leukoerythroblastic reaction.[132] However, the findings depend on the underlying disease and the extent of the necrosis. Elevated lactate dehydrogenase levels and ferritin are often present.

On gross examination, the bone marrow aspirate may appear brown with poorly defined particles. The Wright-stained aspirate shows eosinophilic, necrotic cells in a granular background (**Fig. 11-18A**). The clot section and core biopsy show necrotic smudgy cells with nuclear pyknosis (see **Fig. 11-18B**). The necrosis may be extensive or focal, with viable normal marrow present in the remainder of the biopsy.

The underlying abnormality in bone marrow necrosis is thought to be occlusion of small blood vessels, leading to disruption of blood supply to the marrow.

Fever of Unknown Origin

Determination of a hematologic malignancy is much more likely than an infectious etiology if a bone marrow is performed for a fever of unknown origin.[135] Some studies have shown no increased yield compared with blood culture, whereas others show a higher yield with bone marrow culture.[136]

BONE MARROW IN NON-INFECTIOUS SYSTEMIC AND INFLAMMATORY DISORDERS

Non-infectious Granuloma

Granulomas in the bone marrow have a variety of non-infectious causes, including Hodgkin lymphoma, non-Hodgkin lymphoma, non-hematopoietic malignancies, sarcoidosis, drug reactions, and a variety of autoimmune diseases.[137] Five percent of patients with Hodgkin lymphoma have granulomas,[138] as do 2% to 3% of those with non-Hodgkin lymphoma,[139,140] regardless of whether the marrow is involved by lymphoma. Granulomas have been described with numerous other malignancies, including B-lymphoblastic leukemia, acute myeloid leukemia, plasma cell myeloma, and lung, colon, ovarian, and breast carcinoma[141-143]; as in lymphomas, granulomas may be seen regardless of whether the marrow is involved by disease. Drugs most often implicated are procainamide and amiodarone; many others, including penicillamine, chlorpropamide, and tolmetin have been associated with granuloma formation.[144-147] A wide variety of autoimmune diseases have been associated with granulomas, although most reports are of isolated cases. Patients with granulomatous hepatitis may also have non-caseating granulomas within the bone marrow.[148] Small non-caseating granulomas, which are likely non-specific in nature, are often seen in the marrow after stem cell transplantation.[149] In up to 13% of patients with granulomas, no apparent cause is identified.[147]

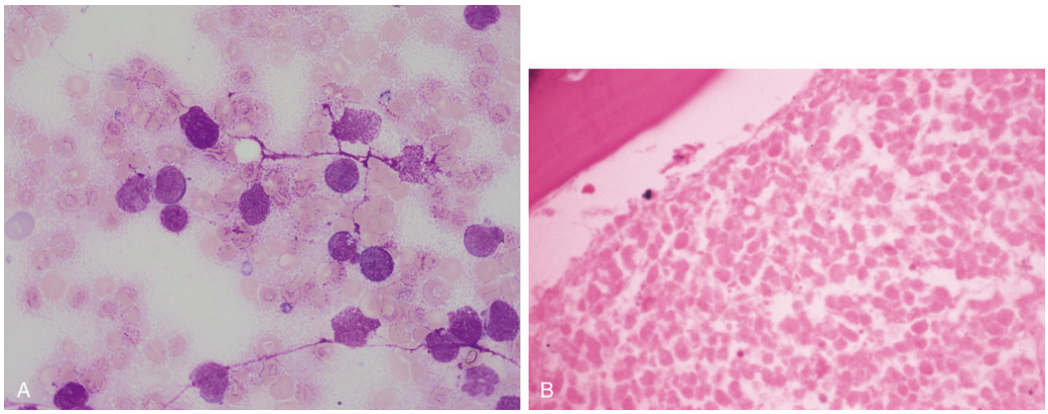

FIGURE 11-18 Bone marrow aspirate smear **(A)** and core biopsy **(B)** showing severe marrow necrosis. Only degenerated cellular material is seen.

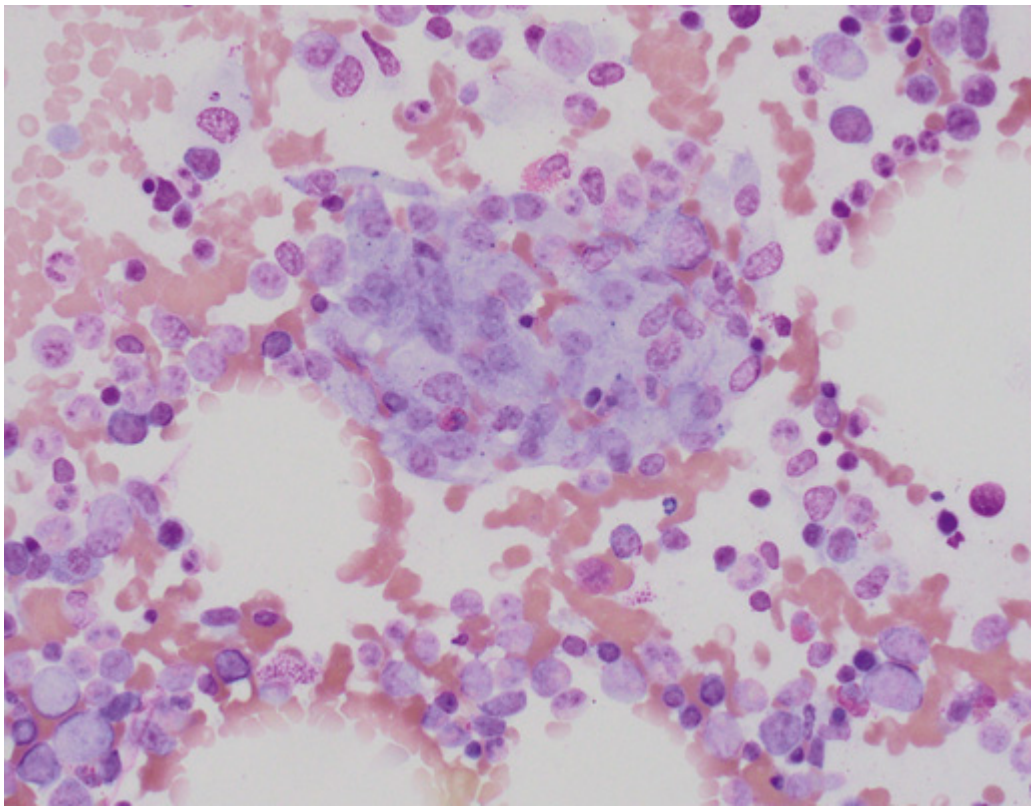

FIGURE 11-19 Bone marrow aspirate smear with a small granuloma.

Non-caseating granulomas are seen primarily on clot and core biopsy sections, although in rare cases aspirate smears contain granulomas (**Fig. 11-19**). No characteristic morphologic findings have been associated with any of the aforementioned underlying causes. Special stains for acid-fast bacilli and fungi should be performed on these specimens to eliminate the possibility of an underlying infectious disease. Repeat biopsy with culture may be needed if an infectious cause is suspected.

Lipogranulomas may be seen in up to 4% of marrow biopsies.[150] These collections of microvesicular fat, lymphocytes, and histiocytes are often associated with benign lymphoid aggregates (**Fig. 11-20**).

These granulomas have no clinical significance, and no further evaluation is required.

The differential diagnosis of granulomatous lesions within the bone marrow includes the lesions of systemic mastocytosis, marrow involvement by Hodgkin lymphoma, non-Hodgkin lymphoma (particularly T-cell and T-cell–rich B-cell lymphomas), and focal involvement by hairy cell leukemia.

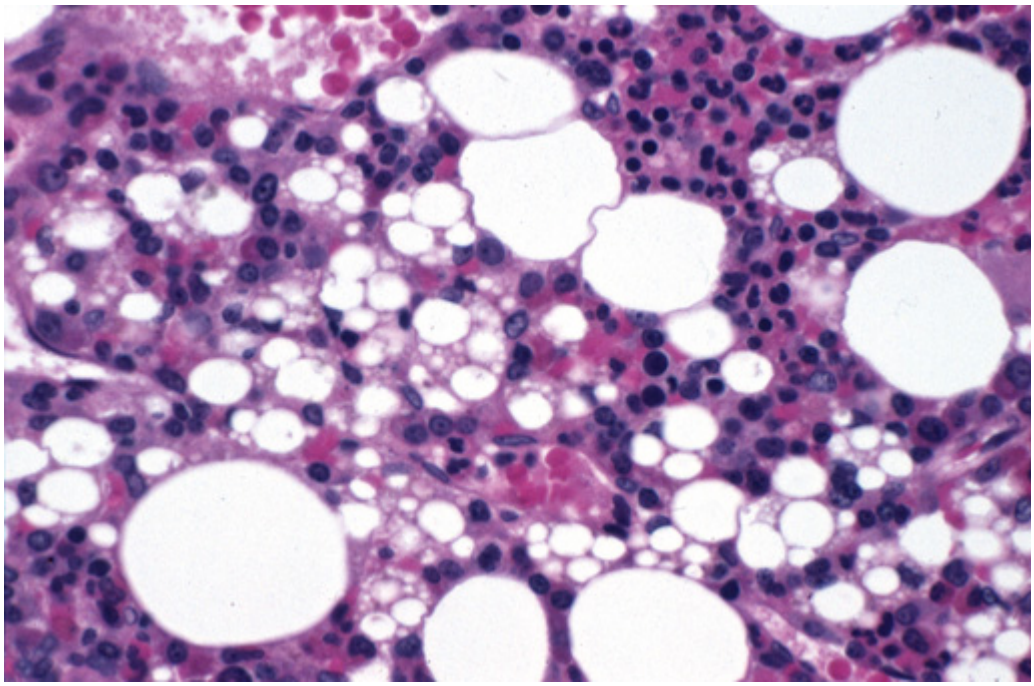

FIGURE 11-20 Bone marrow core biopsy showing a typical lipogranuloma consisting of histiocytes, lymphocytes, and small fat cells.

Systemic Rheumatic Disease

Peripheral blood and bone marrow abnormalities have been associated with a variety of systemic rheumatic diseases, including systemic lupus erythematosus (SLE), RA, mixed connective tissue

disease, systemic sclerosis, Sjögren syndrome, and polymyositis.[151] These patients have a variety of abnormalities in the peripheral blood and bone marrow that may be related to their underlying disease or its treatment (**Box 11-5**).

Cytopenias are common in patients with systemic rheumatic diseases. In SLE, there may be a variety of underlying causes (**Box 11-6**).[152] Anemia may be caused by chronic inflammation, renal insufficiency, immune hemolysis, and, in rare cases, pure red cell aplasia.[153] Neutropenia and thrombocytopenia may also be seen.[154] A microangiopathic hemolytic anemia and thrombocytopenia may be seen in thrombotic thrombocytopenic purpura, which has been reported in association with SLE.[155] Thrombocytopenia may also be a complication of vasculitis with peripheral consumption of platelets.[156] Rare cases of amegakaryocytic thrombocytopenia have also been described in SLE, systemic sclerosis, and adult onset Still disease caused by immune-mediated suppression of megakaryocyte-colony formation.[157] Small platelets are typically seen on the peripheral blood smear owing to decreased production within the bone marrow.

Box 11-5 Systemic Rheumatic Disease and the Bone Marrow

Laboratory Findings

- Anemia
  - Anemia of chronic inflammation
  - Hemolytic anemia

- Red cell aplasia
- Immune-mediated neutropenia
- Steroid-induced neutrophilia
- Eosinophilia
- Thrombocytopenia
  - Immune mediated
  - Amegakaryocytic thrombocytopenia
- Thrombocytosis

Morphologic Findings

- Variable cellularity
- Megaloblastic change
- Lymphoid aggregates
- Plasmacytosis
- Increased iron stores
- Granulomas
- Bone marrow fibrosis

Box 11-6 Hematologic Findings in Systemic Lupus Erythematosus

- Anemia
  - Anemia of chronic inflammation
  - Autoimmune hemolytic anemia
  - Renal-insufficiency anemia

- Pure red cell aplasia
- Microangiopathic hemolytic anemia
- Neutropenia
- Thrombocytopenia
- Myelofibrosis
- Hemophagocytic syndrome
- Necrosis

In RA, the most common cause of anemia is anemia of chronic inflammation, and the severity parallels the disease activity. Neutropenia is seen in Felty's syndrome, which consists of neutropenia, splenomegaly, and RA. Neutrophil counts range from 0.5 to 2.5 × 10^9/L. The bone marrow is typically hypercellular, with a maturation arrest at the myelocyte stage of development (**Fig. 11-21**). A proliferation of large granular lymphocytes with a T-cell phenotype may be found in patients with Felty's syndrome, and Felty's syndrome and large granular lymphocytic leukemia and have very similar presentations; however, T-cell clonality and *STAT3* gene mutations are much more common in the latter.[158]

Thrombocytosis may be seen in patients with chronic inflammatory conditions. Typically, platelet counts are less than 1 million, and thrombocytosis is not associated with an increased risk for either thrombosis or hemorrhage.

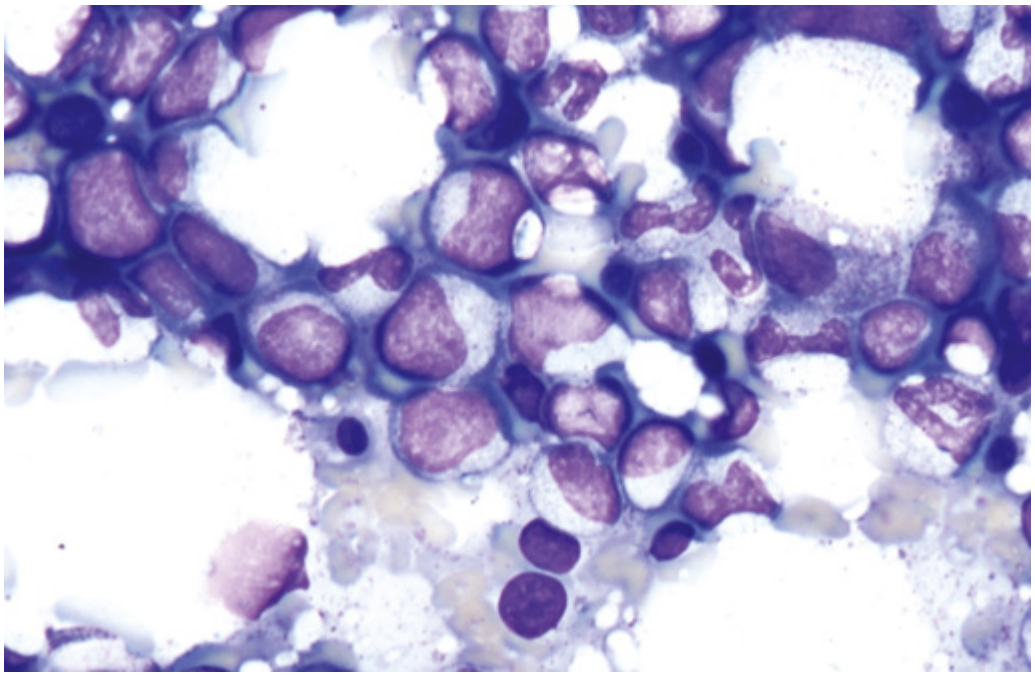

FIGURE 11-21 Bone marrow touch preparation showing a maturation arrest of the myeloid cell line in a patient with Felty's syndrome.

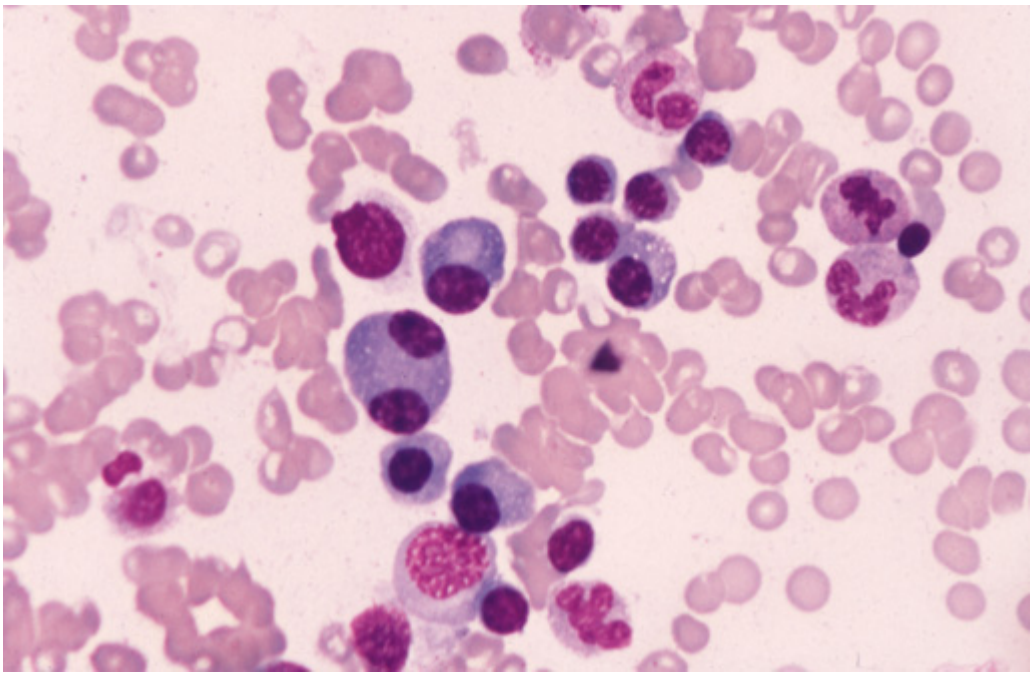

FIGURE 11-22 Increased reactive plasma cells are seen in the aspirate smear from a patient with rheumatoid arthritis.

Leukocytosis is frequently present in patients with polymyalgia rheumatica, Still disease, and Behçet disease, which may be because of increased cytokine (granulocyte colony-stimulating factor) activity.[159]

Bone marrow specimens from patients with any of the systemic rheumatic diseases may contain benign lymphoid aggregates and increased reactive plasma cells (**Fig. 11-22**). Granulomas are rarely seen and are typically non-infectious; however, care must be taken to exclude an infectious cause, because these patients are often immunosuppressed. Rheumatoid nodules can rarely be seen within the marrow space. Increased polyclonal plasma cells have been rarely described in IgG4-related disease.[160]

Other bone marrow findings include dyserythropoiesis, megaloblastic change, serous fat atrophy, necrosis, and hemophagocytosis.[161,162] Macrophage activation syndrome, which is similar to hemophagocytic lymphohistiocytosis, is associated most commonly with juvenile arthritis.[163] Necrosis has been documented as a complication of antiphospholipid antibody syndrome.[164]

Patients have been described with autoimmune myelofibrosis (AIMF).[165] These patients may have SLE or progressive systemic sclerosis, but they may also have non-specific immune symptoms such as hemolytic anemia or synovitis. The bone marrow is variably cellular. In some cases, the bone marrow may be depleted (**Fig. 11-23**), whereas in others the marrow is cellular and even has prominent megakaryocytic hyperplasia, which raises the possibility of a myeloproliferative neoplasm. In the latter case, however, the megakaryocytes are not clustered or atypical, as is commonly observed in myeloproliferative neoplasms, and basophilia is not seen. Marrow reticulin but not collagen fibrosis is present; cytopenia(s) in AIMF patients responds to corticosteroid therapy.[166] Benign lymphoid aggregates and plasmacytosis, particularly in perivascular locations, may accompany the fibrosis. Prior to making this diagnosis, testing for JAK2, calreticulin, and MPL mutations should be performed.

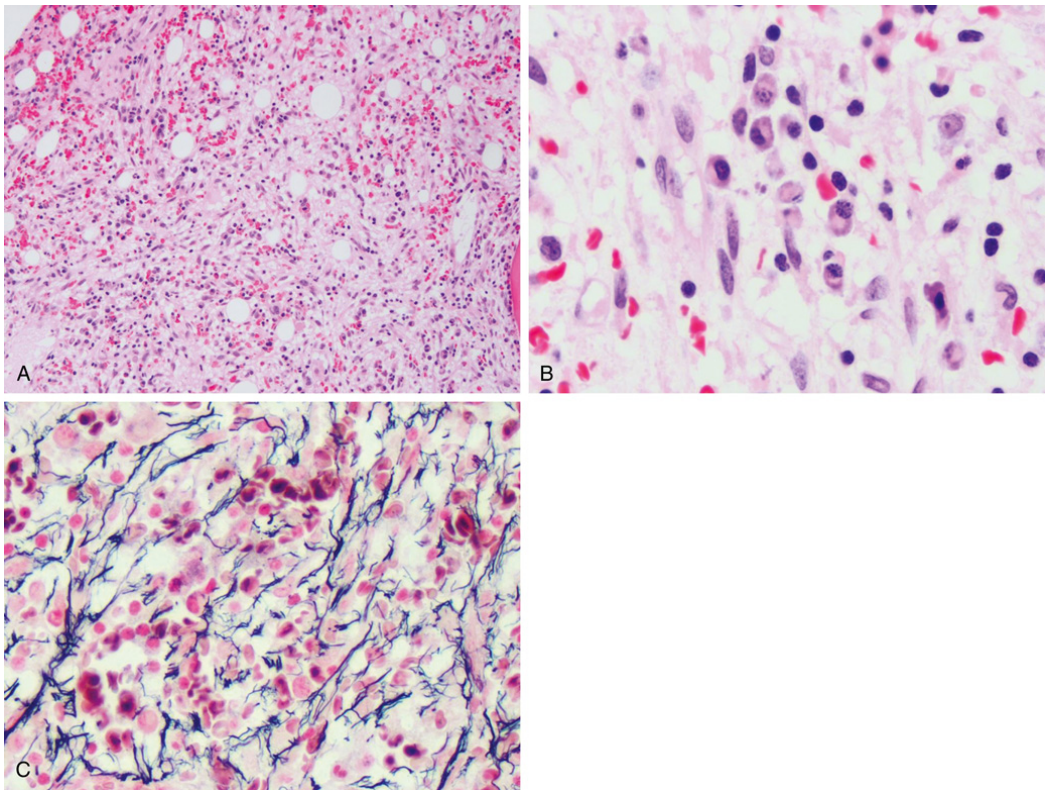

FIGURE 11-23 **A–C,** Hypocellular bone marrow from a patient with systemic lupus erythematosus who developed pancytopenia. The marrow is depleted but shows numerous plasma cells, sometimes associated with vessels, and reticulin fibrosis.

Systemic therapy for rheumatic disease may also cause peripheral blood and bone marrow abnormalities. Corticosteroid therapy is associated with a peripheral neutrophilia caused by increased release from bone marrow stores. Lymphopenia is caused by apoptosis of lymphocytes. Eosinophils may also be decreased. Gastrointestinal blood loss caused by non-steroidal anti-inflammatory medications may cause iron-deficiency anemia. Azathioprine can cause leukopenia, thrombocytopenia, or pancytopenia and can give the

bone marrow a dysplastic appearance.[167] Methotrexate causes an increase in mean corpuscular volume in 50% of patients treated with this drug. Leukopenia and thrombocytopenia may also occur. Pancytopenia can also rarely be seen.[168] Alkylating agent chemotherapy is associated with myelodysplastic syndrome and acute myeloid leukemia caused by DNA damage by these drugs.[169,170]

Sarcoidosis

Patients with sarcoidosis may have anemia and leukopenia.[171] Increased eosinophils are common but rarely constitute more than 10% of the peripheral white blood cell count.[172] Peripheral blood eosinophilia does not correlate with tissue eosinophilia in sarcoidosis.

Bone marrow biopsies may contain granulomas and the incidence varies depending on the study, age, gender, and ethnicity.[173] Granulomas can be singular, multiple, or confluent within the marrow biopsy (**Fig. 11-24**). The granulomas are typically non-caseating and composed of epithelioid histiocytes. Asteroid bodies, Schaumann bodies, and calcium oxalate crystals may be seen. Stains for acid-fast bacilli and fungi are negative. Hemophagocytosis has been described in rare patients.[174]

Alcohol Abuse

Ethanol abuse causes numerous hematologic effects that often overlap with the findings in liver disease. Laboratory studies show anemia with macrocytosis caused by the direct toxic effect of ethanol, liver disease, or concomitant folate deficiency[175]; stomatocytes may

also be seen. Granulocytopenia and impaired function of granulocytes may be seen leading to an increased risk of infection.[176] Thrombocytopenia is caused by the direct toxic effect of ethanol on megakaryocytes or increased splenic sequestration. Leukopenia can be a result of splenic sequestration or a maturation arrest at the promyelocyte stage. Leukoerythroblastosis may be found if alcoholic hepatitis is present.[177]

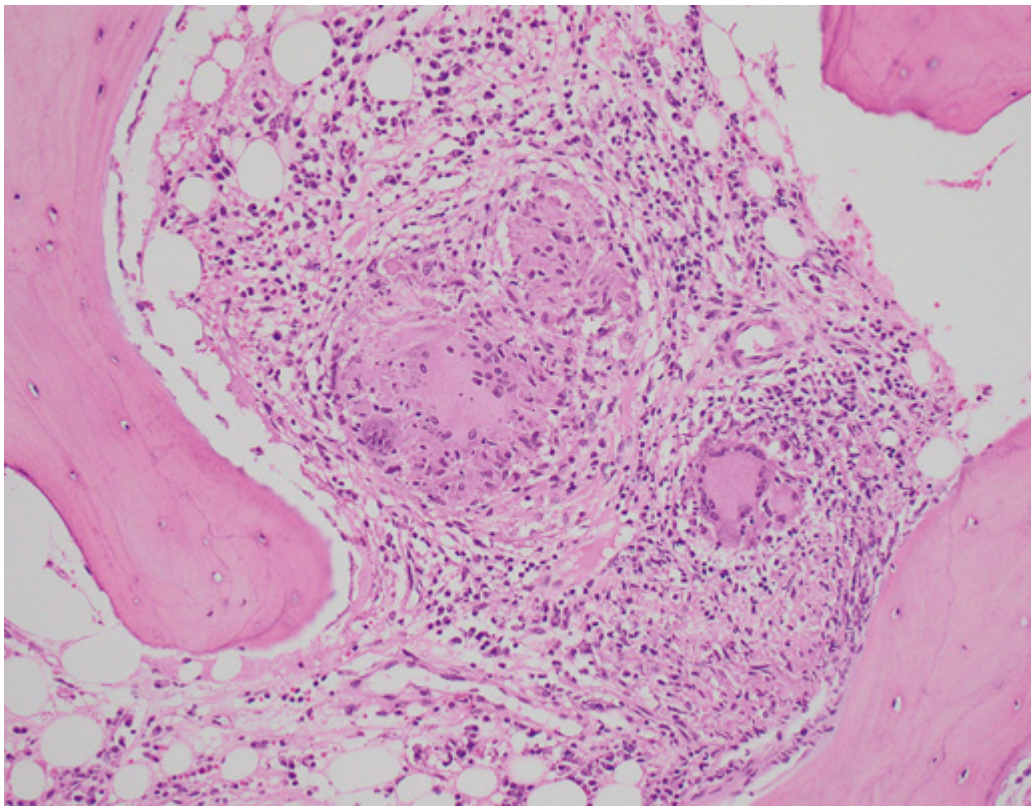

FIGURE 11-24 Bone marrow core biopsy showing a non-caseating granuloma with a multinucleated giant cell from a patient with sarcoidosis.

Bone marrow aspirate smears show a decreased myeloid-to-erythroid ratio, vacuolated erythroid and myeloid precursors,[178,179]

megaloblastic change, and multinucleated erythroid precursors (**Fig. 11-25**).[180] Megakaryocytes may be decreased or absent. Ring sideroblasts are often seen.[181,182] Plasma cells are often increased and stain for cytoplasmic iron, a finding almost exclusively found in chronic alcoholism. Iron stores are often increased. If bleeding leads to iron deficiency, storage iron is absent.

Bone marrow sections may show decreased cellularity, a rare finding.[183] Precursor vacuolization, ring sideroblasts, and hypoplasia may resolve with abstinence from alcohol.[184,185]

Hepatic Disease

Numerous peripheral blood and bone marrow findings have been described in patients with liver disease (**Box 11-7**). Some of these findings overlap with the hematologic effects of alcohol. Anemia because of bleeding is common in these patients because of coagulation abnormalities and esophageal or gastric varices.[186] Macrocytic anemia is often present, with target cells seen. Severe liver disease may lead to hemolytic anemia, in which numerous acanthocytes or spur cells may be seen on the peripheral blood smear (**Fig. 11-26**). The development of hemolysis is associated with a poor prognosis.[187] Hypersplenism caused by portal hypertension can cause pancytopenia.

Hypersplenism is often associated with hypercellular bone marrow in which all three hematopoietic cell lines are increased. Aplastic anemia has been described in patients with viral hepatitis and after orthotopic liver transplantation.[188,189]

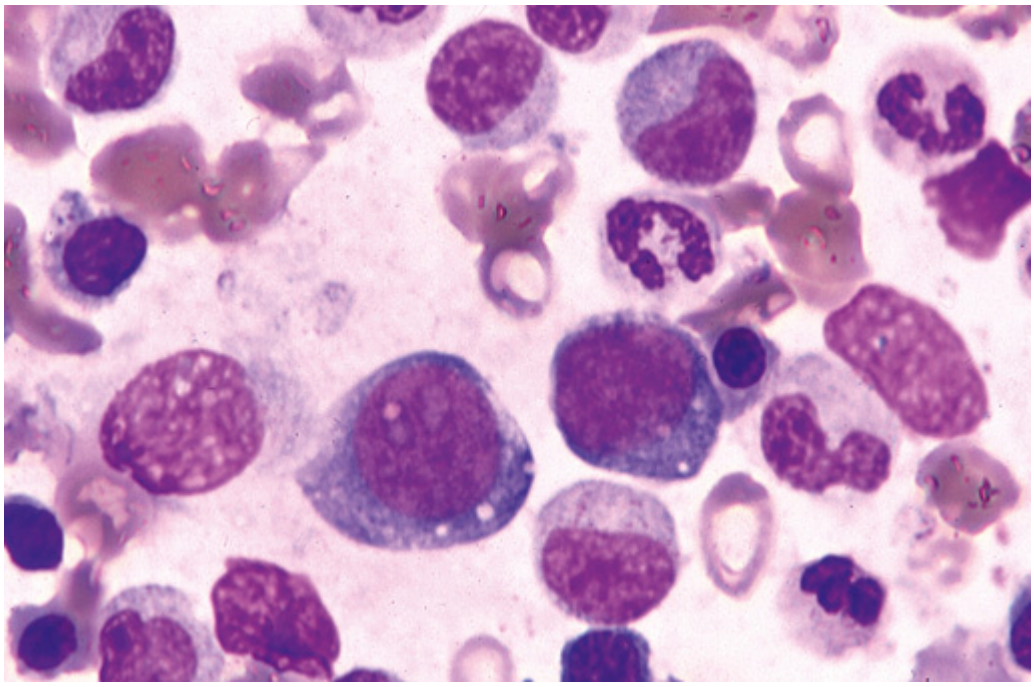

FIGURE 11-25 Bone marrow aspirate smear showing vacuolated erythroid precursors caused by alcohol abuse.

Box 11-7 Hepatic Disease and the Bone Marrow

- Thrombocytopenia
- Pancytopenia
- Aplastic anemia
- Hypersplenism
- Hemolytic anemia

Renal Disease

Peripheral blood and bone marrow abnormalities in patients with both acute and chronic renal insufficiency have been described. Patients with chronic renal failure are anemic primarily because of erythropoietin deficiency. Other causes include iron and folate deficiency, aluminum overload, hemolysis, and secondary hyperparathyroidism with osteitis fibrosa.[190] Patients also may have a bleeding diathesis caused by abnormalities of platelet function. Neutropenia may be seen after kidney transplant, related to drug therapy or an immune mechanism.[191] Treatment with recombinant erythropoietin therapy has lessened transfusion dependency in these patients.

Acute renal failure can also lead to impaired erythropoietin production, but anemia is typically related to the disorder causing the renal impairment. For example, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and systemic vasculitis cause hemolysis, and red blood cell fragmentation can be seen on the peripheral blood smear.

The anemia of chronic renal insufficiency is normochromic and normocytic, with burr cells or echinocytes seen on the peripheral blood smear. The white blood cells and platelets are normal in number and morphologically unremarkable.

The erythroid precursors may be slightly decreased on the aspirate smear but are morphologically normal. Biopsy sections may reveal bony abnormalities caused by secondary hyperparathyroidism. Bone changes that have been described include paratrabecular fibrosis, widened osteoid seams, and increased bony remodeling (**Fig. 11-27**). The amount of fibrosis can be extensive and lead to pancytopenia in some cases. The myeloid-to-erythroid ratio is often slightly high, and

there is an increase in storage iron. Exogenous erythropoietin decreases the myeloid-to-erythroid ratio owing to an increase in erythroid precursors and an increase in overall marrow cellularity.[192,193] Patients with extensive marrow fibrosis because of hyperparathyroidism may be resistant to treatment with erythropoietin.[194] Storage iron in the bone marrow may be completely or relatively depleted after treatment with recombinant erythropoietin, and iron replacement therapy may be needed.[195]

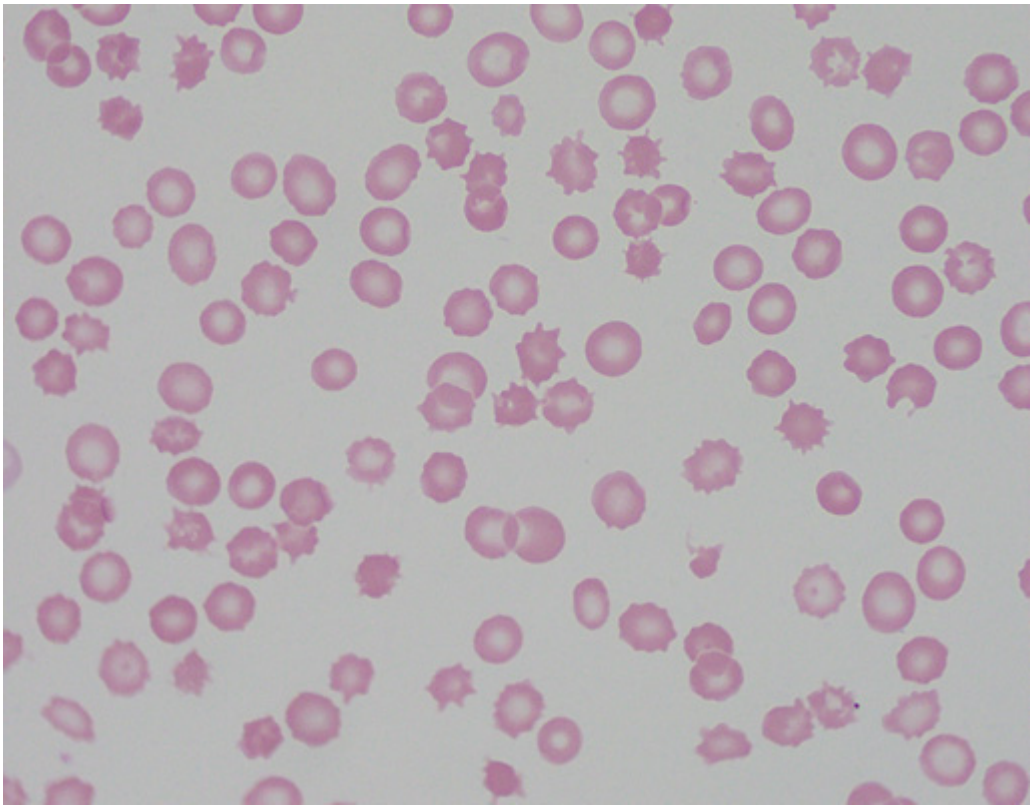

FIGURE 11-26 Peripheral blood smear with numerous acanthocytes caused by severe liver disease.

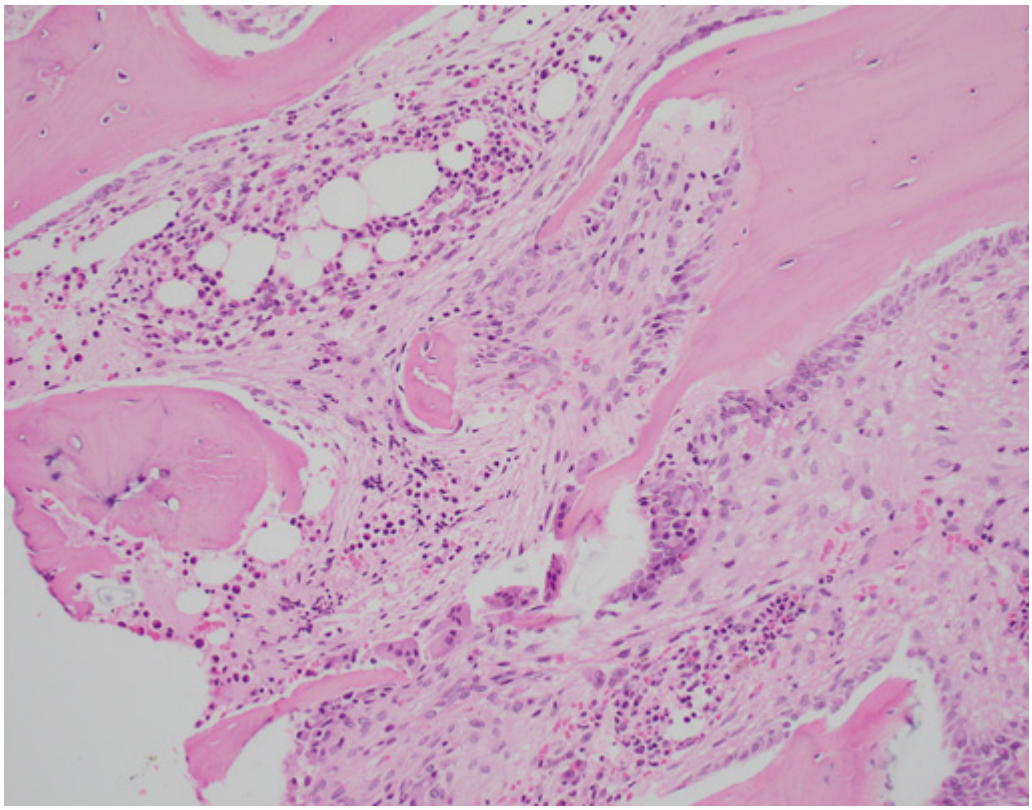

FIGURE 11-27 Bone marrow core biopsy showing widened osteoid seams and paratrabecular fibrosis in a patient with chronic renal failure.

Hypothyroidism

Hematologic findings in hypothyroidism mainly include macrocytosis with or without anemia, decreased reticulocytes, and decreased plasma levels of erythropoietin.[196] Rarely, in severe hypothyroidism, all hematopoietic cell lines can be affected, resulting in pancytopenia. Bone marrow biopsy may reveal hypoplasia.[197] In myxedema, findings similar to gelatinous transformation of the bone marrow may be seen.[198]

Hyperthyroidism

The hyperthyroid state causes anemia and neutropenia that reverses with treatment. Microcytosis is common, with or without anemia. Graves' disease may lead to autoimmune hemolytic anemia. Treatment with propylthiouracil and methimazole can cause agranulocytosis. Exposure to radioactive iodine (^{131}I) has not been shown to increase the risk for leukemia or myelodysplastic syndromes.[199]

CONCLUSION

In this chapter, a wide variety of findings in inflammatory, infectious, and metabolic conditions have been discussed. In many cases, the findings are non-specific, but often the bone marrow findings are indicative of a specific cause. Clinicopathologic correlation is essential to an accurate diagnosis of these disorders.

Pearls and Pitfalls

- Atypical lymphoid aggregates morphologically suggestive of lymphoma are seen in patients with viral infections such as Epstein-Barr virus or hepatitis C virus.
- Marrow dyspoiesis suggestive of a myelodysplastic syndrome can be seen with cytomegalovirus infection or treatment with immunosuppressive agents.
- Small-clefted (cleaved) lymphocytes, suggestive of follicular lymphoma, may be seen in peripheral blood in *Bordetella pertussis* infection.

- Reactive lymphocytosis is almost always composed predominantly of T cells.
- Persistent polyclonal B-cell lymphocytosis is often characterized by lymphocytes with moderate amounts of cytoplasm and bilobed nuclei; in the bone marrow they may occur in an intrasinusoidal or intravascular pattern.

INTRODUCTION

HISTORICAL BACKGROUND

THE ICC AND WHO 5TH ED. PROPOSALS: SIMILARITIES AND DIFFERENCES

- **Mature B-Cell Neoplasms**
- **Mature T- and NK-Cell Neoplasms**
- **Immunodeficiency Disorders**

CONCLUSION

INTRODUCTION

This chapter will set the stage for the subsequent chapters that examine mature lymphoid neoplasms. It will discuss the historical background of the classification of lymphomas, and the biological principles used today to define lymphoid neoplasms. This book uses the *2022 International Consensus Classification* as the primary basis for the discussion of neoplastic disorders of lymphoid, myeloid, and histiocytic neoplasms.[1] However, the text will provide synonyms, where appropriate, for the World Health Organization (WHO) 5th edition classification based on the published overview,[2] and briefly explain where there are significant differences. The actual 5th edition WHO *Blue Book* is not yet published in final form (as this chapter goes to press). Therefore there could be changes from what is included here, which is based solely on the overview of the 2022 WHO classification as published by Alaggio et al.[2]

The *2022 International Consensus Classification* was coordinated by the European Association for Haematopathology (EA4HP) and Society for Hematopathology (SH). It represents a revision of the 2016 WHO classification and relies heavily on decisions made at a September 2021 Clinical Advisory Committee (CAC) meeting, following the basic process established in the mid-1990s for the modern WHO classifications.[1] Each of those proposals were published as review articles, following the respective CAC meetings, and in the 3rd, 4th, and revised 4th editions of the *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*.[3-8]

HISTORICAL BACKGROUND

As lymphoma classification has evolved from the functional lymphoma classifications that related lymphomas, where possible, to the normal cells they most closely resembled, with recognition of new entities and new solutions for problematic categories, the basic principles underlying the modern WHO classifications and now the ICC are essentially unchanged from those of the Revised European American Lymphoma (REAL) classification of lymphoid neoplasms published by the International Lymphoma Study Group (ILSG) in 1994.[9] The REAL classification represented a new paradigm in the classification of lymphoid neoplasms (**Fig. 12-1**), focusing on the identification of "real" diseases rather than a global theoretical framework such as survival, as had been used in the working formulation,[10] or cellular differentiation, as had been applied in the Kiel[11,12] and Lukes-Collins[13] classification systems. Key events in the evolution of the classification of lymphoid malignancies are summarized in **Table 12-1**.[14-50]

The REAL classification defined distinct entities with a constellation of features: morphology, immunophenotype, genetic features, and clinical presentation and course. Each of these elements plays a part, and no one feature takes precedence over the others consistently. For some diseases, morphology is highly characteristic, although at least phenotypic studies are required prior to making a definitive diagnosis. Most cases of chronic lymphocytic leukemia (CLL) or follicular lymphoma (FL) presenting in lymph nodes fall into this category. For other diseases, knowledge of the underlying genetics may be essential, such as in the diagnosis of anaplastic lymphoma kinase (ALK)–positive anaplastic large-cell lymphoma (ALCL) (**Fig. 12-2**). The relative importance of each of

these features varies among diseases, depending on the state of current knowledge, and there is no one gold standard by which all diseases are defined. Still, lineage is a defining feature and forms the basis for the classification system's structure, recognizing B-cell, T-cell, and natural killer (NK)-cell neoplasms. In addition, a basic premise is the distinction between precursor lymphoid neoplasms and those derived from mature lymphoid cells.

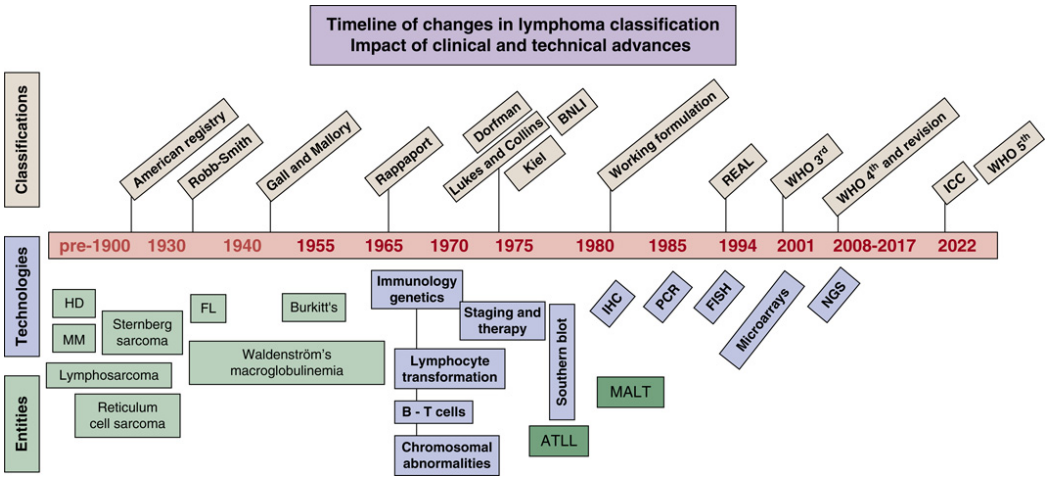

FIGURE 12-1 Diagram illustrating advances in the classification of lymphoid malignancies *(above the time line)* and corresponding events *(below the time line)* related to insights into the biology of lymphoid cells, the recognition of significant clinicopathologic entities, and advances in treatment and clinical evaluation. Technologic advances identifying the heterogeneity of lymphoid cells in the 1960s and 1970s precipitated a flurry of new classification systems that related lymphoid malignancies to the normal cells of the immune system. Improvements in the treatment and clinical evaluation of patients with lymphoid malignancies facilitated the recognition of clinical correlations and made accurate classification essential for patient management. The Revised European American Lymphoma (REAL) and World Health Organization (WHO) classifications represented a new perspective, emphasizing the

recognition of disease entities and integrating morphologic, immunophenotypic, molecular, and clinical data. The introduction of NGS methodology in the last decade has facilitated increasingly rapid discovery of genetic aberrations on clinical samples. This multiparameter approach provides objective criteria for diagnosis, facilitating reproducibility and consensus. *ATLL,* Adult T-cell leukemia/lymphoma; *BNLI,* British National Lymphoma Investigation; *FISH,* fluorescence in situ hybridization; *FL,* follicular lymphoma; *HD,* Hodgkin disease; *ICC,* International Consensus Classification; *IHC,* immunohistochemistry in frozen and, later, paraffin-embedded sections; *MALT,* marginal zone lymphoma of mucosa-associated lymphoid tissue; *MM,* multiple myeloma; *NGS,* next-generation sequencing; *PCR,* polymerase chain reaction studies (for rearrangements of immunoglobulin and T-cell receptor genes).

In the twentieth century, the field of immunology shed light on the functional and immunophenotypic complexity of the immune system.[51] Traditional morphologic approaches were recognized as insufficient to decipher the many benign and malignant cellular components of lymphoid malignancies. Monoclonal antibody technology provided a seemingly endless array of immunophenotypic markers that could delineate the various cell

types,[52] and technologic advances soon permitted the immunohistochemical detection of most relevant antigens in routinely processed formalin-fixed, paraffin-embedded sections.[53] Many lymphoid malignancies have characteristic immunophenotypic profiles, but even among some very homogeneous entities, immunophenotypic variation may be seen. For instance, not all cases of CLL are CD5 positive and CD23 positive; not all FLs are BCL2 positive or CD10 positive. CD5 may be expressed in otherwise classical FL. Expression of ALK is essential for the diagnosis of ALK-positive ALCL, but it is also expressed in ALK-positive large B-cell lymphoma and some histiocytic and mesenchymal tumors, mainly in children. Thus knowledge of the immunophenotype is a highly effective tool, but one that must be used in context.

There has been equally dramatic progress in understanding the genetics of lymphoid malignancies. Recurrent cytogenetic abnormalities have been identified for many lymphoma subtypes. The first to be recognized were the t(14;18)(q32;q21) translocation of FL and the t(8;14)(q24;q32) translocation of Burkitt lymphoma (BL).[34,35,44] Subsequent studies led to the cloning of the genes involved in these translocations. The laboratories of Leder and Croce in 1982 both identified *MYC* as the gene that was translocated into the immunoglobulin genes in human BL[42,43]; other similar discoveries soon followed, such as *IGH*::*BCL2* in FL[54] and *IGH*::*CCND1* in mantle cell lymphoma.[55,56] The most common paradigm for translocations involving the immunoglobulin heavy-chain gene, IGH at 14q24, is that a cellular proto-oncogene comes under the influence of the IGH promoter. The list of important chromosomal aberrations in B-cell neoplasms has continued to

rapidly expand and become integrated into clinical practice, such as the *IRF4* translocations in large B-cell lymphoma with *IRF4* rearrangement—a distinct clinicopathologic entity.[57,58] There are also less frequent but parallel alterations involving the T-cell receptor genes in T-cell malignancies, as well as other chromosomal aberrations.

The REAL classification recognized the importance of genetic abnormalities in defining disease entities. However, it has become clear that a purely genetic approach to defining diseases is not feasible. Although the *MYC* translocation is nearly universally present in BLs, *MYC* translocations involving the immunoglobulin genes are found as either secondary or, less commonly, primary genetic abnormalities in other lymphoid malignancies, including some diffuse large B-cell lymphomas (DLBCLs), plasmablastic malignancies, and some cases of B-lymphoblastic leukemia/lymphoma. Similarly, *IGH*::*BCL2* is found in 85% to 90% of FLs and is present in up to 25% to 30% of de novo DLBCLs with no prior clinical evidence of FL.

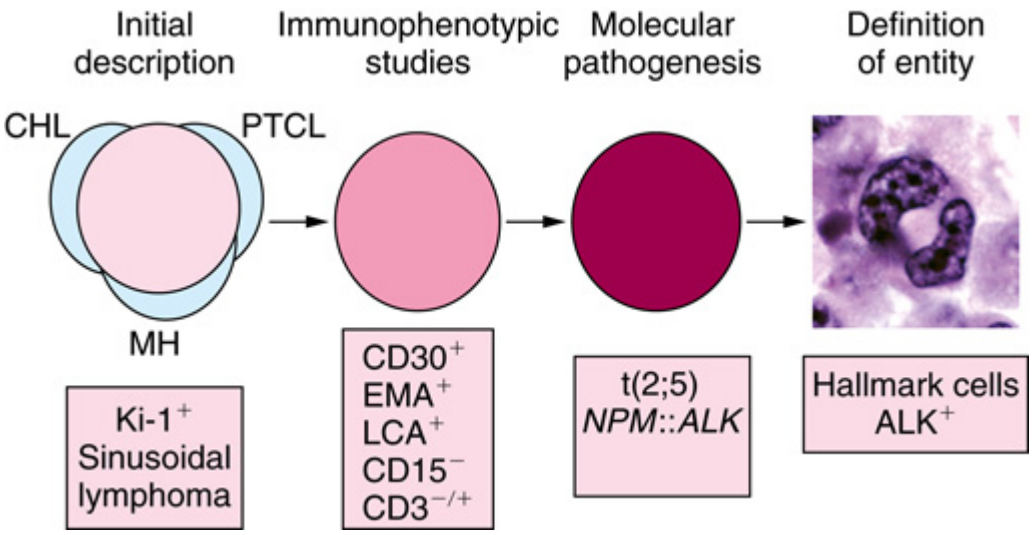

FIGURE 12-2 The recognition of anaplastic lymphoma kinase (ALK)-positive anaplastic large-cell lymphoma (ALCL) is emblematic of the stepwise advances in the identification of new disease entities. ALCL was first recognized by distinctive morphologic features. The identification of a characteristic immunophenotype, with strong expression of CD30, led to better recognition of the entity and facilitated studies to determine its molecular pathogenesis. Identification of the nucleophosmin *NPM*::*ALK* translocation, with high levels of ALK expression, led to the development of polyclonal and, later, monoclonal antibodies to identify ALK in formalin-fixed, paraffin-embedded sections. These tools, when incorporated into daily practice, both broadened and narrowed the original concept of ALCL as a morphologic entity. Small-cell variants were

included, whereas highly anaplastic and Hodgkin-like forms were largely excluded from the disease spectrum. *CHL,* Classic Hodgkin lymphoma; *MH,* malignant histiocytosis; *PTCL,* peripheral T-cell lymphoma.

Even more recently, there is an ever-growing contribution of molecular genetic studies in understanding lymphomas, in helping to better define both older and newer distinct entities and of increasing utility as prognostic/predictive markers important for the practice of precision medicine. They are being integrated more and more into clinical practice, although much remains to be learned. Though not common, some entities are strongly associated with specific mutations such as *BRAF* V600E mutations in hairy cell leukemia and *MYD88* L265P mutations in lymphoplasmacytic lymphoma (LPL). However, similar to what we have learned from other phenotypic and cytogenetic findings, none of these can be interpreted in isolation. *BRAF* V600E mutations are seen in a variety of lymphoid and non-lymphoid malignancies, and *MYD88* L265P mutations are seen in a variety of DLBCL that are not related to LPL. Although not quite ready for incorporation into our classification at this time, there is great interest in the use of molecular/cytogenetic categorization of DLBCLs via high throughput sequencing as reported by several different groups of investigators[59-63] that do not all directly correlate with the distinction of GCB and ABC DLBCL and which have both prognostic and predictive implications. It has been said that "It seems inevitable, on the basis of the results of the [molecular genomic] classification studies, that a more detailed genetic subclassification is poised to supersede the COO [cell of origin]

framework."[64] Consistent with this, the ICC report indicates that "cell-of-origin is retained for the present time with the expectation that transition to a molecular genetic classification will be feasible in the near future." Use of such a molecular genomic classification for the DLBCL also may lead to reorganization of some entities that we currently recognize as distinct, but which share an important molecular landscape. Newer molecular studies also are greatly affecting the area of T- and NK-cell neoplasms. For instance, the concept of follicular helper T-cell lymphomas is strongly supported by their overlapping characteristic mutational findings (e.g., with *TET2, DNMT3A,* and *RHOA* mutations).[65] Interestingly, some mutations, such as $IDH2^{R172}$, may be associated with distinctive morphologic features within the angioimmunoblastic subtype.[66,67] Nevertheless, individual mutations by themselves cannot be used to define an entity. Finally, the inclusion of clinical criteria was one of the novel aspects of the ILSG approach.[68] The REAL classification recognized that the site of presentation is often a signpost for underlying biological distinctions, such as in extranodal lymphomas of mucosa-associated lymphoid tissue (MALT),[69] primary mediastinal large B-cell lymphoma, and many types of T/NK-cell lymphomas. Even very recently, the importance of a mediastinal location in what is now known as mediastinal gray-zone lymphomas (MGZL) provided evidence that this entity should be segregated from other aggressive B-cell neoplasms with Hodgkin-like cells that had also been considered to have "gray zone" features, with mediastinal and non-mediastinal cases manifesting different genetic profiles.[70-72] The ILSG appreciated that accurate diagnosis cannot take place in a vacuum and requires knowledge of the clinical history, because

biologically distinct entities may appear cytologically similar. Integration of clinical features is an essential aspect in the definition of disease entities and in accurate diagnosis in daily practice. The pathologist must be provided with relevant clinical details to arrive at a correct diagnosis, and it is the pathologist's responsibility to insist on sufficient clinical data if it is not provided. Each of the chapters covering the lymphoid neoplasms emphasizes the pertinent clinical features, knowledge of which contributes to an accurate diagnosis. It is also evident that clinical features are important prognostic indicators, and in many instances, the treatment approach chosen is based on the clinical setting in conjunction with the pathologic diagnosis. For instance, some patients with FL can be followed with a "watch and wait" approach, whereas in others a heavy tumor burden at diagnosis mandates immediate therapy. Response to therapy is influenced not only by underlying clinical features but also by biological and prognostic factors. Cytologic grade varies in many disease entities and is discussed in the chapters that follow. Other prognostic factors are based on tumor cell biology[73,74] or host factors, such as the tumor microenvironment.[75] For this reason, it is not possible to stratify lymphoma subtypes in a linear fashion according to their clinical aggressiveness. The pathologist and clinician are part of a management team that determines the therapeutic approach in each case.

The REAL classification was based on the building of consensus, and it recognized that a comprehensive classification system was beyond the experience of any one individual or a small group of individuals. The 19 members of the ILSG contributed their diverse perspectives to achieve a unified point of view. In addition, the ILSG

made the decision to base its classification exclusively on published data; thus for an entity to be included in the REAL classification, it had to be validated in more than one publication.

Recognition that the development of classification systems should be a cooperative effort was expanded with the 3rd edition of the WHO classification.[6] Contacted by Dr. L. Sobin and subsequently Dr. P. Kleihues, Dr. E. S. Jaffe, President-Elect of the SH, was invited in 1994 to develop the WHO classification for the 3rd edition of the WHO *Blue Book* tumor series, which, for the first time, would integrate molecular and cytogenetic features, together with clinical, morphologic, and phenotypic features in defining disease entities. The leadership of the SH recognized achieving a broad international perspective was important and invited the EA4HP to join in the effort. This unified EA4HP and SH effort represented the first true worldwide consensus classification of hematologic malignancies and ultimately was the culmination of the efforts of a 7-member steering committee, 11 pathology committee chairs, 75 author contributors, and 44 clinician participants in a critical clinical advisory committee meeting. In 2008, the 4th edition of the WHO classification involved the efforts of 138 authors and 2 clinical advisory committees comprising 62 clinical specialists with expertise in lymphoid and myeloid disorders. The clinical advisory committee meetings were organized around a series of issues, including disease definitions, nomenclature, grading, and clinical relevance. As with the 3rd edition, the effort was coordinated by the EA4HP and the SH, led by the eight editors who served as a steering committee. This model was maintained for the revision of the 4th edition, with a clinical advisory committee meeting held in 2014 to address newly emerging issues

related to the definition of specific entities and with the revised WHO classification published in manuscript form in 2016 and the subsequent WHO *Blue Book* in 2017.[5,8]

Since those publications, there have been many advances in hematopathology, in part because of an explosion in molecular/cytogenetic data and newer therapeutic strategies, so the classification needed to be revised once again. Discussions about the next revision began with IARC in 2019; however, there were some major differences of opinion about how to proceed. Consistent with former revisions, the process led by the SH and EA4HP started with planning for a session that was held at the 2021 EA4HP meeting to begin to get broad-based input from the international hematopathology community. Realizing the continued critical nature of consensus also from clinical hemato-oncologists, the EA4HP and SH once again organized a hybrid CAC with 149 international participants that was held in September 2021 (delayed from 2020 because of the COVID pandemic). This led to the revised classification being published as the *International Consensus Classification*,[1] with additional details provided in a special issue of *Virchows Archiv*.[76] The ICC lymphoma classification was authored by 73 pathologists, clinicians, and biologists representing 20 countries from Europe, North and South America, Asia, and Australia. Unfortunately, in spite of ongoing efforts for a reconciliation, IARC rejected this process. They used an 18-person standing editorial board (which includes 1 hematopathologist) chaired by Dr. I. Cree, IARC Branch Head for Evidence Synthesis and Classification Section, together with a 24-person expert editorial board appointed based on “bibliometrics” and the recommendation

of the standing editorial board members, to develop a proposal for the 5th edition of the WHO classification.[2] This proposal presumably will form the basis for the upcoming 5th edition of the WHO *Blue Book*. Although the two separate revisions have many similarities to each other and to the 2016 WHO classification, as highlighted in **Table 12-2**, there are some major differences between all three classifications, not only in terminology but also in some important concepts.

THE ICC AND WHO 5TH ED. PROPOSALS: SIMILARITIES AND DIFFERENCES

There are important changes in the 2022 ICC[1] and differences from the proposed 2022 WHO[2] that will be discussed in greater detail in the chapters that follow, not all of which are included here. Key changes in terminology are highlighted in **Table 12-2** and in the ICC publication.[1] To assist in understanding the evolution in terminology, the terms used in the revised 4th edition of the WHO classification are shown (center column) in comparison to the ICC on the left, and the proposed WHO 5th edition on the right. Terms in bold print indicate a change from the WHO 4th edition classification. New ICC entities proposed as provisional are shown in italics. Text shown in red (ICC) as opposed to blue (WHO 5th) indicate differences between the two classification systems. However, as this volume goes to print, the final version of the WHO 5th is uncertain. We have relied on the proposed classification as published by Alaggio et al.,[2] but terminology and definitions may differ in the final *Blue Book* publication.

Table 12-2

The listing of the WHO Classification, 5th edition, is that published by Alaggio, et al.,[2] as the WHO 5th edition *Blue Book* was not yet published in the final form when this chapter was finalized. The final fifth edition WHO classification is expected to include some changes from the listing here.

Red and blue indicate those entities that differ between the International Consensus Classification (in red) and the World Health Organization (WHO), 5th edition (in blue).

In **bold**, those entities that introduce significant changes with respect to the WHO 4th edition, revised classification are highlighted.

In *italics,* the provisional entities from the International Consensus Classification.

The listing of diseases differs from that in the published ICC,[1] as it was minimally reorganized to allow comparison among the different classifications.

1. Histologic diagnosis according to accepted criteria and terminology

2. Presence or absence of one or more oncogenic virus(es)

3. The clinical setting/immunodeficiency background.

ALK, Anaplastic lymphoma kinase; *DLBCL,* diffuse large B-cell lymphoma; *EBV,* Epstein-Barr virus; *HGBL,* high-grade B-cell lymphomas; *HHV-8,* human herpesvirus 8; *IgM,* immunoglobulin M; *KSHV,* Kaposi sarcoma-associated herpesvirus; *LPD,*

lymphoproliferative disorder; *MALT,* mucosa-associated lymphoid tissue; *MGUS,* monoclonal gammopathy of undetermined significance; *MM,* multiple myeloma; *NK,* natural killer; *NOS,* not otherwise specified; *PTLD,* post-transplant lymphoproliferative disorders; *TFH,* T-follicular helper; *WHO,* World Health Organization.

* Entities only present in the *International Consensus Classification*.

† "Pediatric-type follicular lymphoma with marginal zone differentiation" has been proposed as a more accurate name for the provisional entity "Pediatric nodal marginal zone lymphoma" as designated in the ICC classification, and slightly modified here to "Pediatric-type nodal marginal zone lymphoma."

‡ This is listed among the large B-cell lymphomas in the WHO classification, 5th edition.

§ The 5th edition of the WHO lymphoma classification adopts the nomenclature proposed at the "Workshop on Immunodeficiency and Dysregulation" organized by the Society of Hematopathology and the European Association for Haematopathology in 2015. In this classification, the nomenclature of lymphomas and lymphoid proliferations associated with immunodeficiency and dysregulation is constructed based on a 3-tier structure as follows:

Some of the key differences will be discussed.

Mature B-Cell Neoplasms

- Clinical participants at the CAC strongly preferred the term *multiple myeloma* (formerly known as plasma cell

myeloma). The ICC also requires cytogenetic analysis for subclassification of multiple myeloma for clinical management, although the 2022 WHO proposal from Alaggio et al.[2] does not.

- Consistent with the criteria of the second International Workshop on Waldenström's macroglobulinemia,[77] the ICC now permits the diagnosis of LPL in the bone marrow, even with <10% involvement, as long as the biopsy demonstrates neoplastic lymphoplasmacytic aggregates with evidence of clonal B cells and plasma cells.
- Two types of IgM MGUS are now recognized in the ICC but not in the 2022 WHO. One subtype of IgM MGUS has the *MYD88* L265 mutation and is considered a precursor to Waldenström macroglobulinemia.
- The 2022 ICC retains the categories of *B-cell prolymphocytic leukemia* and *hairy cell leukemia variant*. The 2022 WHO no longer recognizes the terms, but puts the latter and some of the former cases into a new category of *splenic B-cell lymphoma/leukemia with prominent nucleoli*.
- Both classifications now segregate what has been called *primary cutaneous marginal zone lymphoma* from other extranodal marginal zone lymphomas. In addition, the ICC names this lesion as *primary cutaneous marginal zone lymphoproliferative disorder (LPD)*, rather than *lymphoma* because of its very indolent behavior. As with other entities labeled as *LPD*, there is a desire to avoid labeling patients with a malignant lymphoma diagnosis when not warranted based on clinical outcome data.

- Though the ICC approach to FL remains relatively similar to that of the revised 4th edition, as strongly supported by the clinicians of the CAC, the 2022 WHO recognizes the FL family as including FL, in situ follicular B-cell neoplasm, pediatric-type FL (which is a separate distinct entity in the 2016 WHO and 2022 ICC with a very distinctive molecular landscape), and duodenal-type FL. The WHO recognizes classic FL, which apparently must have an *IGH*::*BCL2* fusion and be in part follicular, but rejects the concept of grading within the category of *classic FL*. Alternatively, the WHO segregates follicular large B-cell lymphoma, which appears to correspond to grade 3B FL and includes a new category of *FL with uncommon features*. The latter includes cases that either have blastoid or large centrocyte cytologic features or a predominantly diffuse growth pattern. The ICC, on the other hand, retains the grading of FL as stipulated in the WHO revised 4th edition, but advises that ancillary studies (FISH for *BCL2*R and immunohistochemistry) be implemented to assist in the recognition of grade 3A versus 3B.
- The 2022 ICC includes a new provisional entity of *BCL2-rearrangement negative, CD23-positive follicle center lymphoma,* which has distinctive clinical and genetic findings and should be segregated from other FL. These cases often have a predominantly diffuse growth pattern, but purely follicular cases exist.
- The ICC also considers *testicular FL* a distinct entity rather than just a subtype of typical FL. Large B-cell lymphoma with *IRF4* rearrangement is now considered a definite entity

in the ICC and thought to be among the group of pediatric lymphomas with a follicular growth pattern.

- The ICC proposes the term *nodular lymphocyte predominant B-cell lymphoma (NLPBCL)* to replace the prior term *nodular lymphocyte predominant Hodgkin lymphoma*. The conclusion reached at the CAC meeting was that NLPBCL is more properly included among the B-cell lymphomas based on its biological features, clinical behavior, and current therapeutic strategies, which differ from those used for classic Hodgkin lymphoma (CHL). While undoubtably there will be a learning curve for acceptance of the new terminology, clinicians at the CAC meeting opined that this change would help ensure appropriate therapy for this disease.
- The ICC now recognizes *primary DLBCL of the testis* as a distinct entity, which has features overlapping those of *primary DLBCL of the central nervous system* and some other extranodal DLBCL of ABC type with the MCD/C5 molecular/genomic features.[60] The 2022 WHO groups testicular, CNS, and vitreoretinal DLBCL together as *primary large B-cell lymphoma of immune-privileged sites* (a category that does not include other lymphomas that may also share similar molecular/cytogenetic features). This was a topic of extensive discussion at the CAC, but the creation of a new umbrella category—that would be larger than just CNS and testicular DLBCL—was felt to be premature.
- Though both the ICC and WHO revised the name for Burkitt-like lymphoma with 11q aberration because it is not related

to Burkitt lymphoma, the ICC considers it a type of large B-cell lymphoma *(large B-cell lymphoma with 11q aberration)* and the WHO, a type of high-grade B-cell lymphoma.

- The ICC uniquely introduced the term *EBV-positive polymorphic B-cell lymphoproliferative disorder, not otherwise specified (NOS)*, described in **Chapter 28**. The term captures a spectrum of EBV-driven lesions that are distinct from posttransplant lymphoproliferative disorders (PTLD) but fall short of criteria for the diagnosis of EBV-positive DLBCL.
- The ICC segregated *high-grade B-cell lymphoma (HGBL) with* MYC and BCL2 *rearrangements* (with or without *BCL6* rearrangements) from a new provisional category of *HGBL with* MYC and BCL6 *rearrangements*. The 2022 WHO does not consider the latter a specific category, believing such cases should be included in DLBCL, NOS. The ICC also now recognizes that some HGBL may express terminal deoxynucleotidyl transferase (TdT) without necessitating the diagnosis of a B-lymphoblastic neoplasm.
- Both new classifications eliminated the unwieldy name of *B-cell lymphoma, unclassifiable with features intermediate between DLBCL and classic Hodgkin lymphoma,* but continue to recognize the category of *MGZL*. In the ICC, non-mediastinal cases with similar morphology are subsumed as variants of DLBCL, based on significant clinical and biological differences from MGZL.

Mature T- and NK-Cell Neoplasms

- Both classifications downgraded *primary cutaneous acral CD8-positive T-cell lymphoma* to a LPD (although the WHO overview dropped "T-cell" from the name).
- Both classifications now recognize *indolent T-cell and NK-cell LPDs of the GI tract* and both acknowledge greater concern for possible progression among the T-cell–derived cases. The ICC preferred the term *indolent clonal T-cell LPD of the gastrointestinal tract* over *indolent T-cell lymphoma of the gastrointestinal tract*, as an indication that these lesions should not be approached clinically as conventional T-cell lymphomas.
- The ICC added *type II refractory celiac disease* to the classification as a precursor lesion for enteropathy-associated T-cell lymphoma.
- Both classifications recognize a largely unified group of *follicular helper T-cell lymphomas*, with three subtypes specified as (1) angioimmunoblastic, (2) follicular, and (3) NOS.

Immunodeficiency Disorders

- The ICC approach to the *immunodeficiency-associated LPDs* is similar to that of the 2016 WHO. The category of *posttransplant LPDs (PTLDs)* is retained, with the suggestion to classify non–post-transplant iatrogenic immunodeficiency-associated LPDs using similar principles. The ICC places major emphasis on the underlying disorder leading to immune deficiency because this has a major effect on clinical management and on the pathobiology of the

subsequent B-cell or T-cell proliferation. In contrast, the 2022 WHO has eliminated the category of *PTLD* from its classification, refocusing the cause of the immune deficiency to a secondary factor. The WHO proposal combines all *lymphoid proliferations and lymphomas associated with immune deficiency and dysregulation* under a common heading, which is then further subdivided into (1) hyperplasias, (2) polymorphic LPDs, (3) lymphomas arising in immune deficiency/dysregulation, and (4) those occurring in the setting of inborn errors of immunity.

This approach had been rejected by the 2021 CAC and ICC because of the clinical importance of a PTLD diagnosis, the extensive PTLD literature that does not necessarily pertain to the other immune deficiency–associated LPDs, difficulties sometimes with the subjective assessment of histologic type of PTLD, the major differences between many of the iatrogenic-associated LPDs and HIV-associated lymphomas, and the fact that some PTLDs are of T-cell type. These issues are more fully discussed in **Chapters 28**, **53**, and **54**.

CONCLUSION

The ICC classification is a continuation of the successful international collaboration among pathologists, biologists, and clinicians interested in the hematologic malignancies.[1] The 2001 WHO classification was rapidly adopted for clinical trials and successfully served as a common language for scientists comparing genetic and functional data. The explosion of data derived from high-throughput genomic studies conducted over the past few years

addressed many ambiguities in the classification, although advances will continue to occur. The chapters that follow embrace these new data and provide guidelines for accurate diagnosis and patient management.

Pearls and Pitfalls

- The accurate diagnosis of lymphoid neoplasms requires integration of morphologic immunophenotypic, genetic, and clinical features.
- Obtaining an adequate clinical history is a key part of the diagnostic process. If you do not get an adequate clinical history, ask for it.
- Properly fixed and sectioned material is essential for accurate histologic interpretation.
- Making the primary diagnosis of lymphoma on a core biopsy specimen may be hazardous. If the biopsy specimen is insufficient, defer your final diagnosis.
- Order sufficient immunohistochemical stains to address the differential diagnosis, but do not order a huge panel of stains irrelevant to the diagnostic question.
- The judicious use of cytogenetic and genetic sequencing studies may be key to the recognition of some disease entities.

- Chronic lymphocytic leukemia/Small lymphocytic lymphoma (proposed World Health Organization [WHO] 5th edition)[3,4]

Definition of Disease

B-cell chronic lymphocytic leukemia (B-CLL) is a clonal disorder of mature B lymphocytes with specific immunophenotypic features. Updates to the diagnosis, classification, and workup of lymphoid neoplasms, including chronic lymphocytic leukemia (CLL), have been made.[1,2,3,5] CLL is heterogenous and encompasses a diverse spectrum of morphologic, immunophenotypic, and genetic variants (see **Table 13-1**).[1,6-9]

The CLL leukemia cells are characterized by small, round nuclei; highly condensed chromatin; inconspicuous nucleoli; scant cytoplasm; and unique immunophenotype (IP). Admixed are occasional large prolymphocytes with prominent nucleoli, which usually account for less than 10% of leukemic cells.[1,2,7]

Peripheral blood and bone marrow are typically involved in CLL. Lymph node is, by definition, the primary site of involvement in small lymphocytic lymphoma (SLL). Liver and spleen are also often involved; involvement of other extranodal sites occurs less frequently.[2,10]

Diagnostic criteria for CLL per ICC and proposed WHO guidelines include that, in the absence of extramedullary tissue involvement, there must be a sustained, persistent monoclonal lymphocytosis of $\geq 5.0 \times 10^9$/L with a CLL IP in the peripheral blood (PB).[1,3] Although bone marrow lymphocytosis is also present, bone marrow

examination is often not required for a diagnosis of CLL.[7] Exceptions include patients with unexplained cytopenias in whom bone marrow evaluation is indicated.[11] Many CLL cases can be successfully diagnosed by morphologic review of blood smears with immunophenotypic confirmation.[7,10] Prognostic workup is also typically done on the PB.

Table 13-1

Primary Entities and Variants/Subtypes

Entity	Variants/Subtypes
CLL/SLL[†]	Atypical CLL (morphology) Atypical CLL (immunophenotype) Accelerated CLL CLL with Hodgkin (Reed-Sternberg) cells Transformations of CLL/SLL
Monoclonal B-cell lymphocytosis	Low count and high count
B-prolymphocytic leukemia	*MYC* or *TP53* mutation(s) subtypes Not recognized as such in proposed WHO 5th edition

CLL/SLL, Chronic lymphocytic leukemia/small lymphocytic lymphoma.

[†] Borderline with monoclonal B lymphocytosis in blood, bone marrow, and lymph node important to appreciate.

Hodgkin lymphoma variant of Richter transformation: morphology, Epstein-Barr virus status, clonality, and survival analysis—with comparison to Hodgkin-like lesion. *Hum Pathol*. 2016 Sep;55:108-116; Autore F, Strati P, Laurenti L, et al. Morphological, immunophenotypic, and genetic features of chronic lymphocytic leukemia with trisomy 12: a comprehensive review. *Haematologica*. 2018 Jun;103(6):931-938.

The term *SLL* is used for non-leukemic cases (i.e., below 5.0 × 10^9/L threshold) with the tissue morphology and IP of CLL.[1,2] The distinction between CLL versus SLL is based primarily on disease distribution and the number of circulating leukemia cells. Disorders with a predominant extramedullary disease distribution and <5.0 × 10^9/L circulating leukemia cells in blood are termed *SLL* (see **Box 13-1**).[2] Within the lymph node, larger cells (so-called "prolymphocytes/paraimmunoblasts") often form pale foci called *proliferation centers* in a background of monotonous small lymphocytes.

CLL and SLL have been generally regarded as the same disease with different manifestations, although differences in chemokine and

integrin expression, as well as genetic differences, may explain why some cases are primarily “leukemia” and others “lymphomatous.”[12]

Richter transformation (RT) is defined as transformation of CLL into a more aggressive lymphoma. It occurs in 2% to 10% of CLL/SLL patients. The vast majority of transformations are to diffuse large B-cell lymphoma (RT-DLBCL), although transformation to Hodgkin lymphoma (RT-HL) sometimes occurs.[2,13,14] Rarely, transformation to other types of lymphomas may occur.[14-21]

Epidemiology and Incidence

CLL is the most common leukemia of adults in Western countries. Because of prolonged survival rates, the prevalence of CLL is steadily increasing.[22] CLL is also the most common familial leukemia.[1,22-24] The incidence of CLL rises dramatically with age, and the incidence reaches 50 per 100,000 in men older than 80. CLL is more common in men than in women, with a male-to-female ratio of 1.9:1.[25] It is most commonly diagnosed in the 70-to-79 years age group, with a median age at diagnosis of 73 years.[7,23,25,26] A study on CLL in patients younger than 55 years reveals slightly different biology and clinical course than CLL in older patients.[27] Younger patients are more likely to have Rai stage I or II disease, with immunoglobulin heavy chain variable region genes (IGHV) unmutated, and ZAP70 expression. The time to treatment is shorter compared with older patients. Although survival of CLL patients younger than 55 years is longer than older CLL patients, their survival is profoundly shortened compared with the age-matched and sex-matched normal population.[27] CLL has also been reported in adolescents and young adults (AYA).[28] In one large series of AYA patients, disease course

and outcome generally correlated with similar prognostic markers as seen in older patients. Factors linked to overall survival (OS) included advanced stage, elevated beta2-microglobulin level, unmutated IGHV, del(11q) and del(17p).[28] CLL is very rare in the Asian population, although data have shown an increase in incidence, suggesting an environmental role.[29]

Box 13-1 Major Diagnostic Criteria of Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

CLL, Chronic lymphocytic leukemia; *IgD,* immunoglobulin D; *IgM,* immunoglobulin M; *SLL,* small lymphocytic lymphoma.

CLL

- Sustained absolute mature, monoclonal lymphocytosis ≥5 × 10^9/L
- Monoclonal B cell with mature phenotype, CD5 and CD23 co-expression, weak CD20, weak CD22, weak SIg (IgM/IgD)

SLL

- Extramedullary sites of disease predominate, especially lymph node
- Diffuse infiltrate of small lymphocytes, proliferation centers
- Monoclonal B cells <5.0 × 10^9/L in blood
- Monoclonal B cell with mature phenotype, CD5 and CD23 co-expression, weak CD20, weak CD22, weak SIg (IgM/IgD)

Data from Sander B, Campo E, Hsi ED. Chronic lymphocytic leukaemia/small lymphocytic lymphoma and mantle cell lymphoma: from early lesions to transformation. *Virchows Arch*. 2023 Jan;482(1):131-145. *Erratum in: Virchows Arch*. 2023 Jan 12.

Environmental, medical, and occupational risk factors for CLL have been extensively studied with inconclusive results. Studies linking CLL with radiation exposure have had inconsistent findings as well. Most studies on populations exposed to environmental, medical, or occupational sources of ionizing radiation have not found evidence of a connection.[30-32] Chemical exposures do appear to be associated with increased risk for developing CLL, particularly in farmers and other agricultural workers, rubber workers, and petroleum workers.[33]

Genetic factors play a role in the pathogenesis of CLL. Family history of CLL or other related diseases—such as monoclonal B-lymphocytosis (MBL) and non-Hodgkin lymphoma, especially low-grade B-cell lymphoma—is one of the strongest risk factors for the development of CLL.[7,24] In epidemiologic case-control and cohort studies, the relative risk for CLL in first-degree relatives of CLL patients is increased 6-fold to 12-fold.[34] The risk for developing other lymphoproliferative neoplasms (LPNs) and MBL is also increased.[35,36] Familial CLL patients present about 10 years earlier than those with sporadic CLL and may have a more aggressive clonal expansion.[24]

Clinical Features

CLL typically occurs in older adult patients who usually have an indolent clinical course. Up to 80% of patients are asymptomatic at presentation, and the disease is discovered incidentally by routine complete blood count (CBC) and blood smear review.[1,37] Other patients may present with various signs and symptoms, including peripheral lymphadenopathy, hepatosplenomegaly, autoimmune cytopenia, systemic symptoms (weight loss, fever, night sweats), or cytopenia-related symptoms (weakness, fatigue, or bleeding). Low-level monoclonal paraprotein may present in up to 50% of CLL patients.[38]

Cytopenia is often related to leukemic infiltrate of the bone marrow, leading to compromised hematopoiesis. Cytopenia can also be secondary to autoimmune phenomenon, hypersplenism, treatment, or non–CLL-related etiology. Autoimmune complications are seen in 4% to 25% of CLL/SLL patients and include autoimmune hemolytic anemia (AIHA), immune thrombocytopenic purpura (ITP), pure red cell aplasia, and autoimmune agranulocytosis.[39-41] AIHA is reported in 2% to 25% of CLL patients, whereas ITP is seen in approximately 2% of CLL patients.

CLL is associated with a profoundly impaired immune system resulting in recurrent infections or failure of antitumor immune response. CLL patients have a decreased number and function of B cells, resulting in defective humoral immunity. These patients also have defective cell-mediated immunity with decreased T-cell subsets and natural killer (NK) cells. Abnormalities in complement activity, in monocytes, and in neutrophils are also common. CLL patients may also have an increased number of regulatory T cells and nurselike cells.[42,43] Hypogammaglobulinemia is common in CLL

and is a contributing factor to recurrent infections. Its severity increases with duration and stage of the disease.[40] Although there is still limited understanding of the initiating events of immunodeficiency in CLL, reports indicate that progressive loss of plasmacytoid dendritic cell (pDC) function underlies the major immunodeficiency affecting CLL patients.[44] pDCs are highly specialized immune cells that play a major role in promoting innate and adaptive immune responses. Decreased pDC function results in decreased interferon alpha (IFNα) production, and the latter is a cytokine that is critical in immunity and has well-described antitumor activity.[44]

Morphology

Lymph Node

SLL accounts for about 5% to 10% of CLL/SLL overall.[10] Genetic abnormalities [a high incidence of trisomy 12 and lower incidence of del 13(q)] are more common in lymph node in CLL patients than in bone marrow. These differences may underlie the different clinical presentations.[12]

Lymph node involvement in CLL/SLL is generally characterized by diffuse effacement of the architecture with variably preserved sinuses.[1,2,10] The infiltrate consists of small, round lymphocytes with condensed chromatin and scanty amounts of cytoplasm, imparting a dark color on low magnification. Mitotic activity is virtually absent in these areas. Interspersed among these diffuse sheets of small, round lymphocytes are proliferation centers that produce a vague, pale, nodular pattern (**Fig. 13-1A**).[2,10] On high magnification, proliferation centers are composed of larger lymphoid cells (so-called

"prolymphocytes" and "paraimmunoblasts") with more abundant cytoplasm and more conspicuous nucleoli (**Fig. 13-1B–C**). By assessment of DNA synthesis such as Ki67 staining, these proliferation centers represent the mitotically active portion of the neoplastic clone. It is important to recognize that proliferation centers may be cyclin D1 positive in ~20% of cases.[45] Although lacking *CCND1* translocations, this cyclin D1 expression may mislead the diagnostician into considering a diagnosis of mantle cell lymphoma (MCL). Enhanced MYC expression protein has also been documented in proliferation centers in CLL/SLL lymph nodes, also not associated with rearrangement or gain of function of the *MYC* gene.[46]

Occasionally, proliferation centers may be very large and confluent, raising concern for transformation to large cell lymphoma (**Fig. 13-2**).[10,47] In these lymph node sections, proliferation centers are expanded and contain larger lymphoid cells with increased mitotic activity (**Fig. 13-2C**).[47] Low magnification assessment is essential to detect the vague macronodular appearance of these expanded proliferation centers to avoid an incorrect diagnosis of overt diffuse large cell lymphoma, RT, in these cases. Although expanded accelerated proliferative centers are linked to a more aggressive disease course and a higher rate of overt large cell lymphoma transformation, distinction from overt large cell lymphoma is still important. Studies report that artificial intelligence–assisted mapping of proliferation centers can aid in the distinction of this process from overt diffuse large cell lymphoma.[48]

In a minority of CLL/SLL cases, the pattern of lymph node infiltration is interfollicular or exhibits a perifollicular/marginal

zone-type pattern, resulting in potential differential diagnostic confusion with MCL, marginal zone lymphoma (MZL), or other B-cell neoplasms.[49] Likewise, some cases exhibit greater nuclear irregularity of the small lymphocytes, reminiscent of MCL or even follicular lymphoma (FL).[10] However, the presence of proliferation centers, the distinctive immunophenotypic profile including LEF1 expression, and the absence of cyclin D1 and SOX11 expression support a diagnosis of CLL/SLL, as long as cyclin D1 expression in proliferation centers is taken into account (see the section on differential diagnosis).[2,10,45,50,51] In some lymph node biopsy specimens assessed by upfront flow cytometric immunophenotyping (FCI), a small CLL/SLL-type clone will be detected that is not apparent on morphologic review. Inconspicuous, small lymph node infiltrates of CLL/SLL cells that are found in lymph nodes that are not enlarged, do not form proliferation centers, and do not efface architecture, are regarded as nodal monoclonal B lymphocytosis.[1,2] However, in patients with multiple sites of nodal enlargement, there is the possibility that overt CLL is present in other sites.

Spleen

Although the degree of splenomegaly is highly variable in CLL patients, some patients exhibit significant and symptomatic splenic involvement. Splenic involvement by SLL/CLL is characterized by white pulp expansion producing a miliary micronodular appearance grossly (**Fig. 13-3**).[52] The white pulp infiltrates consist of small, round lymphocytes with scant cytoplasm similar to those seen in lymph node (**Fig. 13-4**). Although occasional prolymphocytes and paraimmunoblasts may be present, typical proliferation centers

generally are not readily apparent. Extension of the lymphoid infiltrate into the periarteriolar lymphoid sheath, along the splenic trabeculae, and into both the red pulp cords and sinuses is common.[52]

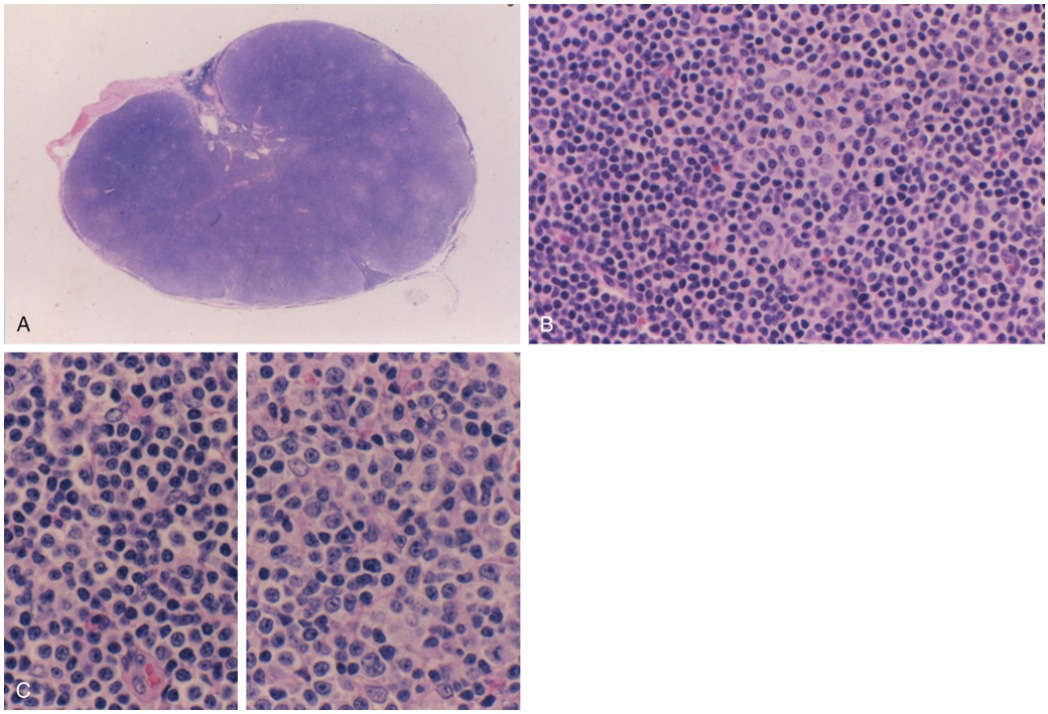

FIGURE 13-1 **A,** Low-power photomicrograph of a lymph node shows diffuse effacement with multiple pale proliferation centers. **B,** High-power photomicrograph of proliferation center in a lymph node illustrates larger lymphoid cells with more abundant cytoplasm and more dispersed nuclear chromatin. **C,** This composite illustrates the side-by-side comparison of the small lymphocytes of chronic lymphocytic leukemia/small lymphocytic lymphoma *(left)* with the larger lymphoid cells comprising a proliferation center *(right)*.

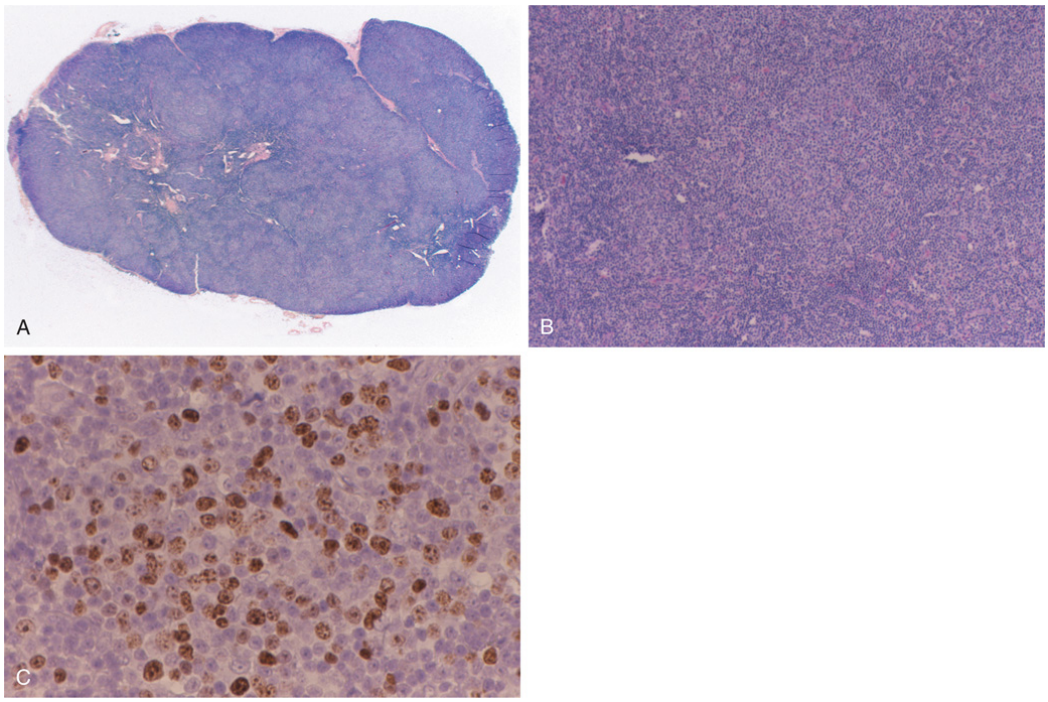

FIGURE 13-2 **A,** More prominent and confluent pale proliferation centers (so-called "accelerated") are evident on this low-power photomicrograph of a lymph node in a patient with accelerated chronic lymphocytic leukemia/small lymphocytic lymphoma. **B,** Higher-power magnification shows confluent pale proliferation centers. **C,** Ki67 positivity is fairly prominent in the confluent proliferation centers in this case (H&E and Ki67 stains by immunoperoxidase).

Blood

A mature lymphocytosis is a diagnostic requirement for CLL, with at least 5.0×10^9/L as a minimum absolute monoclonal lymphocyte count with CLL IP (see **Box 13-1**).[1,2] These lymphocytes are typically

monotonous with relatively homogeneous features, including small, round nuclei with highly condensed nuclear chromatin and inconspicuous nucleoli (**Fig. 13-5**). The exaggerated chromatin clumping may give a “cracked mud/soccer ball” appearance to these nuclei. These leukemic lymphocytes are easily disrupted during smear preparation, creating smudge cells, which may be numerous (**Fig. 13-6**). Larger lymphoid cells or lymphocytes with irregular nuclear contours may be evident, but these cells usually comprise less than 2% of the leukemic population (**Fig. 13-7**). In cases in which these “atypical” forms are conspicuous, a diagnosis of atypical/mixed CLL or CLL/prolymphocytic may be preferred to convey to the clinician these aberrant morphologic features (see the section on morphologic variants).[53] In general, the agranular cytoplasm is scant, but some CLL cases will demonstrate moderate amounts of cytoplasm. Distinctive cytoplasmic vacuoles, crystals, or globules are noted occasionally.[54]

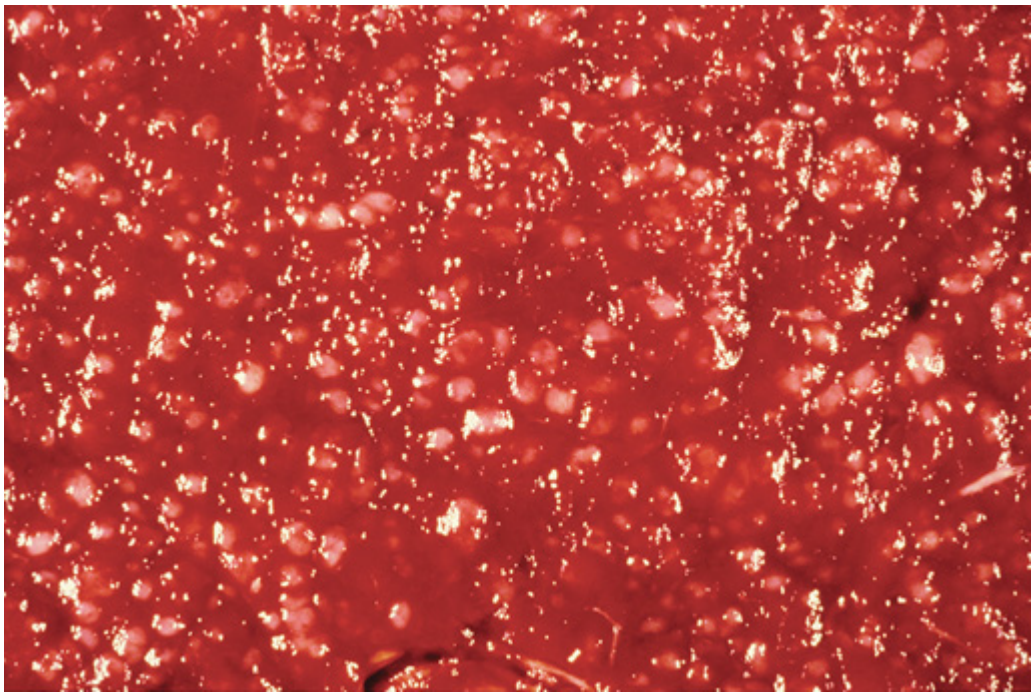

FIGURE 13-3 Photograph of a spleen in a patient with chronic lymphocytic leukemia/small lymphocytic lymphoma shows a miliary white-pulp pattern of infiltration (Gross).

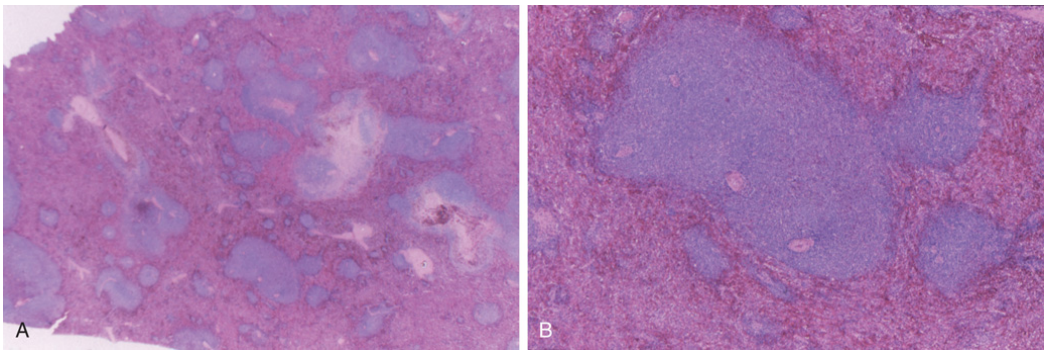

FIGURE 13-4 Expanded dark-staining white-pulp infiltrates of chronic lymphocytic leukemia/small lymphocytic lymphoma are evident at low **(A)** and intermediate **(B)** magnification in this spleen.

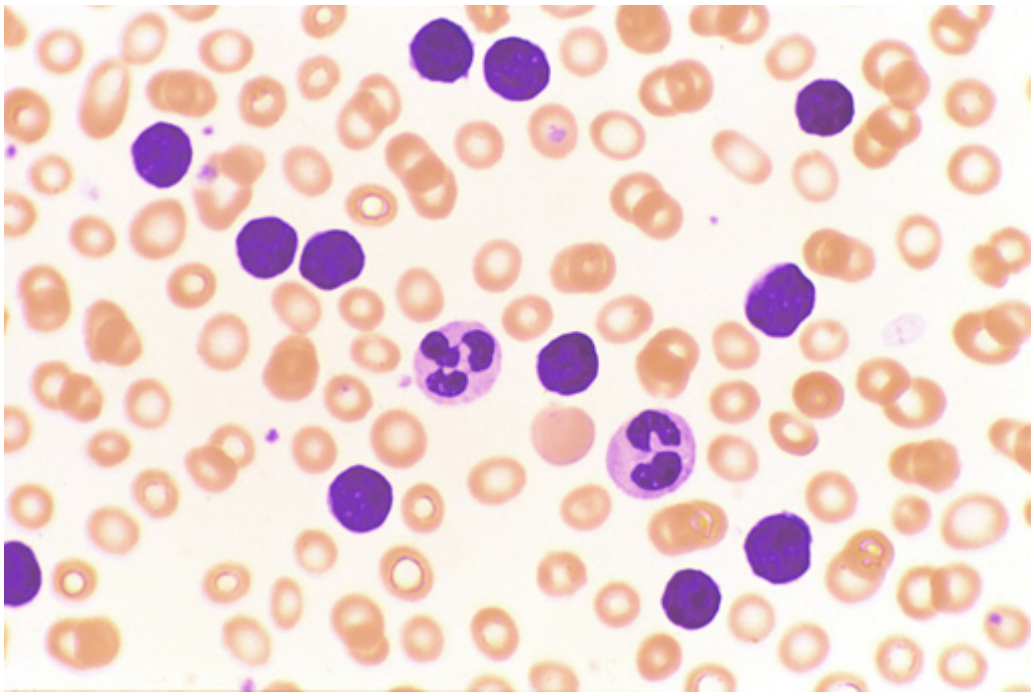

FIGURE 13-5 A marked mature lymphocytosis characterized by round nuclei with highly condensed chromatin and scant cytoplasm is evident in blood from a patient with chronic lymphocytic leukemia (Wright's stain).

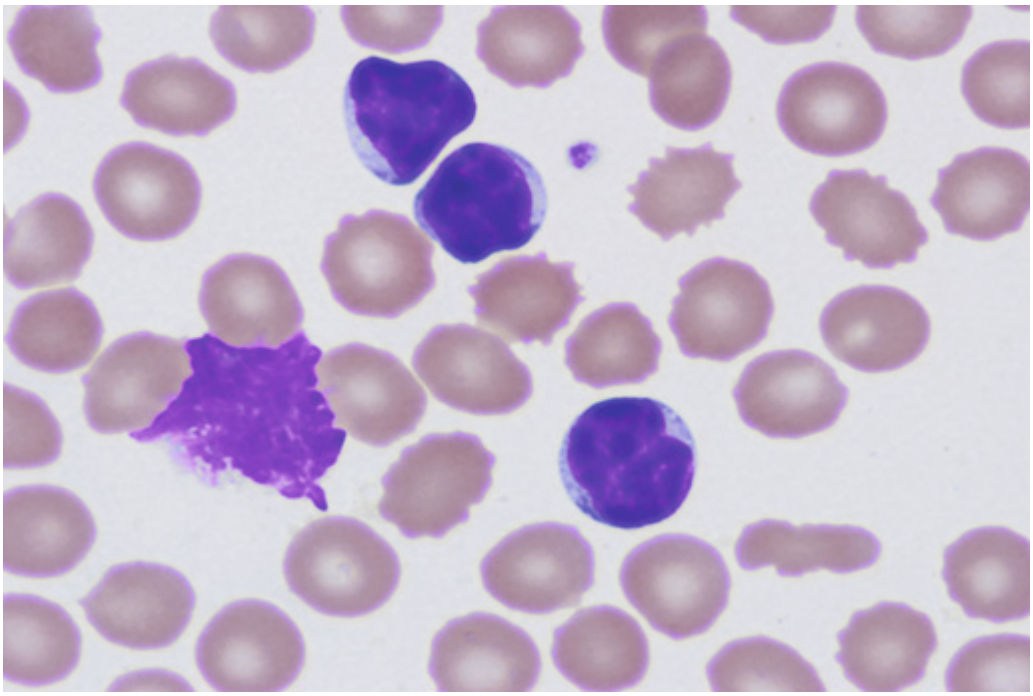

FIGURE 13-6 Broken chronic lymphocytic leukemia (CLL) cells (so-called "smudge cells") are evident on this peripheral blood smear from a patient with CLL. Smudge cells consist largely of nuclear material (Wright's stain).

The number of prolymphocytes, clonal cells with a larger nuclear size and a single, distinct nucleolus, should be assessed (see **Fig. 13-7**). In some patients, an increasing proportion of prolymphocytes may be a harbinger of clonal transformation, whereas other stable CLL cases demonstrate consistently high numbers of prolymphocytes.[55,56] Any significant change in the blood picture should prompt reevaluation of the patient's disease status.

Bone Marrow

Although not usually necessary for diagnosis, bone marrow examination in CLL patients may be useful in assessing residual

hematopoiesis and in determining the pattern and extent of bone marrow effacement. On aspirate smears, CLL cells exhibit similar cytologic features to circulating clonal cells (see **Box 13-2**).[56] These small, mature lymphocytes are generally abundant on aspirate smears, although variability is expected because of the multifocal nature of neoplastic infiltration of the bone marrow. The extent of bone marrow replacement by CLL generally parallels the proportion of lymphocytes on differential cell counts, although the extent of disease is best assessed on core biopsy specimens. In most cases, there is substantial residual preserved hematopoiesis, reflecting the typical blood finding of normal red blood cell, neutrophil, and platelet counts.

On core biopsy sections, the pattern of bone marrow infiltration may be useful for both distinction of CLL from other differential diagnostic considerations and in possibly providing prognostic information.[56-58] In CLL, the bone marrow core biopsy may exhibit a range of infiltration patterns including focal, non-paratrabecular nodules; an interstitial infiltrate in which CLL cells are admixed with hematopoietic elements; and effacing diffuse solid lesions (Figs. **13-8** and **13-9**). Multiple patterns may be evident in a single core biopsy specimen. The typical nodular infiltrates of CLL are readily apparent on low magnification because their dark appearance is quite distinct from paler normal hematopoietic cells. This dark appearance is caused by closely packed nuclei with scant cytoplasm that typifies this disorder (see **Box 13-2**). On high magnification, the densely packed nuclei exhibit round contours and minimal, if any, mitotic activity. The borders of these non-paratrabecular nodules may show infiltrative margins with diffusion of lymphocytes into adjacent

hematopoietic tissues. Likewise, diffuse interstitial infiltrates of CLL may be evident throughout the bone marrow widely separated from discrete nodular lesions. In these interstitial areas, adipose cells and hematopoietic elements are at least partially preserved; note that the CLL infiltrates impart a darker appearance on low magnification than uninvolved bone marrow (see **Fig. 13-8**). The most extensively effaced bone marrow core biopsy sections are characterized by solid areas of complete replacement of both hematopoietic and fat cells by CLL filling the entire hematopoietic cavity between bone trabeculae. The presence of extensive diffuse, solid infiltrates would predict for cytopenia(s) and, consequently, higher clinical stage. Similarly, a diffuse pattern of bone marrow infiltration has also been linked to ZAP70 expression.[58] The extent of bone marrow effacement in CLL is best estimated from technically optimal core biopsy specimens of at least 10 mm in length that do not consist of significant portions of hypocellular subcortical regions.

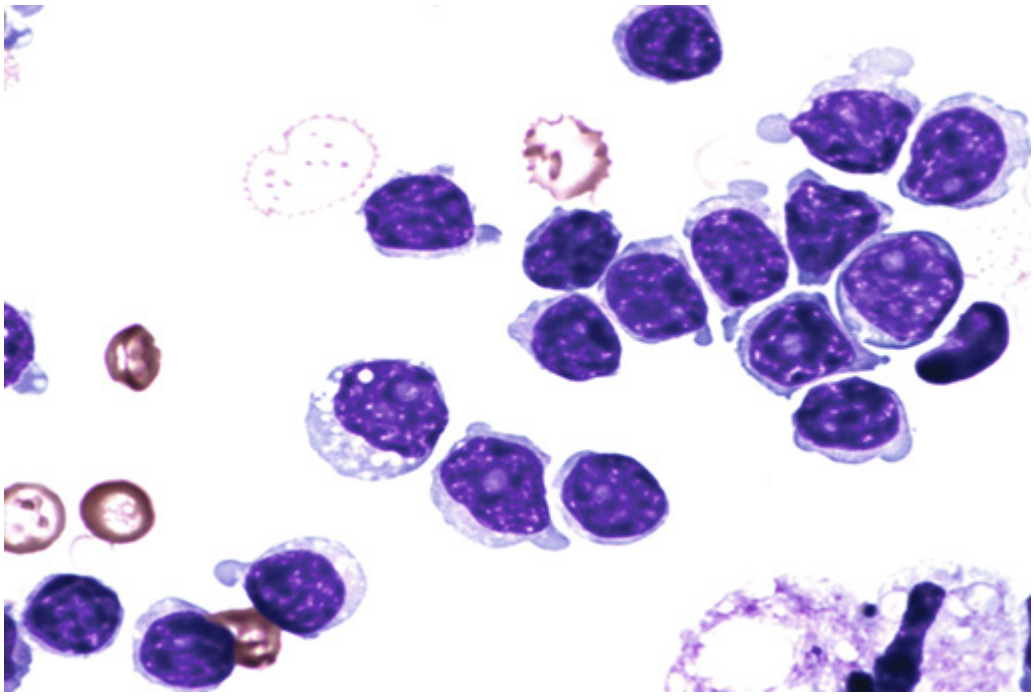

FIGURE 13-7 Larger lymphoid cells with more dispersed chromatin and distinct nucleoli (so-called "prolymphocytes") are evident on this cytospin in blood from a patient with chronic lymphocytic leukemia (Wright's stain).

Box 13-2 Bone Marrow in Chronic Lymphocytic Leukemia

Morphology

- Small lymphoid cells with round nuclear contours, condensed chromatin, and inconspicuous nucleoli analogous to appearance in blood

- Extent of bone marrow involvement variable; ≥30% lymphocytes is considered characteristic

Core Biopsy

- Non-paratrabecular lymphoid nodules with closely packed round nuclei, scant cytoplasm, and minimal mitotic activity
- No predilection for paratrabecular localization
- May also see a diffuse increase in interstitial lymphocytes admixed with hematopoietic elements
- Diffuse solid bone marrow effacement relatively uncommon
- Proliferation centers may be present, but true germinal centers only rarely described

---

Data from: Sander B, Campo E, Hsi ED. Chronic lymphocytic leukaemia/small lymphocytic lymphoma and mantle cell lymphoma: from early lesions to transformation. *Virchows Arch*. 2023 Jan;482(1):131-145. *Erratum in: Virchows Arch*. 2023 Jan 12; Foucar K. Mature B- and T-cell lymphoproliferative neoplasms. In: Foucar K, Reichard R, Czuchlewski D. *Bone Marrow Pathology,* 4th ed. ASCP Press.

Although proliferation centers are a readily apparent, typical feature of nodal infiltrates of CLL/SLL, proliferation centers in bone marrow core biopsy/clot sections in CLL patients are not as distinct of a finding, possibly because of issues of specimen size and quality (**Fig. 13-10**). In one study, proliferation centers were evident on scanning in 75% of cases; no correlation was found between BM proliferation centers and any CLL parameters including flow cytometric IP and genetic features in this study.[59] Only very rarely

are true germinal centers evident in bone marrow specimens from CLL patients; the presence of these germinal centers should prompt systematic exclusion of other B-chronic lymphoproliferative neoplasms (B-CLPNs).[60] In rare CLL patients, foci of large cell lymphoma transformation will be first appreciated in bone marrow specimens. Because of the large overall cell size and the presence of moderate amounts of cytoplasm, these large cell lymphoma infiltrates are quite distinct, even on low magnification in which they are a pale pinkish color (see the section on transformation).

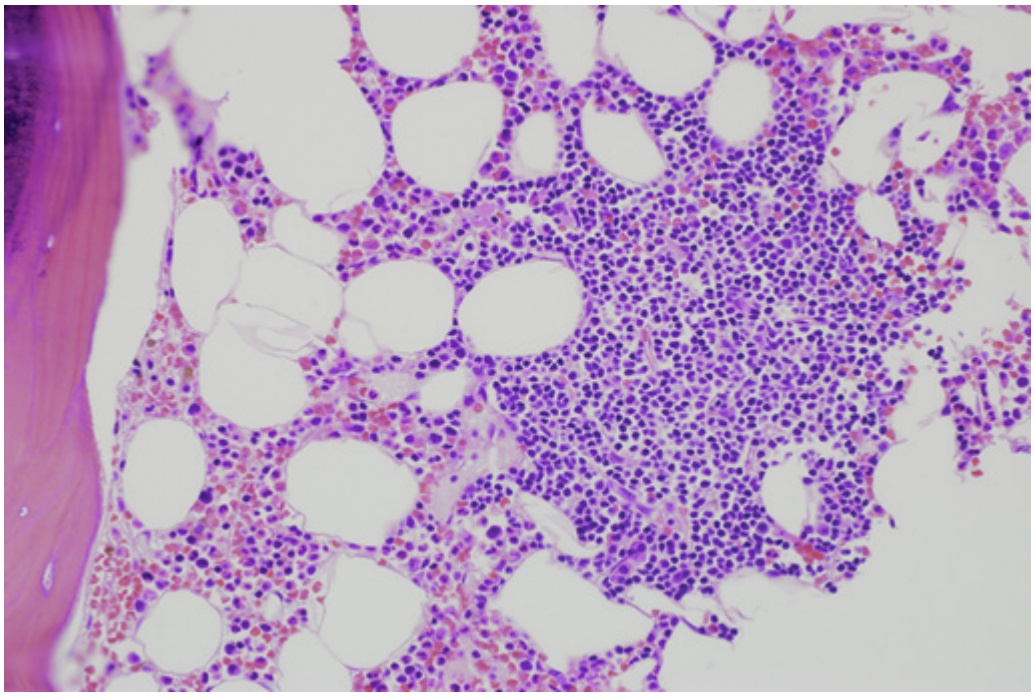

FIGURE 13-8 Bone marrow core biopsy section from a patient with chronic lymphocytic leukemia (CLL) illustrates a focal, non-paratrabecular infiltrate of leukemia.Note the dark blue color of this infiltrate caused by the back-to-back nuclei that typify CLL infiltrates.

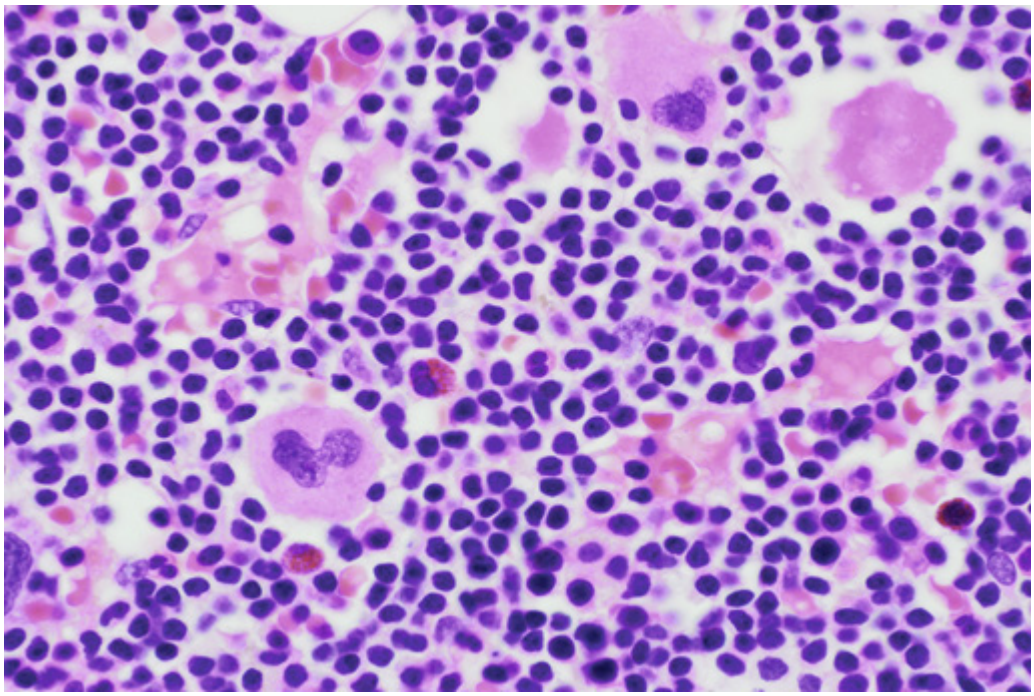

FIGURE 13-9 Bone marrow biopsy section from a patient with chronic lymphocytic leukemia illustrates the diffuse, interstitial infiltration that can occur in some patients. Note abundant preserved megakaryocytes.

Other Organs

Infiltrates of CLL in a variety of extramedullary/extranodal sites have been well described in autopsy reports and individual site-specific studies (Figs. **13-11** and **13-12**).[61] Leukemic infiltrates as a cause of disease manifestations have more recently focused on cases of CLL in the skin and central nervous system (CNS). Unique features of leukemia cutis include prevalence in cartilage-rich sites (ear, nostrils), likely association with prior cutaneous infections, and genetic features including trisomy 12, t(14;18) *(IGH::BCL2)*, and *NOTCH1* mutations.[62] Cutaneous CLL usually manifests at disease

presentation in otherwise low-stage CLL. Most cases showed dermal infiltrates of small lymphocytes with CLL IP; rare cases of cutaneous large cell lymphoma have also been reported in CLL patients.

Similarly, both CLL and RT (also called transformation) have been reported in the CNS.[63,64] CNS involvement by CLL is rare, about 4% of CLL cases, and is usually diagnosed by flow cytometry of CSF or by imaging studies with biopsy. The outcome of CLL patients with CNS involvement is better for previously untreated CLL patients and generally parallels the molecular genetic characteristics of the CLL (**Fig. 13-12**).[64]

Morphologic Variants

Atypical/Mixed Chronic Lymphocytic Leukemia

Any discussion of so-called "atypical CLL" (aCLL) must begin by pointing out that the term *aCLL* has been applied to cases based on either morphology or immunophenotyping (see **Box 13-3**). In addition, the definition of aCLL based on either morphology or immunophenotyping is neither standardized nor applied consistently.[53] Nonetheless, diagnosticians are very familiar with cases of likely CLL in which the morphology shows larger cells, prolymphocytes, or cells with nuclear irregularity, or the flow cytometry shows bright monotypic light chain expression or other aberrancies from the classic CLL flow profile (Figs. **13-13** and **13-14**).[53,55] Morphologic or immunophenotypic aberrancies should prompt consideration of other differential diagnoses, as well as prompting a thorough molecular genetic assessment to possibly delineate a genetic finding, such as trisomy 12 and *TP53*^{m}, that are both linked to aCLL (either morphologic or

immunophenotypic).[55,65-67] The diagnostician rendering a diagnosis of “atypical” should explain the justification for this label and indicate additional studies that could identify a genetic cause for the atypical diagnosis.

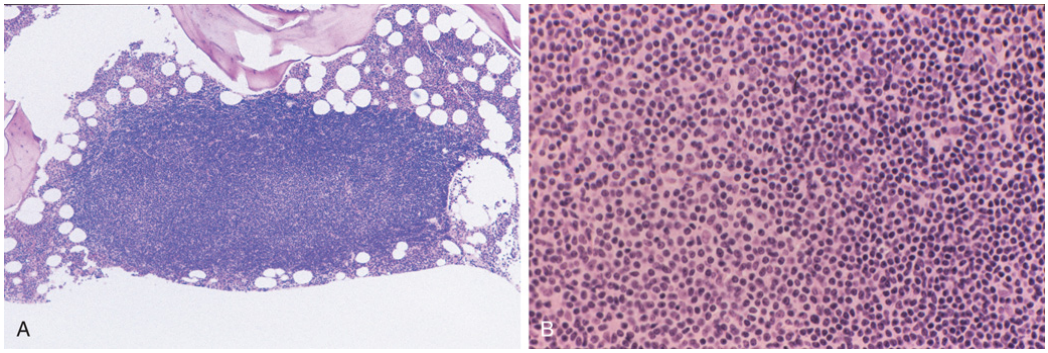

FIGURE 13-10 **A,** Low-power photomicrograph of a bone marrow core biopsy from a patient with chronic lymphocytic leukemia (CLL) illustrates a large focal infiltrate with a pale central proliferation center, a less common finding in bone marrow specimens than in lymph nodes. **B,** High-power photomicrograph shows the larger prolymphocyte-like cells *(left)* making up the proliferation center compared with the small, dark typical CLL cells *(right)* with scanty cytoplasm and highly condensed chromatin.

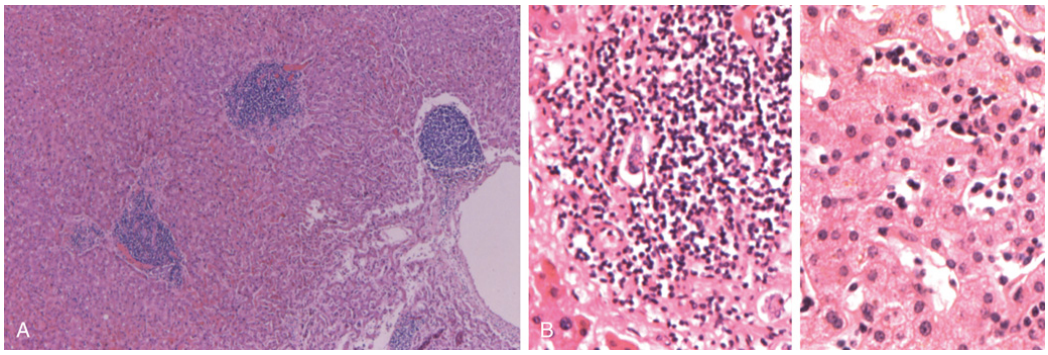

FIGURE 13-11 **A,** Low-power photomicrograph of liver from a patient with chronic lymphocytic leukemia (CLL) shows distinctive portal infiltrates. **B,** Composite of liver sections illustrates both portal and sinusoidal infiltrates in a patient with CLL/small lymphocytic lymphoma (SLL).

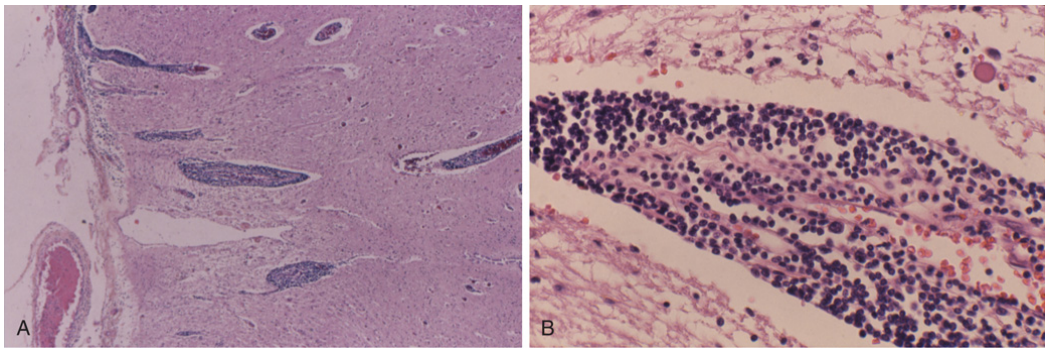

FIGURE 13-12 **A,** Low-power photomicrograph of brain from an autopsy on a patient with chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) shows prominent infiltration of dark lymphoid cells in Virchow-Robin spaces. **B,** On high power, the lymphoid infiltrate consists of small, round, mature lymphocytes with scanty cytoplasm typical of CLL/SLL.

Accelerated Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

As discussed, some cases of CLL/SLL show confluent and expanded proliferation centers with increased prolymphocytes and paraimmunoblasts or increased mitotic activity >40%[2,4,47] (see **Fig. 13-2** and **Box 13-3**). These cases are designated as accelerated CLL/SLL.[2] Although distinction from overt RT is important, the outcome for cases with this "accelerated" morphology is more adverse than prototypic CLL/SLL.[2,4,47]

CLL/SLL With Hodgkin (Reed-Sternberg) Cells

Hodgkin (Reed-Sternberg)–like cells can be encountered in CLL/SLL in two general patterns. One group manifests the clinical and hematologic features of straightforward stable CLL/SLL and the Hodgkin (Reed-Sternberg) cells are encountered as an incidental finding admixed with the sheets of small round lymphocytes that typify CLL/SLL (see **Box 13-3** and **Fig. 13-15**).[68] In other patients, the detection of Reed-Sternberg–like cells within CLL/SLL infiltrates is more suggestive of an overt transformation analogous to Hodgkin-type RT.[68] In the former group of cases, Hodgkin (Reed-Sternberg) cells are sparsely dispersed among extensive infiltrates of small, round lymphocytes, whereas more discrete areas of overt Hodgkin-like transformation may be encountered in the second group (see **Fig. 13-21**). In a single large series, including both patterns, overall outcome was similar in both groups. The Hodgkin (Reed-Sternberg) cells were typically Epstein-Barr virus (EBV) positive in both groups, and the incidence of clonality between the CLL and the Hodgkin cells was similar in both groups.[68]

Immunophenotype

Immunophenotypic assessment in CLL is essential not only in establishing the diagnosis but to assess for prognostic factors and distinguish CLL from other B-CLPN (see **Table 13-2**). The classic immunophenotypic profile of CLL is best determined by multicolor flow-cytometric immunophenotyping with evaluation of both intensity of antigen expression as well as patterns of antigen co-expression.[1,2,4,10,56] Prototypic CLL cases are characterized by expression of weak monotypic surface immunoglobulin (SIg), weak CD20, weak CD22, and weak-to-negative CD11c, CD79b, CD25,

CD103, CD81, and FMC7, whereas moderate expression of CD19, CD5, CD23, CD200, and ROR-1 is detected (**Fig. 13-16**).[2] Rare biclonal CLL cases have been described, although some of these cases may represent CLL and MBL.[69]

Box 13-3 Morphologic Variants of Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

B-CLPN, B-chronic lymphoproliferative neoplasms; *CLL,* chronic lymphocytic leukemia; *CLPN,* chronic lymphoproliferative neoplasm; *SLL,* small lymphocytic lymphoma.

"Atypical"/Mixed CLL

- Term generally applied to CLL cases in which nuclear irregularity is fairly prominent or increased numbers of lymphocytes with distinct nucleoli are present
- Cases exhibit morphologic and immunophenotypic spectrum with some, but not all, features of classic CLL/SLL; overlap with other B-CLPN is common
- Atypical features noted in both blood and lymph node specimens
- May be linked to distinct genotypic subtypes
- Linked to more advanced stage, adverse outcome, and rapid disease progression

Accelerated CLL

- Expanded proliferation centers with increased mitotic activity
- Linked to increased risk of overt Richter transformation

CLL With Reed-Sternberg (Hodgkin) Cells

- Large, pleomorphic cells with morphologic features of Reed-Sternberg cells may be admixed sparsely with otherwise typical CLL/SLL or compose a distinct type of lesion
- Hodgkin-like overt transformation; both groups are linked to adverse outcome
- Clonal link to background CLL/SLL established in some, but not all cases

Diagnostic difficulties occur when cases exhibit some but not all of the immunophenotypic features of classic CLL, and the term *aCLL* may be applied to these cases (see **Fig. 13-14**).[53,56] In these cases, other differential diagnostic considerations should be systematically excluded; correlation of IP with clinical and morphologic parameters is essential. Some otherwise straightforward CLL cases will exhibit an atypical immunophenotypic profile including either bright surface immunoglobulin, bright CD20, FMC7 expression, and, rarely, absent CD5 co-expression. However, the proportion of seemingly bona fide CLL cases that lack CD5 expression is low.[70] The diagnosis of CD5-negative CLL should be considered only after systematic exclusion of other B-CLPNs. Some bona fide CLL cases can exhibit a flow

cytometry IP indistinguishable from MCL, especially when more limited flow studies are performed.[71]

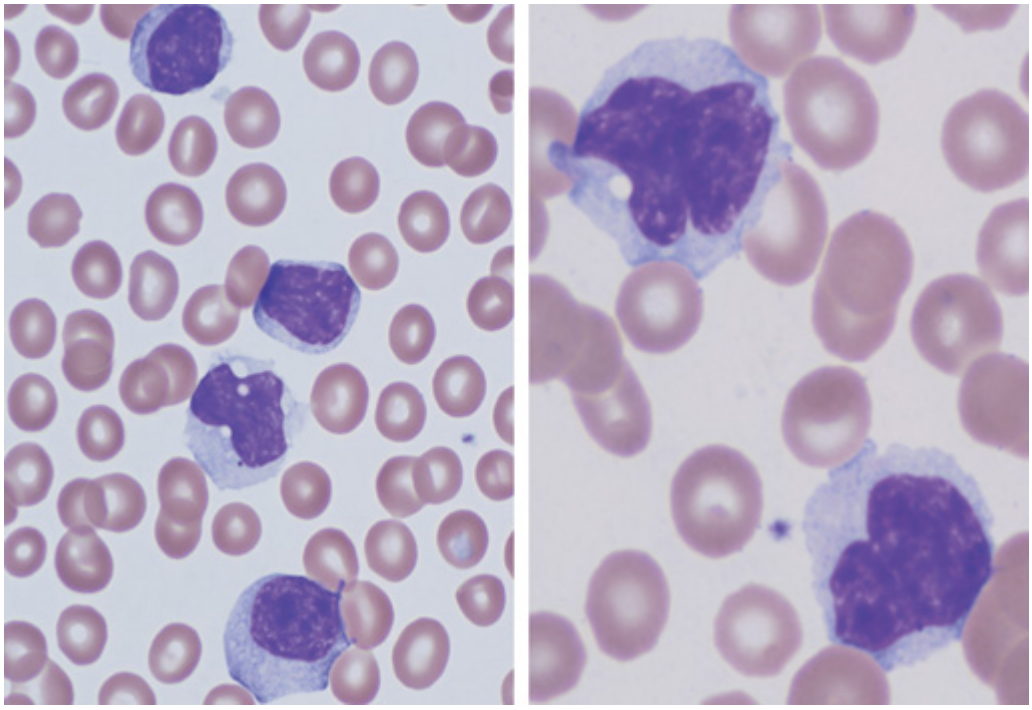

FIGURE 13-13 A composite of peripheral blood shows the range of atypical cells evident in two atypical/mixed chronic lymphocytic leukemia (CLL) cases.Cases of atypical CLL are linked to specific genetic abnormalities (Wright's stain).

Immunohistochemical (IHC) staining can also be used to assess CLL/SLL infiltrates in bone marrow and other sites (**Fig. 13-17**). Strong expression of nuclear LEF-1 is highly characteristic of CLL; LEF-1 is not expressed in other mature B-cell leukemia/lymphomas, but T cells are LEF-1 positive.[10,72] SOX11 is typically negative in CLL and positive in MCL, although SOX11 negative MCL has been reported.[72,73] The intensity of CD20 and CD5 expression can be

assessed by IHC, although evaluation by flow-cytometric immunophenotyping is more optimal for this type of qualitative assessment. Importantly, cyclin D1 assessment by IHC is essential to detect cases of MCL, although the diagnostician must be aware that proliferation centers in CLL/SLL may show dim cyclin D1 positivity in about 20% of cases.[45] Other potential challenges in the IHC assessment for CLL/SLL are that rare cases of MCL may be CD23 and CD200 positive, and cases of SOX11-negative MCL have also been reported, especially in non-nodal leukemic MCL, which is often the main differential diagnostic consideration in blood and bone marrow specimens.[73,74]

In addition to establishing the diagnosis of CLL/SLL, multiparameter FCI provides substantial prognostic information (see Tables **13-2** and **13-4**) (see the section on clinical course and prognosis). The flow-cytometrically detected antigens of greatest prognostic significance are CD38, ZAP70, and CD49d.[75-80] Overexpression (≥30% of leukemia cells) of any of these antigens is linked to adverse outcome (**Fig. 13-18**). Assessment of CD38 and ZAP70 has been largely replaced by CD49d assessment, since multi-institutional studies indicate that CD49d expression is the most significant and robust flow prognosis marker.[75]

Genetic and Molecular Features

Genomic abnormalities in CLL have been demonstrated to have important implications for disease behavior, prognosis, and treatment decisions. At minimum, complete workup of CLL requires assessment of cytogenetic abnormalities, IGHV mutational status, and identification of *TP53* mutations.[1,81,82] Additional information can be gained from assessment of BCR stereotypes and assessment of additional genomic alterations including mutations in *NOTCH1, BIRC3, SF3B1, BTK, PLCG2,* and *BCL2*.[2,3,83-86] Cytogenetic and fluorescence in situ hybridization (FISH) studies for recurrent abnormalities are well-recognized customary components of the workup for CLL. Commercial FISH panels are available to assess for the most common recurrent abnormalities. More than 80% of CLL cases have acquired chromosomal abnormalities, including deletions of 13q14, 17p13, 11q22-23, and trisomy 12 (**Table 13-3**).[87] These alterations are neither sensitive nor specific for a CLL diagnosis, as they are absent in 20% of CLL cases and may be seen in other malignancies, including B-cell lymphomas, and have also been identified in normal patients.[88] Standard karyotype can identify

additional abnormalities to those detected by commonly used FISH panels, including deletion of 6q21, gain of 2p, and recurrent translocations such as t(14;19). In addition to assessment of cytogenetic abnormalities, testing for IGHV mutational status is a standard of care in CLL providing key prognostic information. This testing can also identify specific variant chain usage, which plays a role in disease pathogenesis and clinical behavior.[9,89-91] *TP53* aberrations, including mutational status, have been established as a key driver of poor prognosis and resistance to treatment.[8,92] Although not formally incorporated into current risk stratification schemes and treatment guidelines, identification of BCR stereotyped receptors, which use a restricted set of IGH gene segments, can predict response to treatment with BCR inhibitors such as ibrutinib.[8,91] Somatic mutations in a number of genes, including *SF3B1, ATM, NOTCH1,* and *TP53,* have been identified as having diagnostic or prognostic effect and are increasingly being incorporated into the clinical workup of CLL.[9] These mutations are generally associated with unfavorable prognosis and poor treatment response. *TP53* mutations, for example, are associated with poor outcomes and have been formally incorporated into National Comprehensive Cancer Network and European Research Initiative on CLL guidelines.

Cytogenetic Abnormalities

Because the neoplastic cells in CLL are resistant to replication in culture, older studies of CLL underestimated the number of cytogenetically abnormal cases. Introduction of B-cell mitogens has improved the ability of conventional karyotyping to detect clonal abnormalities in CLL.[93] With these methods, abnormalities may be detected at a rate similar to that of interphase FISH.[94] However, the use of FISH panels allows consistent detection of even small deletions, and these panels are standardly used in the workup for CLL. The most common abnormalities are deletion of 13q, trisomy 12, deletion of 11q, and deletion of 17p. Karyotyping and other methods of chromosome evaluation such as microarray and optical genome mapping can demonstrate additional recurrent abnormalities, most commonly deletion of 6q, gain of 2p, and translocations, and can also identify cases with complex karyotypes. These additional abnormalities are associated with adverse outcome. The ability to detect recurrent abnormalities by conventional karyotyping or FISH testing has allowed more refined risk

stratification and is recommended at diagnosis or disease progression in CLL.[95]

13q Deletion

Deletion of 13q14 is the most common cytogenetic abnormality in CLL and is seen in 50% to 80% of cases either as the sole abnormality or with other alterations.[96] Deletion of 13q is more common with PB involvement than in tissue disease. The deletion may be monoallelic or biallelic, with a subset of cases showing a mixture of both monoallelic and biallelic deleted cells. This suggests that loss of the second copy may represent a clonal evolution in a subpopulation of cells, although biallelic deletion does not consistently correlate with more advanced or aggressive disease. Deletion of 13q14 occurs in other hematopoietic neoplasms, including MCL and myeloma. Deletion of this region can occur through multiple pathways, including complete loss of the chromosomal arm, interstitial deletion ranging in size from 300 Kb to more than 70 Mb, loss of heterozygosity, and through unbalanced translocations.[97] In addition, epigenetic modifications may silence genes in this region. Cases with high percentage of 13q deletion have shorter time to first treatment and shorter OS; however, the percentage used to define this group has not been consistent between studies.

Genes and microRNA coding regions of interest are located in this region and may play a role in the pathogenesis of CLL. The best studied of these is the *RB1* tumor suppressor gene, although it has been demonstrated that this gene is preserved in the characteristic microdeletion type of 13q14 deletion.[98] It is therefore not believed to

be a key player in CLL development. Deletion of *RB1* is detected in 41% of cases.[99] Studies have shown conflicting clinical effects of loss of the *RB1* gene, with some showing deletion correlating with shorter time to first treatment and lower OS[100] and others showing no effect.[99,101,102] Other genes in this region, including *DLEU1* and *DLEU2,* have also been investigated.

DLEU1 and *DLEU2* may function as tumor suppressors.[9] Research has focused on two microRNAs (miRNAs) in the minimal deleted region with tumor suppressor activity, *MIR-15A* and *MIR-16-1,* which are located in this area. Although these sequences are not always deleted in small 13q deletions, they may also be silenced via epigenetic modification, and their expression is decreased in many CLL cases.[103] These miRNAs play a role in modulating the translation mRNA of many genes, including downregulation of BCL2.[9,104] Loss of these miRNAs, therefore, leads to increased BCL2 signaling and inhibition of apoptosis. CLL cases with monoallelic deletion of 13q14 show decreased miRNA expression compared with controls, and cases with biallelic deletion show even lower levels.[105] These miRNAs have also been demonstrated to be deleted in cases without detectable 13q deletion by FISH or cytogenetics, including cases with other recurrent abnormalities such as 11q deletion, 17p deletion, and trisomy 12.[106]

Gene-expression profiling studies demonstrate two distinct groups of 13q14 deletion CLL, correlating with the percentage of cells showing the deletion, with larger clone size correlating with worse outcomes.[107] Patients with deletion in more than 80% of cells show deregulation of genes related to cell proliferation, apoptosis, and cell signaling, and deregulated miRNAs. The gene expression signature in cases with more than 80% deletion is similar to that seen in patients with deletion of 11q and 17p and correlates with poor prognosis. Other studies have suggested a lower threshold, with >60% of cells showing deletion of 13q correlating with shorter treatment free survival.[102]

Deletion of 13q14 is associated with normal CLL morphology, absence of CD38 expression, and hypermutated IGHV. Both monoallelic and biallelic deletions are associated with a favorable prognosis; however, when the deletion is present in a high percentage of cells (>65%), there is shorter time to first treatment.[101]

Trisomy 12

Trisomy 12 is seen in 10% to 20% of CLL cases and appears to represent a heterogeneous clinical entity with regard to clinical behavior and outcome (**Fig. 13-19**). The effects of trisomy 12 may be caused by gene dosage effect, with increased expression of a number of genes, including *HIP1R, CDK4,* and *MYF6,* located on chromosome 12.[108] The clinical significance of these genes in CLL is unknown; however, CDK4 overexpression may lead to increased transcription factor signaling and proliferation.[109] In addition, these cases show decreased expression of *P2RY14* and *CD200*, genes located on chromosome 3. A large fraction (25%–30%) of cases with

trisomy 12 are associated with deletions of the miR-15a/16-1 cluster located on chromosome 13, leading to overexpression of BCL2.[106] These deletions vary in size and may be too small to be identified by routine FISH techniques.

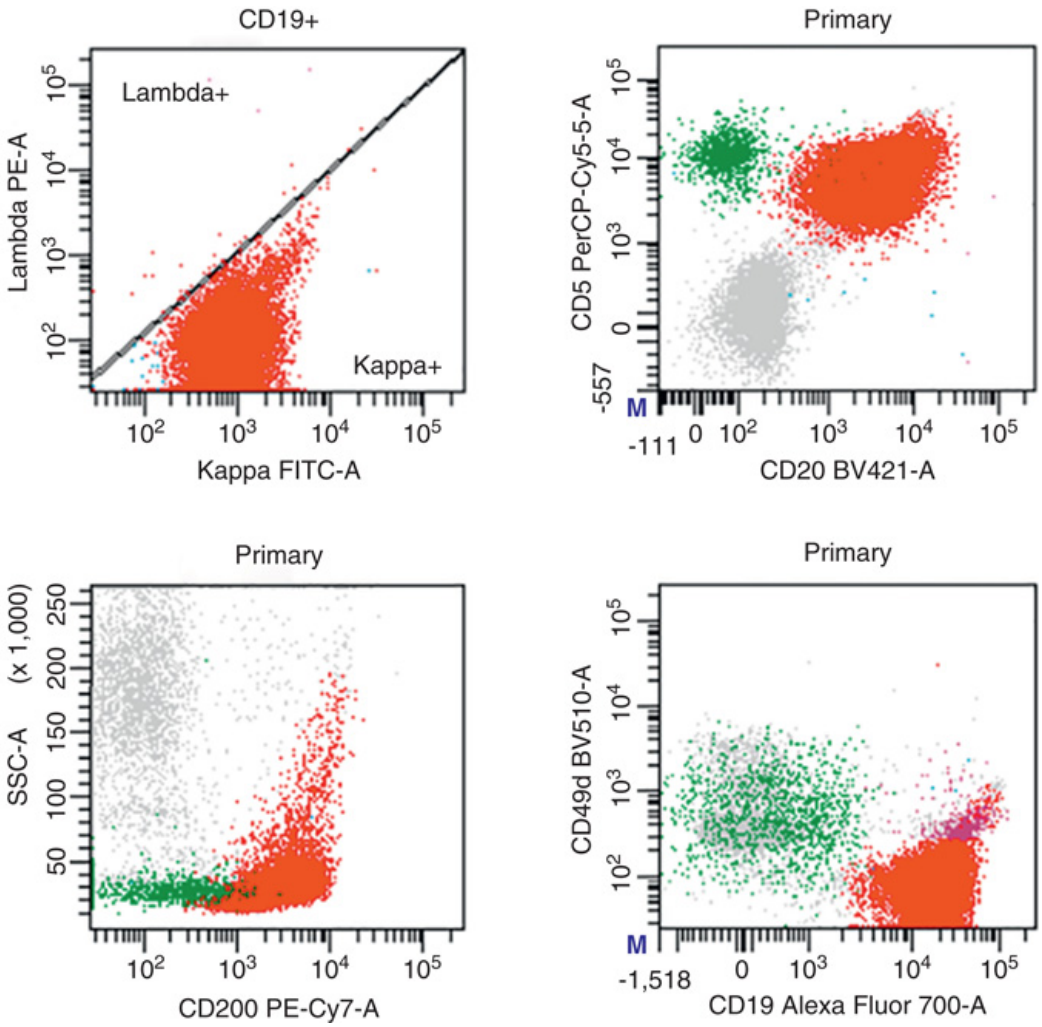

FIGURE 13-16 This flow-cytometric histogram illustrates the classic immunophenotypic profile of CLL/SLL, including dim kappa restriction, CD5 co-expression, and CD200 positivity.Note that CD49d is expressed on <30% of CLL cells.

Trisomy 12 is associated with mutations in the *NOTCH1* gene, located on chromosome 9, although the mechanism underlying this relationship is not clear.[110] Cases with both trisomy 12 and *NOTCH1* mutation show worse outcomes compared with cases without *NOTCH1* mutation.

Trisomy 12 is linked to aCLL morphology and bright CD20 expression.[111] There is also an association with increased CD49d expression.[112] Trisomy 12 is more common in SLL, where it is seen in 30% of cases. It is also associated with RT.[113] Patients with trisomy 12 have an overall intermediate prognosis.

11q22-23 Deletion

Deletions of 11q22.3-23 in CLL are large in size and encompass a number of protein-coding genes, including the tumor suppressor gene *ATM*. This gene functions in DNA damage detection and is known to be involved in lymphomagenesis.[114] CLL cases with deletion of 11q22-23 are associated with chromosomal instability, possibly as a result of decreased *ATM* DNA damage detection.[115] A subset of CLL patients show *ATM* mutation, and these cases are clinically similar to those with 11q22 deletion.[116] Gene expression profiling shows downregulation of genes located in the deleted region, including *ATM* and *DDX10*.[117]

Although *ATM* is the best characterized gene in the region, numerous other genes are included in the deleted region and may play a role in pathogenesis, such as *RDX, RAB39, CUL5, ACAT1, NPAT, KDELC2, MRE11, H2AFX,* and *BIRC3*. Mutation or deletion of the *BIRC3* gene, located near the *ATM* gene at 11q22, is associated with a very high-risk subgroup. *BIRC3* is a negative regulator of the

NF-κB signaling pathway, and loss of gene function leads to constitutive NF-κB signaling.[118] Although mutations in *BIRC3* are rare at diagnosis, they are more commonly identified later in the disease course. Mutations in this gene are associated with aggressive disease and resistance to treatment with fludarabine. In addition, *BIRC3* mutation or deletion is mutually exclusive with *TP53* abnormalities.[119]

11q23 deletion is associated with high white blood cell count, splenomegaly, and lymph node involvement. Many studies have demonstrated a shorter survival and adverse prognosis in patients with 11q deletion. These cases are more likely to show unmutated IGHV.[115,120]

17p13 Deletion

17p13 deletion is associated with loss of the *TP53* tumor suppressor gene and is found in 3% to 8% of patients at diagnosis of CLL. This incidence increases to 40% after chemotherapy in treatment-refractory patients and up to 60% in patients with RT.[121] Patients with deletion of 17p13 harbor mutations in the remaining *TP53* gene in 67% of cases.[122] Patients may also harbor mutations in both copies of the gene in the absence of 17p13 deletion. There is evidence that loss of 17p13 follows mutation in the *TP53* gene because of increased genomic instability.[123,124] *TP53* is an important regulator of cell cycle control and functions in DNA damage detection, causing cell arrest and DNA repair or apoptosis. This function may underlie the resistance of 17p13-deleted CLL to alkylating therapies, which cause DNA damage and rely on activation of the apoptosis pathway. *TP53* mutation or deletion is associated with presentation in

advanced stage, rapidly progressive disease, treatment refractoriness, and RT.[125,126] There is correlation between the percent of cells with 17p deletion and outcome, with higher percentages associated with worse prognosis.[127,128] One study reports that a cutoff range of 10% to 20% for the number of cells that are *TP53* positive by conventional cytogenetics or FISH as the lower limit linked to adverse outcome, although this is not widely applied in clinical practice.[128]

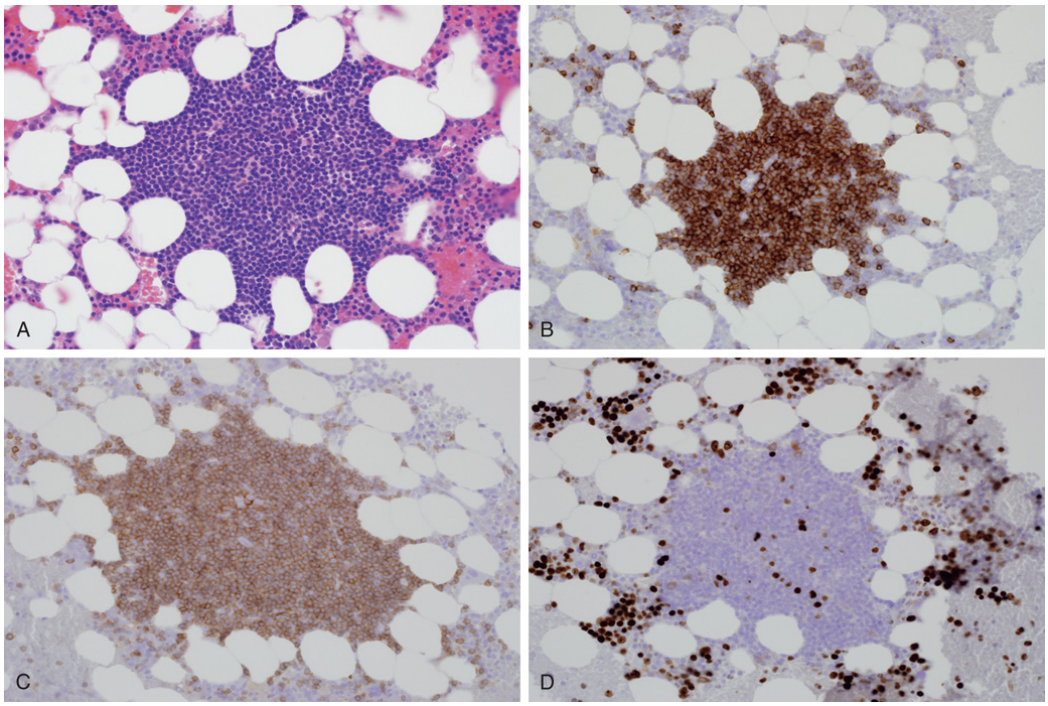

FIGURE 13-17 **A,** A composite of chronic lymphocytic leukemia (CLL) in a bone marrow biopsy illustrates morphology; **B,** bright CD20 expression; **C,** dim CD5 expression; and **D,** minimal mitotic activity with comparison to Ki67 positivity in the adjacent normal bone marrow (H&E, CD20, CD5, and Ki67 stains).

Gene expression profiling shows numerous changes in 17p13 deleted cases, including downregulation of tumor suppressor genes and genes involved in mRNA and protein processing, such as *DPH1, GABARAP, GPS2, NCOR1, NLRP1,* and *CAMTA2*. Additional genes are overexpressed, including *CCND2,* which is increased in cell cycle progression, and *NME1* and *STT3A,* which have been demonstrated to be overexpressed in other neoplasms.

Cases with 17p13 deletion may show aberrant (i.e., atypical) IP with bright CD20, FMC7, and surface immunoglobulin expression. It

is associated with other poor prognostic markers such as CD38 and ZAP70 expression and unmutated IGHV.[129] Patients with 17p deletion and *TP53* mutation may be considered for stem cell transplant.[130]

Other Cytogenetic Abnormalities

Additional recurrent cytogenetic abnormalities, including translocations, not covered by the typical FISH panel, have been well described in CLL, although the significance of these findings is uncertain in most cases. These findings may represent sole abnormalities or be associated with other more common changes. Around 30% of CLL cases with normal FISH studies harbor abnormalities not identified by the standard panel, including 14q deletions, 7q deletions, 6q deletions, 14q32 translocations, and 3q deletions.[131] 14q deletions are heterogeneous in size and may or may not involve the IGH gene at 14q32. These deletions are associated with typical CLL IP and unmutated IGHV.[132] Patients with 6q deletion may represent a clinically distinct group with higher white blood cell count, splenomegaly, atypical morphology, positive CD38 expression, and intermediate prognosis.[133,134]

Translocations are seen in approximately 8% of CLL cases. Of cases with translocations, 74% are balanced and 26% are unbalanced.[135] Translocations involving IGH at 14q32 have been best studied. The prognostic significance of these translocations is governed by the partner gene. The t(14;19)(q32;q13) creates an *IGH*::*BCL3* fusion gene with *BCL3* protein overexpression. These cases have atypical morphology and IP, association with trisomy 12 and complex karyotype, and unmutated IGHV.[136] *MYC*

translocations are also rarely seen in CLL and correlate with poor prognostic features including increased prolymphocytes, 17p deletion, and complex karyotype.[137]

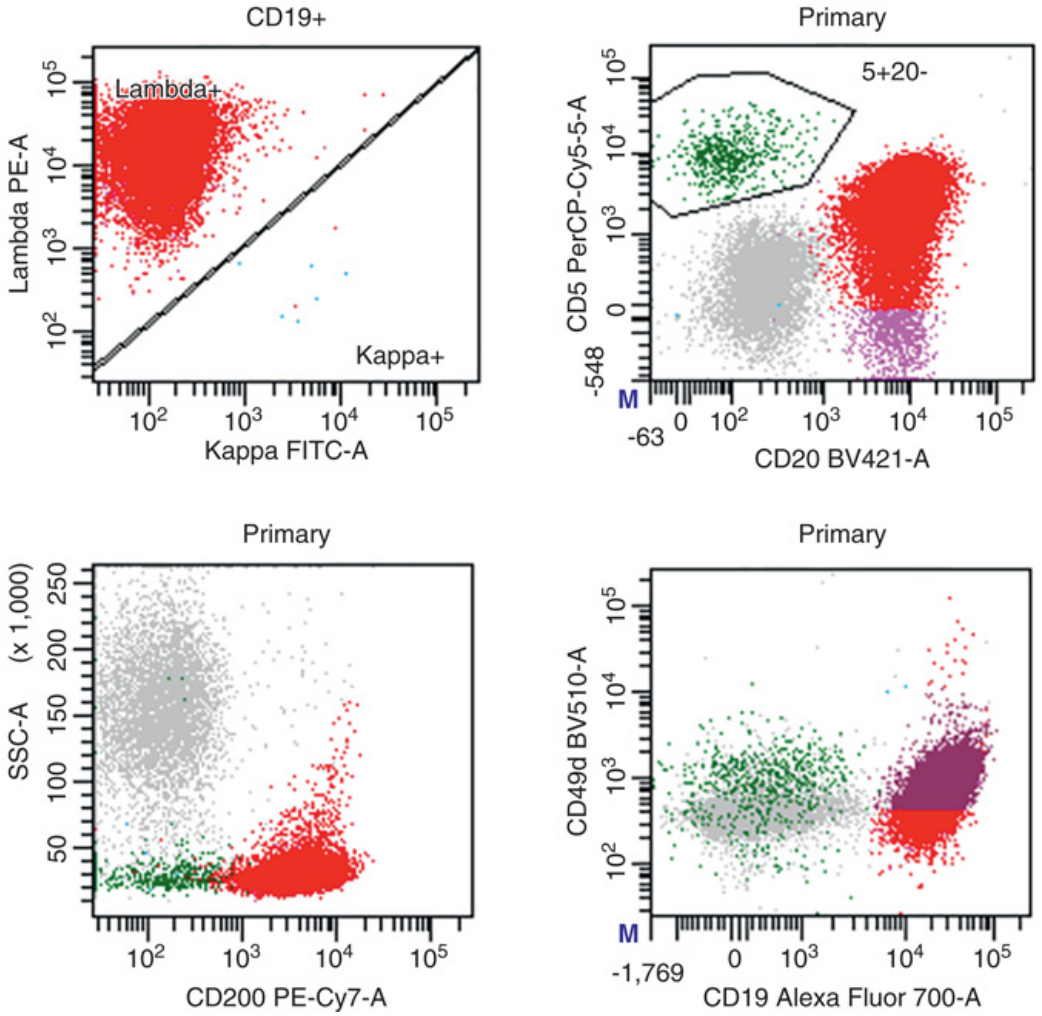

FIGURE 13-18 Chronic lymphocytic leukemia immunophenotype with moderate SIg, weak CD20, co-expression of CD5, and CD200. CD49d expression is evident, which is associated with adverse prognosis.

Complex karyotype is defined as three or more structural or numerical abnormalities. It has been associated with aggressive disease and treatment resistance; however, there is evidence that the specific abnormalities and number of changes present may influence the specific prognosis. High complexity karyotypes, with five or more abnormalities, have been identified as an independent marker of poor prognosis. Cases with three or four trisomies in the absence of other changes, however, have a more indolent course.[95] Cases with three or four abnormalities show a stronger correlation with worse prognosis in the presence of *TP53* loss caused by deletion or mutation.

Somatic Mutations and Genomic Profiling

In addition to the well-studied chromosomal abnormalities, increasing numbers of somatic gene mutations have been identified that may be useful in the diagnosis and risk stratification of CLL.[138-141] In general, the frequency of somatic mutations in CLL cases increases with the length of disease, and these mutations are thought to be acquired over the course of disease.

Alterations, including mutations, in the *TP53* tumor suppressor gene have been incorporated into prognostic systems for CLL, including the National Comprehensive Cancer Network and the European Research Initiative on CLL (ERIC) guidelines.[82,97] *TP53* aberrancies are associated with poor outcomes because of resistance to standard chemotherapeutic regimens, and patients show markedly decreased OS times compared with those without *TP53* aberration.[142]

Though cytogenetic and FISH techniques identify deletion of the *TP53* gene region, use of molecular sequencing techniques identifies mutations causing loss of gene function and use of both methods is recommended for complete assessment prior to starting treatment, and with disease progression necessitating a change in therapy.[92] Mutations are identified in 90% of patients with *TP53* deletion identified by FISH or karyotype; however, approximately 5% of CLL patients have *TP53* mutation without deletion at diagnosis and these patients have similar prognosis to those with 17p deletion. The prevalence of *TP53* mutations is increased in patients with clinically aggressive and treatment refractory disease.[86] Assessment by next generation sequencing methods is generally more sensitive than by Sanger sequencing and may identify smaller clones of clinical importance. At minimum, mutation assessment should include exons 4 to 10, which include the DNA binding domain and oligomerization domain, however, sequencing of all protein coding exons 2 to 11 is preferred for complete assessment.

Single-gene sequencing techniques are often used for targeted sequencing of *TP53;* however, new high-throughput sequencing technologies have identified mutations in a number of other genes with diagnostic and prognostic relevance, and distinct mutation profiles in cases with hypermutated IGHV compared with unmutated cases. *MYD88* and *KLH6* mutations are associated with IGHV hypermutation, whereas *NOTCH1* and *XPO1* are seen in unmutated cases.[143] In addition to *TP53,* commonly mutated genes in CLL include *NOTCH1* and *SF3B1*. Other recurrently mutated genes include *ATM, BIRC3, POT1,* and *XPO1,* Notch pathway genes, and several other less commonly mutated genes.

Clinical significance of TP53, BIRC3, ATM and MAPK-ERK genes in chronic lymphocytic leukaemia: data from the randomised UK LRF CLL4 trial. *Leukemia*. 2020 Jul;34(7):1760-1774; Puiggros A, Collado R, Calasanz MJ, et al. Patients with chronic lymphocytic leukemia and complex karyotype show an adverse outcome even in absence of TP53/ATM FISH deletions. *Oncotarget*. 2017 Apr 21;8(33):54297-54303.

NOTCH1 mutations are found in 10% to 14% of CLL cases at diagnosis, increasing to 20% in advanced disease and 30% in RT. The *NOTCH1* gene encodes a transcription factor that functions in cell differentiation, proliferation, and apoptosis. The most frequently identified mutations in this gene create a more stable protein that is resistant to degradation, leading to increased expression of genes in

the signaling pathway and increased cell survival and resistance to apoptosis.[144] Cells with dysregulation of the Notch signaling pathway show increased expression of the *MYC* oncogene. In addition to mutations in the *NOTCH1* gene, mutations in other genes regulating the Notch pathway including *FBXW7* and *MED12* are found in 2% to 5% of CLL cases and result in similar outcomes and response to therapy.[145] *NOTCH1* mutations are correlated with unmutated IGHV and increased ZAP70 and CD38 expression and decreased CD20 expression. These patients have more aggressive disease, resistance to treatment, particularly with anti-CD20 immunotherapy,[146] a greater risk for RT and poor outcome.[147-149] *NOTCH1* mutations are seen in association with trisomy 12 but are rare in del(13q).[150] *NOTCH1* and other Notch pathway mutations may provide a target for therapy.[151]

SF3B1 encodes a part of the spliceosome, the complex responsible for removing introns from RNA to allow proper protein translation. Mutation in this gene leads to atypical RNA transcripts, typically with premature stop codons. The incidence of mutation in CLL is from 7% to 15% at diagnosis, increasing to 20% in patients with advanced disease. *SF3B1* mutations are associated with aggressive disease and short survival, a higher white blood cell and leukemic cell count, CD38 positivity, and unmutated IGHV.[152] Interestingly, these mutations are not seen in patients with RT. In addition, these mutations are associated with specific variable chain usage and are more common in IGHV3-21 and possibly IGHV1-69 and are mutually exclusive of IGHV1-2. These mutations are more common in patients with normal karyotype or del(11q) and are not seen in patients with trisomy 12.[150]

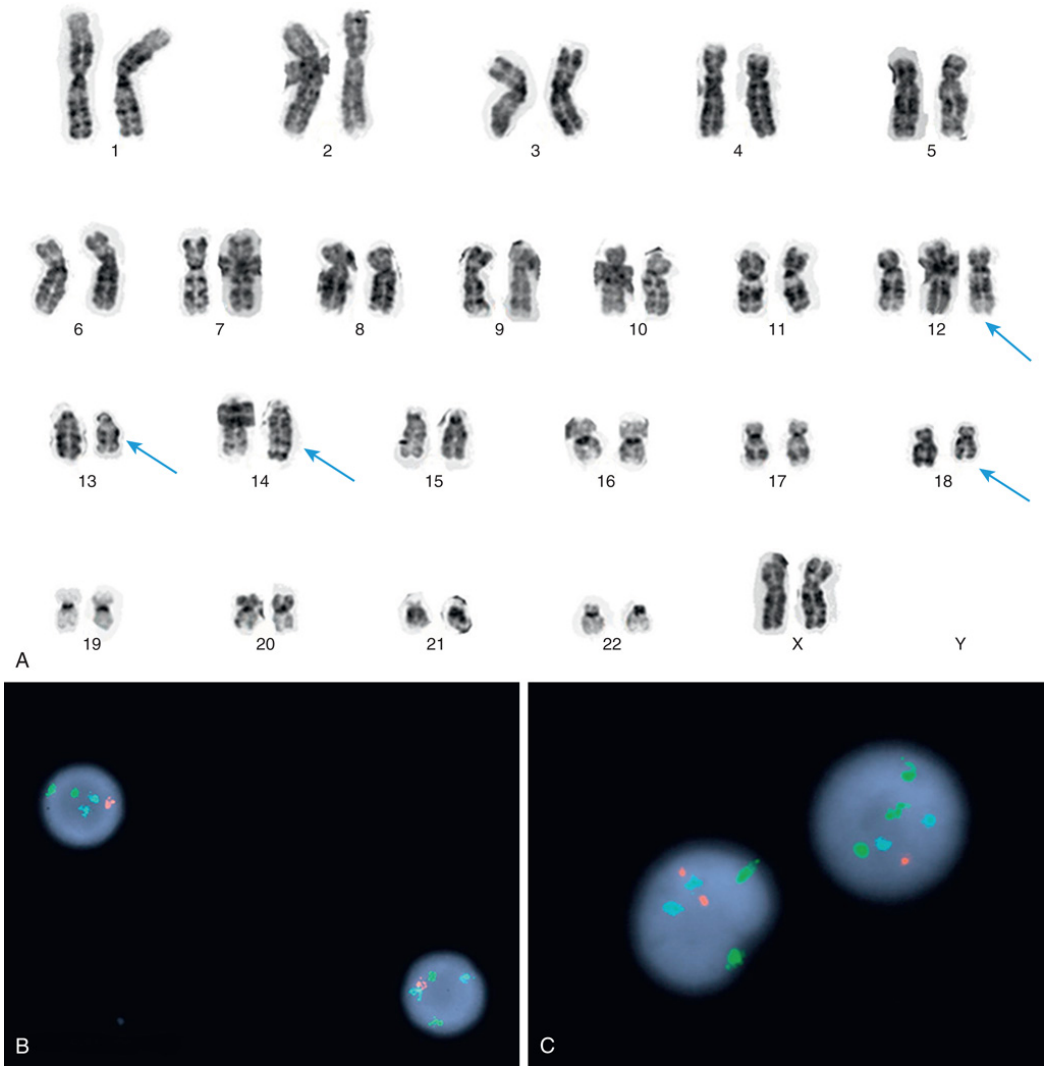

FIGURE 13-19 **A,** This karyotype shows trisomy 12 and deletion of 13q, which were seen on a concurrent chronic lymphocytic leukemia (CLL) fluorescence in situ hybridization (FISH) panel. In addition, there is a t(14;18)(q32;q21) that was not tested for and was therefore missed by FISH. **B,** FISH for the 13q14.3 region *(red signal)* shows only one copy of the region, consistent with monoallelic deletion of the region. **C,** FISH for the centromere of chromosome 12

(green signal) shows three signals, consistent with trisomy 12.

The *ATM* gene, located on chromosome 11q, is mutated in 10% to 21% of CLL. The *ATM* gene functions in DNA damage response. These mutations are more common in cases with del(11q), resulting in loss of both copies of the gene. The prognostic significance of *ATM* mutations has not been fully explored; however, some studies suggest an association with more aggressive disease.[120]

BIRC3 is also located in the commonly deleted area on chromosome 11q and functions in the NF-κB pathway. Mutations have been associated with more aggressive disease, although this may be mitigated with newer treatments such as venetoclax and ibrutinib.[152] Other recurrently mutated genes in CLL include *POT1* and *XPO1*.[153]

Chronic Lymphocytic Leukemia Immunoglobulin Structure and Stereotyped Receptors

B-cell immunoglobulin genes undergo rearrangement in vivo, allowing generation of a large spectrum of unique proteins, each recognizing a different antigen. This rearrangement uses VDJ chains, which are combined in a semirandom fashion and are different in individual cells. Certain chains are associated with increased affinity for certain antigens. After exposure to antigen, somatic hypermutation occurs, leading to further increased antigen affinity. CLL demonstrates both unmutated and hypermutated Ig genes. CLL clones show a preferential usage of certain V regions, with VH4-34 often seen in cases with hypermutation and VH1-69 and VH4-39 seen in unmutated cases.

In addition, 30% of CLL cases show highly similar amino acid sequences in their B-cell receptors, referred to as *stereotyped receptors*.[90,91] Based on these sequences, cases can be divided into subsets that share common clinical and molecular features and associate with different outcomes. For example, subset 2 is associated with poor prognosis and *SF3B1* mutation, while subset 8 is associated with poor prognosis, the highest risk of RT, and *NOTCH1* mutation.[154,155] The findings of recurrent variable chain usage and stereotyped receptors indicate that antigen stimulation by specific structures is likely a key component in CLL pathogenesis. Several possibilities have been explored to identify these antigens. In some cases, autoantigens have been implicated including epitopes that may be exposed during apoptosis.[156] Superantigens including *Staphylococcus aureus* protein A and CMV phosphoprotein pUL32 have also been suggested.[6]

Postulated Cell of Origin and Normal Counterpart Cell

Both IGHV unmutated and hypermutated cases are believed to originate from mature, antigen-experienced B cells. One review detailed B-cell maturation pathways that can give rise to the memory B cell–like cells that could be the cell of origin in CLL.[89] The pathways include classic T-cell dependent germinal center pathway, T-cell dependent extrafollicular pathway, and T-cell independent extrafollicular pathway. The classic germinal center pathway gives rise to IGHV-mutated memory B cells, while the other two pathways often give rise to IGHV-unmutated memory B cells. However, other studies suggested that CLL may originate at the stem cell

stage.[13,38,89,157-159] CLL cells show downregulation of surface IgM but not IgD, a feature seen in cells that have been exposed to antigen and are anergic. Gene-expression profiling shows that both types of CLL show similar expression of activation and proliferation markers as memory and marginal zone B cells. CD5-positive B cells are normally found in very low numbers in the PB of adults. CD5-positive B cells are also found in fetal blood and lymphoid tissue.[160]

Clinical Course and Prognosis

CLL is generally an indolent disease. However, the clinical course is highly varied and some patients may have much shorter time to first treatment and a more aggressive clinical course (**Table 13-4**).[7,8] The International Prognosis Index for CLL (CLL-IPI) was developed as a prognostic model to discriminate different prognostic subgroups.[161] The CLL-IPI analyzed genetic, biochemical, and clinical parameters and came up with five independent prognostic factors: *TP53* status [no abnormality versus del(17p) or *TP53* mutation or both], IGHV mutational status (mutated versus unmutated), serum β2-microglobulin concentration (≤3.5 mg/L versus >3.5 mg/L), clinical state (Binet A or Rai 0 versus Binet B–C or Rai I–IV), and age (≤65 years versus >65 years). CLL-IPI predicts time to first treatment and OS. Each parameter is weighted and the final scores separate patients into low, intermediate, high, and very-high risk categories with a 5-year survival rate at 93.5%, 79.3%, 63.3%, and 23.3%, respectively.

Other methods to predict clinical outcomes are used in certain regions of the world (**Table 13-4**). A machine-learning technology using three classes of variables, including recurrent gene mutations, CLL-IPI variables, and (para)clinical data is predictive of individual risk in four clinical outcomes: death, treatment, infection, and the combined outcome of treatment or infection within both a short-term, 2-year outlook and a long-term, 5-year outlook.[162,163] In this model, the predictive performance of CLL-IPI is improved by adding baseline clinical data. In addition, the risk factors predictive of death within a 5-year outlook are mostly similar to risk factors predictive of infection within a 2-year outlook. The IGHV test is only available in a small subset of patients with CLL around the globe. In most parts of the world, especially in resource-limited settings, IGHV is not practical. Alternative systems have been sought for these regions. One such example is lymphocyte doubling time (LDT), which is proposed in place of IGHV mutation status to predict the clinical outcome of CLL patients.[163] Tumor mutation load using next-generation sequencing is also a strong predictor of time to first treatment in CLL and monoclonal B-cell lymphocytosis, independent of CLL-IPI.[164] Even low variant allele frequency *TP53* mutations are also predictive of short survival in CLL; one study proposed a 10% to 20% threshold for *TP53* abnormalities detected by standard karyotyping or FISH.[128,165]

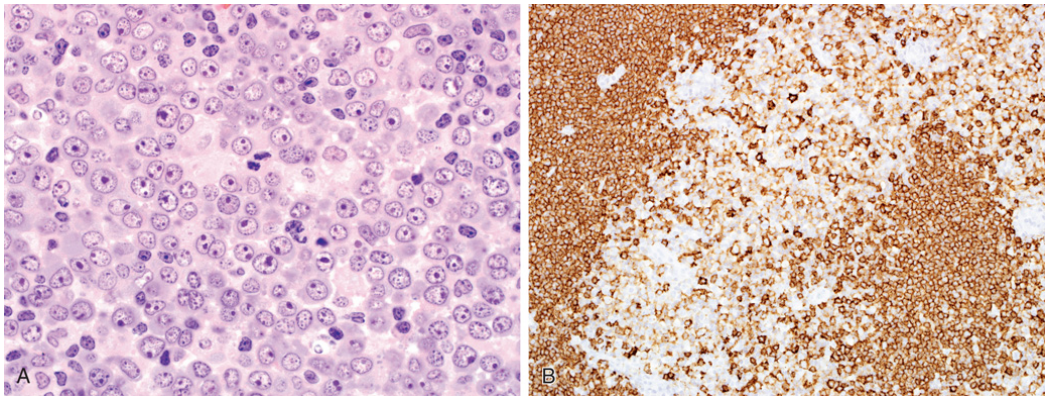

FIGURE 13-20 **A,** Lymph node biopsy from a patient with chronic lymphocytic leukemia (CLL) transformed to diffuse large B-cell lymphoma (DLBCL) illustrates solid sheets of large lymphoma cells *(center)* with background CLL on both sides. **B,** A CD20 stain of lymph nodes on another case with more focal Richter's involvement reveals weaker CD20 expression in the large transformed cells (H&E and CD20 stains).

Translocations are less common in CLL and are reported in approximately ~3% to 8% (range 1.9%–26.1%) of CLL patients in various studies.[166,167] T(14;18) *IGH*::*BCL2*, t(14;19) *IGH*::*BCL3*, t(8;14) *MYC*::*IGH*, and t(2;14) *BCL11A*::*IGH* are among the most commonly reported of these generally rare translocations. Reciprocal translocations involving immunoglobin genes, most commonly the immunoglobin heavy chain (IGH) located at 14q32, translocate genes under active regulatory sequences on 14q32, which results in constitutive activation of the translocated genes. Results are mixed; some studies did not find prognostic significance of the translocations, although one study identified *IGH*::*BCL3*

translocation as prognostically important. It is associated with shorter time to first treatment, short 5-year survival rate and OS rate, and is more likely to have high and very high CLL-IPI.[166]

Serum-free light chain and IgM peak have been proposed as prognostic markers.[168-171] Increased serum thymidine kinase and β2-microglobulin levels are associated with poor prognosis.[172-174] Lactate dehydrogenase (LDH) is a useful indicator for tumor turnover. Expression of CD49d or CD38 by flow-cytometric immunophenotyping in ≥30% of clonal B cells is linked to more aggressive clinical course. CD49d is a subunit of cell surface adhesion molecule integrin and is an independent prognostic marker. CD49d expression is associated with shorter time to treatment and decreased OS. Similarly CD38 positivity is also linked to adverse outcome and can also predict unmutated IGHV gene mutation status in most cases. Zeta-chain-associated protein of 70 kiloDalton (kDa) (ZAP70) expression is a surrogate for IGHV mutation status, and ZAP70 positivity is linked to unmutated IGHV status and predicts aggressive clinical course.

The causes of death in CLL patients include disease progression, CLL unrelated causes, second malignancy, unknown cause, and infection, in descending order.[175,176] Patients in high or very-high risk categories are more likely to have disease progression and die of the disease, while patients in low or intermediate risk categories are more likely to die with the disease.

Transformation

RT is defined as transformation of CLL/SLL into more aggressive lymphomas and is mostly represented by DLBCL (**Fig. 13-20**),

which accounts for 95% to 99% of transformation cases and occurs in 2% to 10% of CLL patients.[2,27,177] Transformation to classic Hodgkin lymphoma is much less frequent, occurring in approximately 0.5% of patients (**Fig. 13-21**).[68,178] Transformation to lymphoblastic leukemia/lymphoma, histiocytic/dendritic cell sarcoma, high grade T-cell lymphoma, hairy cell leukemia (HCL), plasmablastic transformation, or prolymphocytic leukemia have been reported as case reports (**Fig. 13-22**).[14-19,179,180]

Risk factors for RT include genetic findings, laboratory parameters, and clinical characteristics. Mutations or deletions of *TP53, CDKN2A,* and *NOTCH1* genes are associated with increased risk of RT. Unmutated IGHV status or stereotyped B-cell receptor subset 8 are also linked to RT. In addition, complex karyotype, 11q deletion, and trisomy 12 are known risk factors for RT. Overexpression of ZAP70 and CD38, elevated LDH, Binet stage B–C or advanced Rai stage at diagnosis, and lymphadenopathy are recognized risk factors as well.[19] Treatment of CLL with purine nucleoside analogs also significantly increases the risk for RT.[177]

Two main genetic pathways are involved in the transformation of CLL to RT-DLBCL.[181] The first pathway involves either acquisition of aberrations in tumor suppressor gene *TP53* or mutations in cyclin-dependent kinase inhibitor 2A *(CDKN2A)*. Oncogene *MYC* is activated in a subset of patients with *TP53* aberration. These alterations usually occur at transformation. This pathway appears to be the most common genetic aberration leading to RT-DLBCL; it contributes to the development of RT-DLBCL in 50% of cases. *TP53* is one of the most prominent tumor suppressor genes and p53 protein has a critical role in guarding the integrity of the genome.

CDKN2A encodes protein p16INK4A, which negatively regulates progression of G1 to the S phase in the cell cycle via inhibition of Cdk4 and Cdk6 kinase. *CDNK2A* also encodes P14ARF, a MDM2 inhibitor. The loss of *CDNK2A* is often secondary to 9p21 deletion. *MYC* alteration usually occurs via translocation and less commonly because of amplification of 8q24. Activation of *MYC* significantly affects cell proliferation, metabolism, cell adhesion, and cellular function. The second pathway occurs in approximately 30% of RT cases and involves activation of the *NOTCH1* pathway through somatic mutations. These two pathways appear mutually exclusive. *NOTCH1* mutations occur most frequently in CLL stage in patients with trisomy 12, unmutated IGHV, and ZAP70 positivity. Patients with *NOTCH1* mutations have a 45% chance of developing RT within 15 years. *NOTCH1* encodes a transmembrane receptor that in turn affects cell proliferation and apoptosis through downstream genes, including *CCND1, MYC,* and *BCL2*. The remaining 20% of patients with RT have heterogeneous genomic aberrations.

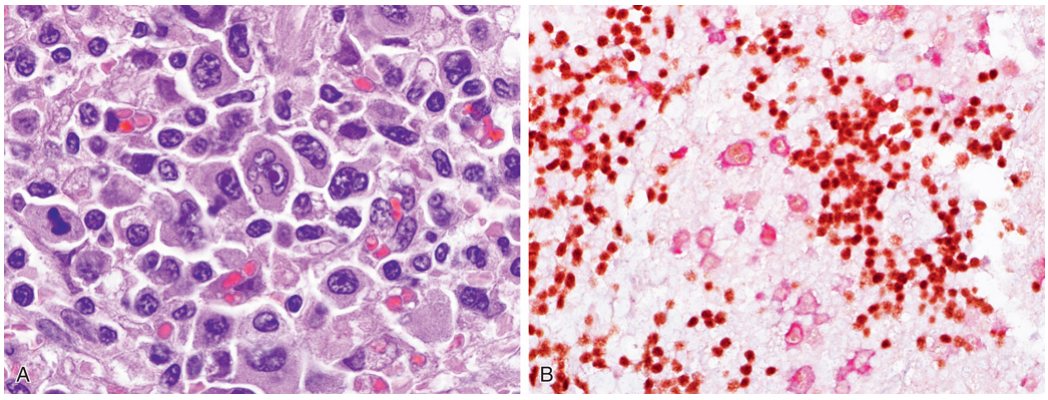

FIGURE 13-21 **A,** Spleen from a patient with chronic lymphocytic leukemia (CLL) transformed to Hodgkin lymphoma illustrates scattered Reed-Sternberg cells and Hodgkin cells. A few small lymphocytes and histiocytes are in the background. **B,** PAX5/CD30 stain reveals weak PAX5 nuclear and CD30 cytoplasmic and membrane staining in Reed-Sternberg and Hodgkin cells (H&E and PAX5/CD30 stains).

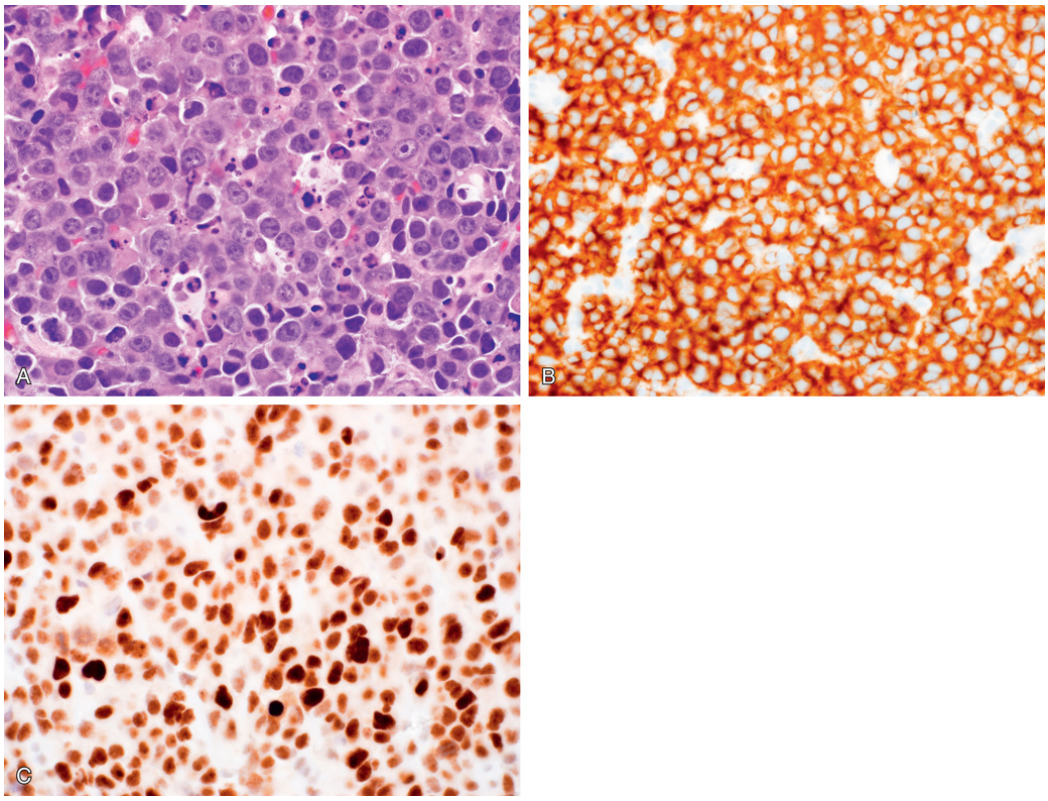

FIGURE 13-22 This composite shows a case of chronic lymphocytic leukemia (CLL) with plasmablastic transformation **(A)** with bright cytoplasmic lambda restriction **(B)** and LEF1 positivity **(C)** (H&E, lambda ISH, LEF1 IHC).

RT-DLBCL developing while on novel therapeutic agents has become more common.[17,182-190] *TP53, CDKN2A, MYC,* and *NOTCH1* are common aberrations in these cases. Over 70% of patients who developed RT on ibrutinib had associated *TP53* alterations. *BTK* and *PLUG2* mutations are also reported in patients who developed RT on ibrutinib. *TP53* alterations are also observed in over 70% of patients who developed RT on venetoclax. This study also showed that RT genomic profiling is intermediate between CLL and de novo DLBCL and that *CDKN2A* inactivation through DNA

loss or mutations is the most frequently acquired lesion at the time of transformation.[181]

It is important for the diagnostician to be aware that RT-like proliferations can develop after cessation of ibrutinib, a phenomenon termed "pseudo-Richter transformation."[1,2] These proliferations regress with reinstitution of BTK inhibitor therapy.

Non-germinal center (non-GCB) phenotype is overrepresented in RT-DLBCL.[13] Biologically RT-DLBCL can be clonally related or unrelated to CLL. Clonally related RT-DLBCL is the most common type (~70% of all RT-DLBCL) and is more commonly seen in IGVH unmutated cases. It carries a very poor prognosis and is often chemotherapy resistant. Clonally unrelated DLBCL is more often seen in IGHV mutated cases and shows a prognosis identical to de novo DLBCL in the setting of immune dysregulation.[181] EBV-associated large B-cell lymphoma occurs in a subset of usually clonally unrelated RT-DLBCL, ranging from 6% to 29%,[21,191,192] particularly in the anti-CD52 antibody alemtuzumab treatment setting, similar to lymphomas arising in the immunodeficiency setting.[193,194]

Clonally related RT-HL is less common and only accounts for ~40% of RT-HL. The majority of RT-HL are clonally unrelated. The risk factors and molecular aberrations of RT-HL are less well understood. The IP of RT-HL is similar to de novo HL and the majority are EBV positive (70%).[17,68]

The median OS for RT-DLBCL is 9 to 12 months, while the median OS for clonally unrelated RT-DLBCL is 62.5 months. The median OS for RT-HL is about 33.5 months.[195,196]

Differential Diagnosis

A spectrum of disorders can manifest PB lymphocytosis. In children and young adults, lymphocytosis is more likely to be benign, whereas in older adults, lymphocytosis is more likely to be neoplastic. Reactive lymphocytosis is typically seen in viral infection, vaccination, autoimmune disorders, or presence of other types of malignancies. The lymphocytes exhibit a heterogeneous morphology ranging from small, mature lymphocytes to large, activated lymphocytes with abundant cytoplasm. A rare phenomenon called benign B-cell polyclonal lymphocytosis reveals stable persistent lymphocytosis.[197-199] The lymphocytes in this disorder are small with scant cytoplasm and round nuclei, with occasional binucleated forms (**Fig. 13-23**). This phenomenon is more commonly seen in young to middle-aged females who often are smokers, and morphologically it is indistinguishable from CLL. Chromosome 3 abnormalities, including isochromosome of the long arm of chromosome 3 and trisomy 3, have been described in a subset of cases.[200,201] An association with the HLA-DR7 haplotype has also been reported.[202-204] In adults with a sustained unexplained lymphocytosis, clinical correlation and workup including flow-cytometric analysis initially, and potential cytogenetic and molecular studies, may be needed to exclude or confirm a neoplastic process, though morphologic and clinical correlation is generally sufficient in children and adults in whom a clinical cause for the lymphocytosis is apparent.

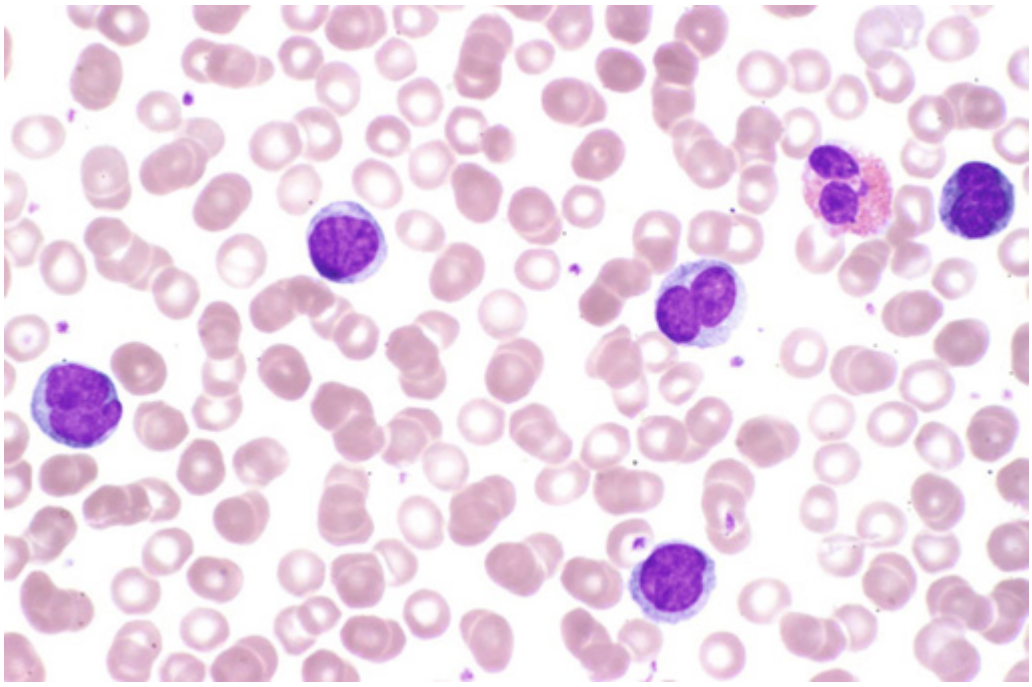

FIGURE 13-23 Peripheral blood smear from a middle-aged female with polyclonal lymphocytosis illustrates small lymphocytes with scant cytoplasm and condensed chromatin. Occasional bilobed lymphocytes are also present (Wright's stain).

When FCI confirms a B-cell neoplasm, differential diagnostic considerations include other lymphocytic leukemias and lymphomas (Tables **13-5**, **13-6**, and **13-7**). Cell morphology is a helpful feature to predict a CLL diagnosis, which typically shows small and uniform lymphocytes, a scant to moderate amount of cytoplasm, highly condensed chromatin with a characteristic "soccer ball" pattern, and inconspicuous nucleoli.[56] Although morphology is highly characteristic in classic CLL cases, flow-cytometric analysis is required to confirm the diagnosis. MCL usually exhibits a spectrum of morphology ranging from small to intermediate to large

lymphoma cells. These cells have irregular nuclear contours, and a subset has prominent nucleoli. However, MCL cells may mimic CLL morphologically, presenting a diagnostic challenge (**Fig. 13-24**). There is also significant morphologic overlap between CLL cases with prolymphocytoid transformation and de novo B-cell prolymphocytic leukemia (B-PLL), which is a diagnosis of exclusion in ICC.[2] Prior history of CLL is very useful in making this distinction.

Other B-cell neoplasms in the differential diagnosis of CLL include FL with blood involvement. FL cells demonstrate a spectrum of cell size with characteristic deeply cleaved nuclear membranes, and blood involvement typically occurs late in the disease course of these patients. Both morphology and IP distinguish HCL, HCL variant (HCLv), and MZL from CLL because of more abundant cytoplasm of these neoplastic cells on PB smear, and FCI features. Rare cases of T-prolymphocytic leukemia (T-PLL) may have a similar presentation and morphologically mimic CLL.

Table 13-6

Pattern and Morphology of Bone Marrow Involvement in B-Chronic Lymphoproliferative Neoplasms

Disorder	Aspirate Morphology	Core Biopsy Features
CLL/SLL	Monotonous small round lymphocytes with scant cytoplasm	Focal non-paratrabecular infiltrates predominate but may see either diffuse interstitial or diffuse solid infiltrates
B-PLL	Intermediate-sized lymphocytes exhibiting round nuclei with relatively condensed nuclear chromatin and prominent central nucleoli	Usually diffuse, interstitial
MCL*	Small to intermediate-sized lymphocytes with variably condensed chromatin and	Usually focal non-paratrabecular and paratrabecular infiltrates evident, although

Disorder	Aspirate Morphology	Core Biopsy Features
	irregular nuclear contours; a variable number of cells may exhibit either prolymphocytic or blastic features	interstitial and diffuse lesions also described
FL*	Variable, but small cleaved lymphoid cells typically predominate	Focal paratrabecular lesions predominate
MZL* (including splenic MZL)	Variable with admixture of plasmacytic forms; some cells may exhibit shaggy cytoplasmic contours that tend to be bipolar	Variable, sinusoidal infiltrates common but usually in association with discrete focal lesions; may see “naked” germinal centers
LPL*	Spectrum of lymphoplasmacytic cells and plasma cells; Dutcher bodies; may see abundant mast cells	Focal, interstitial, or diffuse lesions may be noted; may see amyloid deposition

Disorder	Aspirate Morphology	Core Biopsy Features
HCL*	Distinctive cell with oblong to reniform nuclei, spongy "checkerboard" nuclear chromatin, and moderate to abundant amounts of slightly basophilic cytoplasm exhibiting shaggy contours	Diffuse interstitial and sinusoidal infiltrates characteristic; can be very subtle and is best appreciated by immunophenotypic assessment

B-PLL, B-prolymphocytic leukemia; *CLL/SLL,* chronic lymphocytic leukemia/small lymphocytic lymphoma; *FL,* follicular lymphoma; *HCL,* hairy cell leukemia; *LPL,* lymphoplasmacytic lymphoma; *MCL,* mantle cell lymphoma; *MZL,* marginal zone lymphoma.

In the bone marrow, CLL may exhibit different patterns including non-paratrabecular lymphoid nodules, interstitial infiltrate, and diffuse effacement of the marrow (**Table 13-6**). The bone marrow architecture can be preserved in the early phase of the disease with only interstitial infiltrate, and IHC stain with B-cell markers such as CD20 may be required to reveal the infiltrate. The differential diagnosis in the BM includes MCL, HCL, LPL, HCLv, B-PLL, and SMZL. HCL usually exhibits characteristic “chicken wire” or “fried egg” appearance because of abundant cytoplasm. LPL reveals a spectrum of small lymphocytes, plasmacytoid lymphocytes, plasma cells, and increased mast cells. Dutcher bodies may be observed in the plasma cells. HCLv and SMZL may show interstitial or intrasinusoidal infiltrates; discrete lymphoid aggregates may also be seen in SMZL. MCL usually demonstrates paratrabecular and non-paratrabecular lymphoid aggregates. Of particular note, indolent leukemic, non-nodal MCL with interstitial bone marrow involvement may closely mimic CLL and poses a particular differential diagnostic challenge (**Fig. 13-25**). This type of leukemic, non-nodal MCL is usually associated with a good prognosis.[2,205,206] FL reveals a characteristic paratrabecular infiltrate. The morphologic pattern of bone marrow involvement in B-CLPN is summarized in **Table 13-6**.[2,4,10,56,207]

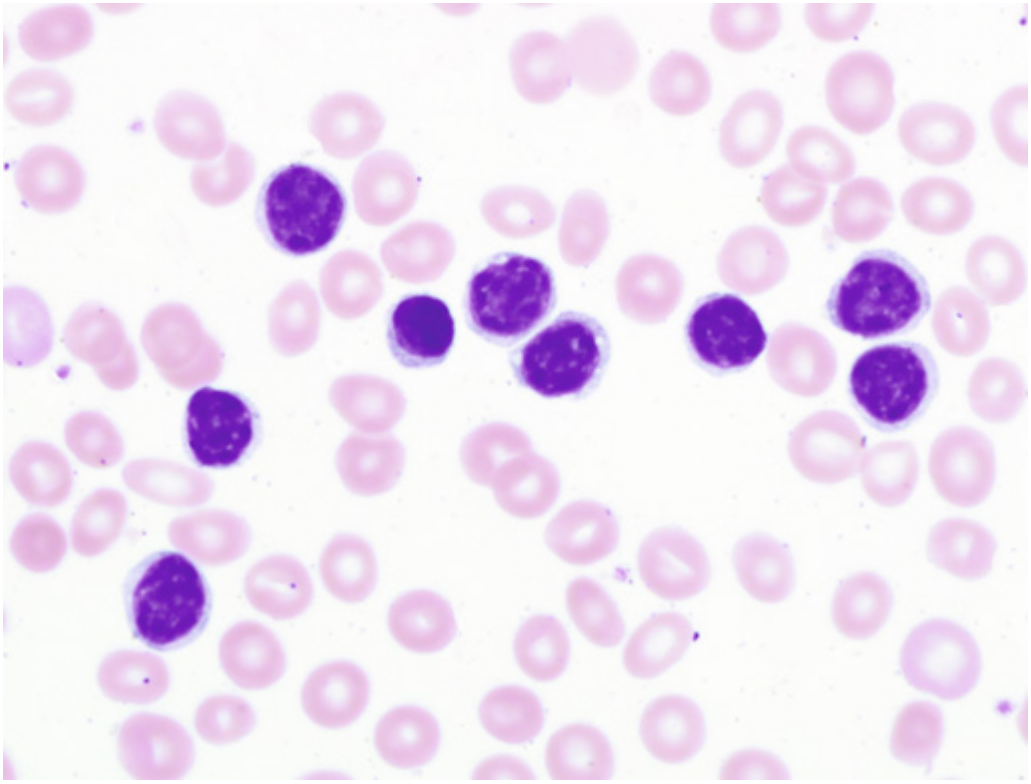

FIGURE 13-24 Peripheral blood smear from a patient with mantle cell lymphoma reveals uniform lymphoma cells that morphologically mimic chronic lymphocytic leukemia (Wright's stain).

In the lymph node, CLL exhibits diffuse effacement with scattered proliferation centers, while MCL and FL usually have a nodular pattern. MZL/splenic MZL (MZL/SMZL) demonstrates expansion of the marginal zone. Rarely, HCL may involve lymph nodes with either diffuse replacement or medullary infiltration.

In the spleen, CLL exhibits primarily white pulp disease with secondary red pulp involvement. MCL and FL also typically involve white pulp, while SMZL also involves white pulp with expansion of the marginal zone. Importantly, both HCL and HCLv involve

primarily red pulp with distinctive blood lake formation in HCL. The morphologic features of B-CLPN in the lymph node and spleen are summarized in **Table 13-5**.[1,2,10,47,56,207]

IP is critical to distinguish these entities. CLL and MCL characteristically co-express CD5. Flow-cytometric analysis is helpful in most cases to distinguish CLL from MCL with dim surface immunoglobulin, dim CD20 expression, presence of CD23 and CD200, and absence of FMC7. In a minority of cases, distinction between CLL and non-nodal leukemic MCL is challenging in that these leukemic MCL cells can be CD23 positive, CD200 positive, and SOX11 negative or FMC7 negative, closely mimicking CLL.[74,208,209] The major immunologic differences of CLL and MCL are summarized in **Table 13-2**. Cytogenetic assessment for t(11;14) is essential in these cases to confirm MCL. Co-expression of CD10 and absence of CD5 by IP is most supportive of a diagnosis of FL. HCL, HCLv, and SMZL are typically CD5 negative and CD10 negative. Flow-cytometric IP reveals expression of T-cell lineage markers in T-PLL. The classic immunophenotypic prolife of B-CLPN is summarized in **Table 13-7**.[1,2,56,207]

Accurate diagnosis of CLL is paramount in guiding clinical management of the patient. Despite the characteristic morphologic and immunophenotypic findings in most cases, a small subset may have atypical morphology or IP and pose a diagnostic challenge.

MONOCLONAL B-CELL LYMPHOCYTOSIS

Definition of Disease

The widespread use of sensitive flow cytometric screening techniques has enabled the detection of small monoclonal B-cell populations in healthy individuals. The term *monoclonal B-cell lymphocytosis (MBL)* is used to describe asymptomatic clonal expansions of B cells where the neoplastic cell count is less than 5×10^9/L.[1,3,210] MBL is the precursor lesion for CLL.[1,3] The majority of MBL cases show an IP that is indistinguishable from CLL, whereas smaller subsets have an aCLL IP or a non-CLL IP. ICC also includes a tissue-based MBL as an incidental nodal finding of an infiltrate of CLL-type cells without proliferation centers in individuals without significant lymphadenopathy.[1,30,31,46] The ICC and proposed WHO 5th ed. separate MBL into low-count MBL of $<0.5 \times 10^9$/L and high-count CLL/SLL-type MBL when the cell count is >0.5 and $<5 \times 10^9$/L.[1,3]

The majority of these clones exhibit an IP similar to that seen in CLL and share many of the same chromosomal and molecular abnormalities.[1] However, cases corresponding to aCLL and other B-cell neoplasms have been identified. Many cases, particularly those with low counts, do not progress to CLL and may represent a normal progression of immunosenescence. The relative risk to progression to overt CLL is approximately 1%/year.[211] Monoclonal B-cell populations can be found in as many as 3.5% of individuals over the age of 40. As the immune system ages, the B-cell population becomes more limited in its immunoglobulin gene repertoire. This leads to an increased incidence of observed clonal populations in chronic infection such as hepatitis C.[212] Monoclonal T-cell populations are also observed in MBL patients, further indicating the presence of immune system dysregulation.[6]

Diagnosis of MBL is more challenging with bone marrow or lymph node involvement. Bone marrow and tissue may show infiltrates of neoplastic B cells with CLL features in the absence of PB involvement or significant lymphadenopathy.[2,31] Patients should not be symptomatic or have lymphadenopathy or other evidence of lymphoma. Specific morphologic features supporting a diagnosis of tissue-based MBL are discussed further. Only a small fraction of patients with MBL progress to CLL; however, retrospective analysis of blood samples obtained prior to diagnosis from CLL patients demonstrates B-cell clones consistent with MBL in the majority of specimens. Patients with low-count MBL are unlikely to progress to overt leukemia/lymphoma, with a risk of 4.3-fold compared with the general population. CLL/SLL-type high count MBL patients have a significantly increased risk of progression of 75-fold, and require clinical monitoring.[210]

Epidemiology and Incidence

Population screening demonstrates that 3% to 4% of healthy adults have monoclonal B-cell populations in the PB. Interestingly, this incidence increases strikingly with age, with MBL being virtually non-existent in individuals younger than 40 years, slowly increasing to nearly 30% of individuals in their 80s, but present in 42% of patients older than 90 years.[210] The true incidence of MBL is difficult to determine, as the greater the sensitivity of the assay used for detection, the greater the number of cases with very low monoclonal B-cell counts identified. For example, a population study using four-color flow cytometry with a minimum of 200,000 events identified a frequency of 3.5% in patients older than 40 years,[213]

whereas a study using eight-color flow and analyzing 5×10^6 events report a frequency of 12% in the same age group.[214] The majority of MBL cases have low neoplastic cell counts and no absolute lymphocytosis. A study looking only at cases with borderline or elevated lymphocyte count identified an incidence rate of 3.5 per 100,000.[215] There is an increased risk of MBL in family members of patients with sporadic CLL and in families with inherited CLL predisposition.[211,216]

Clinical Features

MBL occurs by definition in an asymptomatic individual, and is therefore usually an incidental finding. A subset of patients is identified because of detection of lymphocytosis on a routine CBC. The majority of patients, however, do not exhibit an absolute lymphocytosis and are detected by flow cytometry. Clinically, these patients are often monitored for progression to overt CLL; however, the utility of close follow-up in low-count MBL is low.

Morphology

Peripheral Blood

In the PB, MBL is characterized by mature lymphocytes, which are usually similar to those identified in CLL, with homogeneous features; small, round nuclei; condensed nuclear chromatin; and scant cytoplasm. Because of the lower neoplastic cell counts in MBL, however, the neoplastic cells are generally inconspicuous on peripheral smear review.

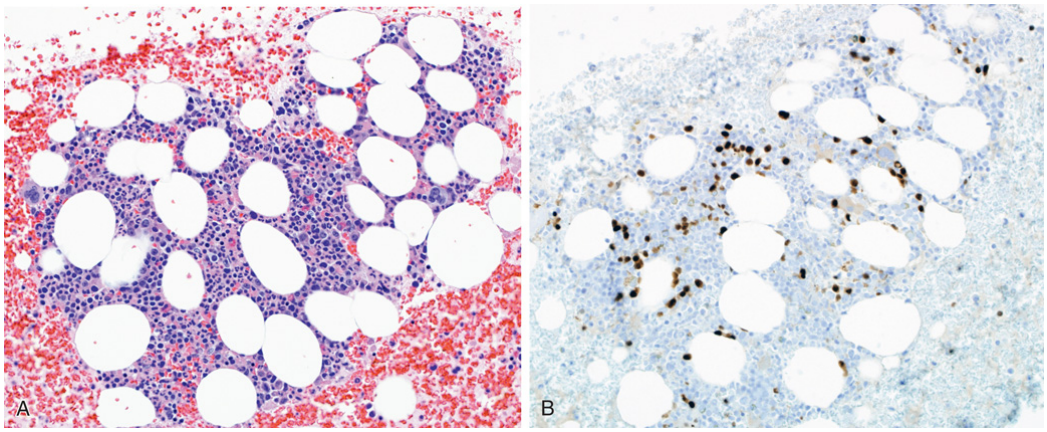

FIGURE 13-25 **A,** Clot section from a patient with clinically indolent mantle cell lymphoma (MCL) illustrates bone marrow with trilineage hematopoiesis an obvious lymphoid infiltrate. **B,** Cyclin D1 stain of the clot sections exhibits scattered positive MCL cells (H&E and cyclin D1 stain).

Bone Marrow

Bone marrow biopsy is not generally performed in patients with MBL; however, MBL in the bone marrow may be identified as an incidental finding in biopsies performed for other indications. Patients with PB MBL almost always exhibit identifiable bone marrow involvement.[31] Neither the ICC nor the proposed WHO 5th ed. define limits of bone marrow involvement by monoclonal B cells that support a diagnosis of CLL versus MBL, and in some cases of MBL with $<5 \times 10^9$/L PB involvement there is significant disease in the marrow. In the ICC, the finding of cytopenias with bone marrow involvement by monoclonal B cells supports a diagnosis of CLL rather than MBL. Percent of bone marrow involvement in MBL is

highly variable, ranging between 4.5% and 81% in one study of 30 cases.[31] Multiple patterns of infiltration in the core biopsy specimen have been identified, with most cases exhibiting either small, interstitial foci of neoplastic cells or scattered neoplastic cells identifiable only by immunohistochemistry (Figs. **13-26** and **13-27**). Occasional cases may show a focal interstitial infiltrate. Diffuse involvement has been rarely identified. The pattern of infiltration may differ with the IP of the neoplastic cells, although this association has not been confirmed in all studies. CD5-negative MBLs are more common in the bone marrow than in the PB.[217] The presence of bone marrow involvement by known MBL or identification of small monoclonal populations of B cells in the marrow in the absence of other suspicion for lymphoma should not prompt a diagnosis of lymphoma.

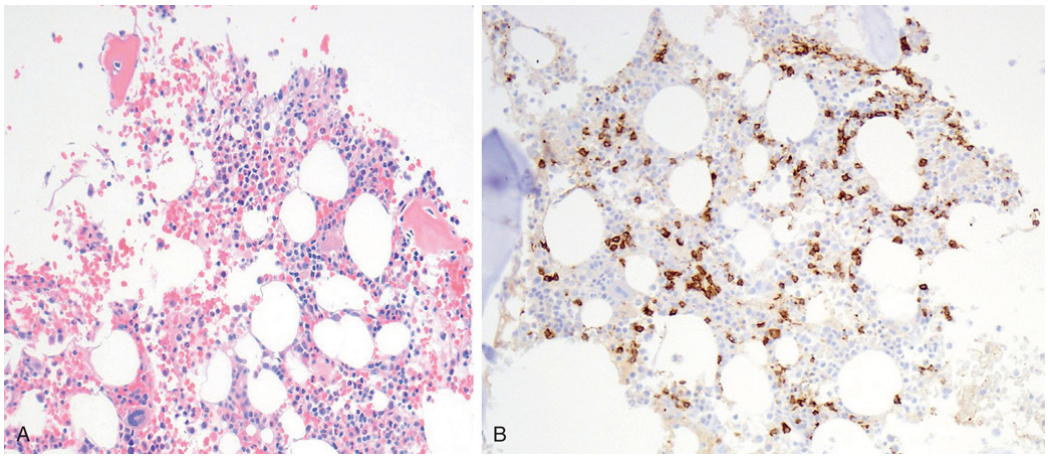

FIGURE 13-26 **A,** Bone marrow core biopsy from a patient with monoclonal B-cell lymphocytosis shows no obvious morphologic involvement by neoplastic lymphocytes. **B,** CD20 immunostain highlights increased numbers of scattered B cells, which were monoclonal by flow cytometry (H&E and CD20 stain).

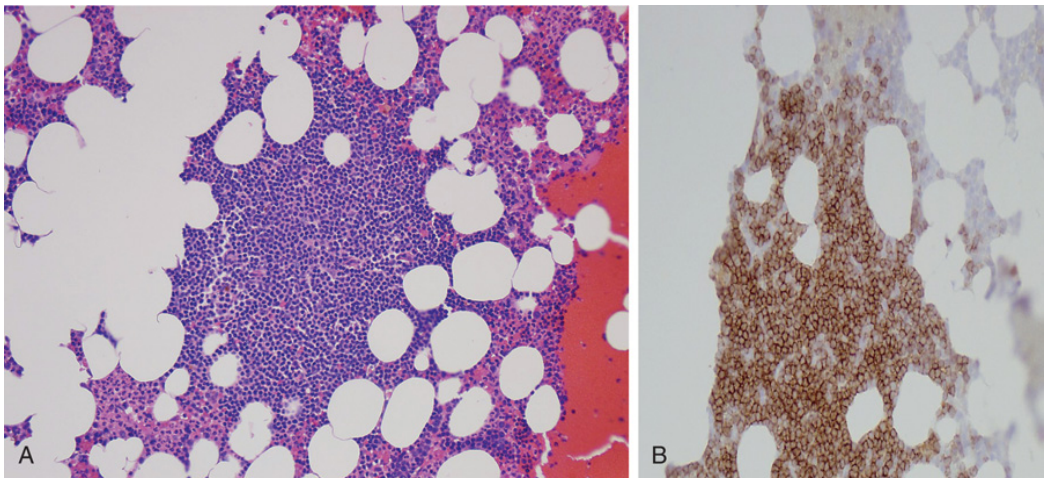

FIGURE 13-27 **A,** Bone marrow clot section from a patient with monoclonal B-cell lymphocytosis shows rare small, well-circumscribed non-paratrabecular lymphoid aggregates. Other features of lymphoma were not present. **B,** CD19 immunostain highlights a predominance of B cells in the aggregate, which were monoclonal by flow cytometry (H&E and CD19 stain).

Lymphoid aggregates are seen in approximately half of patients with MBL and are usually small, well circumscribed, and non-paratrabecular; composed of small lymphocytes; and account for less than 5% of marrow cellularity. In most cases, these aggregates appear to be composed of mixed B cells and T cells and are indistinguishable from benign lymphoid aggregates in the absence of supporting flow-cytometric or IHC confirmation of aberrant phenotype. A subset of cases shows B-cell predominance in the aggregates suspicious for lymphoma.[217] Rare cases of MBL may

show significant involvement, and firm cutoffs for percent involvement in the bone marrow have not been validated.

Lymph Node

The diagnosis of MBL in lymph node specimens can be problematic because of concern for SLL. In lymph nodes with MBL, the nodes are generally removed for other reasons including staging for carcinoma, as the presence of lymphadenopathy caused by the B-cell population precludes the diagnosis of MBL. Lymph nodes should be less than 1.5 cm in size and usually show infiltration by small, mature lymphocytes with round nuclei and clumped chromatin. These cells are difficult to distinguish by morphology alone and are typically identified by flow cytometry or IHC. There should be no distortion of architecture and an interfollicular and intersinusoidal pattern with preservation of follicles and sinuses is most common.[30,31] Occasional cases show a follicular pattern with infiltration of germinal centers. The presence of proliferation centers with CLL IP supports a diagnosis of overt SLL. Other morphologic features, including percentage of lymph node involvement, do not correlate with disease behavior and should not be used to distinguish between SLL and MBL.[46]

Immunophenotype

The majority of MBL exhibit an IP similar to that seen in CLL, with expression of CD5, CD23, dim CD20, and dim surface immunoglobulin (**Fig. 13-28**). Additional cases show a pattern similar to that seen in aCLL, with expression of CD5 and bright CD20 and variable CD23, with bright surface immunoglobulin. Finally, cases may show a “non-CLL” phenotype with negative CD5.

These cases may represent a similar population to CD5-negative CLL or may correlate with a marginal zone B-cell process. There should not be immunophenotypic markers specific for a lymphoproliferative disorder such as HCL. Expression of ZAP70 and CD38 may correlate with progression to CLL.[31]

Genetic and Molecular Features

In general, MBL cases, including both low-count and high-count cases, show the same cytogenetic abnormalities at similar rates as those seen in CLL in most studies, including 13q deletion, trisomy 12, del11q, and del17p.[218] Although individual studies have identified differences in the incidence of specific cytogenetic abnormalities in low-stage CLL and MBL, these have not been confirmed by other studies.[219-221] In addition, cytogenetic abnormalities do not clearly predict MBL progression to overt CLL, although trisomy 12 may be associated with shorter time to treatment.[31,212]

Studies of somatic gene mutations in MBL have demonstrated mutations in similar genes and frequencies as in CLL, including in *SF3B1, NOTCH1, DDX3X, BIRC3,* and *ATM*.[31,222,223] Mutations in *NOTCH1, TP53,* and *XPO1* seem to be present at a lower frequency than in CLL.[224,225] This finding is not unexpected, as the frequency of these mutations is low at diagnosis of CLL and increases over the disease course. These driver mutations are more common in high-count MBL. Identification of clonal expansion can distinguish cases of MBL with increased risk of progression to overt leukemia/lymphoma.[224]

Although the cytogenetic and somatic mutation profiles of MBL and CLL are similar, there are differences in immunoglobulin variant

chain usage and IGHV mutational status. MBL cases show hypermutation in 70% of cases and hypermutation is more frequent in low-count MBL. The most frequently used IGHV segment in MBL is IGHV4-59/61, which is rarely seen in overt CLL. The segments commonly seen in CLL, IGHV4-34 and IGHV1-69, are only infrequently seen in MBL.[226] In addition, low-count MBL cases do not show the phenomenon of stereotyped receptors as observed in CLL; however, their usage can be identified in high-count MBL.[227] This may provide opportunity for identifying patients who may benefit from closer monitoring because of usage of CLL-associated IGHV segments or presence of stereotyped receptors.

Clinical Course and Prognosis

The vast majority of MBL cases, particularly those with low lymphocyte counts, remain stable over time and do not progress to CLL. The 5-year risk for needing therapy has been reported to be 7% in low count MBL (~1% per year) compared with 14% (~5% per year) for Rai 0 stage CLL.[228] In earlier studies, high count MBL carried a risk for progressing to CLL requiring treatment of about 1% per year.[159] The presence of cytogenetic or molecular abnormalities does not reliably correlate with the risk for progression; however, the specific IGHV segments used in the clone may provide some indication of likelihood of progression. Clonal expansion does correlate with progression.[224,229] Currently, the most reliable predictive factor is the absolute monoclonal lymphocyte count.

Although overt immune dysregulation and increased infection support a diagnosis of CLL and should not be present in MBL, MBL patients show an increased rate of hospitalization for infection

compared with unaffected individuals. This risk is greater than the risk for progression to CLL, and MBL patients may benefit from increased surveillance for infection rather than lymphocyte count.[230] In addition, MBL patients show decreased vaccine response and may require additional doses to achieve seroconversion.[231]

B-CELL PROLYMPHOCYTIC LEUKEMIA

B-PLL is a topic of ongoing debate. The two newly published hematolymphoid classification systems have provided different opinions on this entity. The ICC[1,2] has retained this entity as a diagnosis of exclusion. However, the proposed WHO 5th ed.[3] has deleted this entity and has reassigned most of these cases into three categories: MCL, prolymphocytic progression of CLL (with >15% of prolymphocytes in the blood), and the new entity splenic B-cell lymphoma/leukemia with prominent nucleoli.[3]

FIGURE 13-28 Low **(A)** and high **(B)** count monoclonal B lymphocytosis are illustrated. Patients with high count MBL should be monitored for possible progression to CLL.

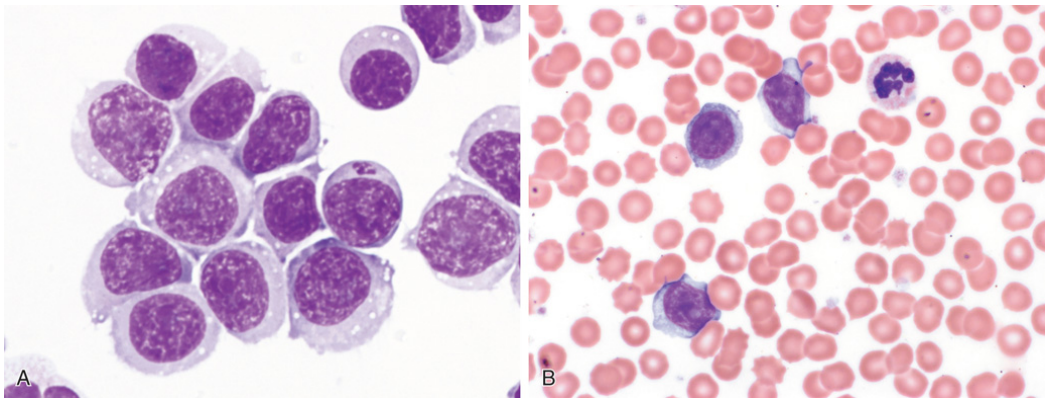

FIGURE 13-29 This composite illustrates two cases of B-cell prolymphocytic leukemia, one on cytospin **(A)** and one blood smear **(B)**. Note predominance of prolymphocytes (Wright's stain).

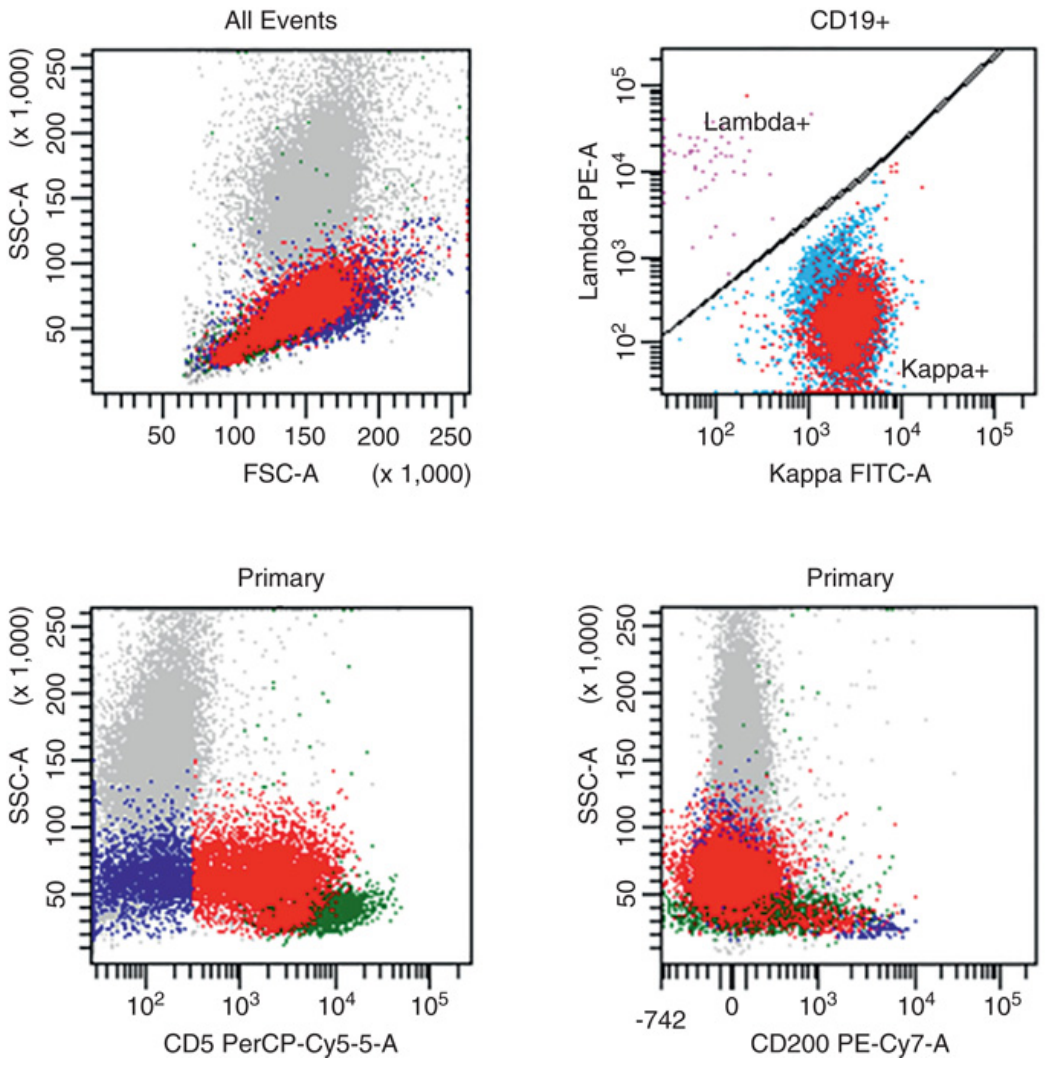

FIGURE 13-30 Flow cytometric immunophenotyping in B-cell prolymphocytic leukemia reveals a monoclonal B-cell population without distinctive features; this case shows CD5 co-expression, which is seen on about 30% of cases. CD200 is negative.

Definition: B-PLL is a neoplasm of B prolymphocytes affecting the PB, bone marrow, and spleen. Prolymphocytes must exceed 55% of lymphoid cells in the PB (**Fig. 13-29**).[2]

Clinical presentation: Patients with B-PLL typically present with rapid onset of B symptoms, marked lymphocytosis (usually >100 × 10^9/L), and massive splenomegaly. Lymphadenopathy is usually not prominent. CNS involvement is rare. A small subset of patients may experience insidious onset of disease and may have a more indolent disease course. The median age at diagnosis is ~72 years old with slight male predominance (60%) and ~82.6% of patients are White.[232,233]

Diagnosis: B-PLL is a diagnosis of exclusion. The diagnosis is made by integrating morphology, IP, and applying genetic assessment. The criteria require >55% prolymphocytes on the PB smear review. Prolymphocytes are intermediate to large cells with moderate light blue cytoplasm, mostly round to occasionally irregular nuclei, slightly open chromatin, and usually prominent central nucleoli. IP of B-PLL shows clonal B-cells with bright CD20 and surface immunoglobulin (SIg). They express surface IgM, CD19, CD22, HLA-DR, CD79b, and FMC7. CD5 is expressed in 20% to 30% and CD23 is expressed in 10% to 20% of cases (**Fig. 13-30**). The IP is not specific, and it overlaps with CLL and many other B-cell non-Hodgkin lymphomas (B-NHL).

Genetics: Chapiro et al.[233] conducted the largest B-PLL case series with genetic characterization. In this study karyotype, FISH, whole-exome sequencing, targeted deep sequencing, IGHV analysis, RNA sequencing, and in vitro cell viability and programmed cell death assays were performed in 34 patients with B-PLL. Complex karyotype (>3 abnormalities) was present in 73% of patients. High complex karyotype (>5 abnormalities) was seen in 45%. Translocations of *MYC* were the most frequent aberrations (62%),

followed by 17p deletion (38%), trisomy 18 (30%), 13q deletion (29%), trisomy 3 (24%), trisomy 12 (24%), and 8p deletion (23%). Twenty-six patients (76%) exhibited *MYC* translocations or gains, which are mutually exclusive.

Molecular studies: Whole exome sequencing identified frequent mutations in *TP53, MYD88, BCOR, MYC, SF3B1, SETD2, CHD2, CXCR4,* and *BCLAF1*. The majority of cases (79%) were IGHV mutated and most cases used IGHV3 or IGHV4 subgroups.

Differential diagnosis: The main differential diagnosis includes CLL with prolymphocytoid transformation, leukemic, non-nodal MCL, lymphoplasmacytic lymphoma, HCL, HCL variant, and SMZL. A comprehensive approach including morphology, IP, cytogenetic studies, and molecular studies is used to exclude these better characterized entities.

Prognosis: The prognosis of B-PLL is largely dependent on the *TP53* mutational status. *TP53* aberration is associated with chemotherapy resistance and worse outcome. The presence of anemia and marked lymphocytosis (>100 × 10^9/L) are also associated with adverse prognosis. IGHV mutations status and expression of ZAP70 or CD38 have no prognostic significance. In an earlier study, the median OS is about 3 years.[234,235] With the incorporation of small molecule targeted therapy, the OS has improved substantially. In Chapiro's cohort, the median OS for the entire cohort was 125.7 months. Patients with B-PLL with *MYC* aberrations have inferior OS compared with patients whose B-PLL lacked *MYC* aberration. Patients with both *MYC* and 17p deletion had the shortest OS. Patients with *MYC* but not 17p deletion have

intermediate OS and patients without either aberration have the best prognosis.[233]

Treatment: The treatment of B-PLL is largely based on *TP53* status. Patients with wild-type *TP53* B-PLL should be considered for chemoimmunotherapy. Patients with *TP53* mutations are typically resistant to chemotherapy and targeted therapy with small molecules should be considered.[235] A combination of ibrutinib, idelalisib, or venetoclax with OTX015 yielded better efficacy than individual agent therapy, particularly in patients with *MYC* translocations. Patients who were treated with ibrutinib alone or in combination with other agents had a variable outcome.[236-238]

Pearls and Pitfalls

Pearls

- Successful diagnosis of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) requires the integration of morphologic and immunophenotypic properties (especially multicolor flow-cytometric immunophenotyping)
- Cyclin D1 expression has a high sensitivity and reasonable high specificity for mantle cell lymphoma (MCL); diffuse cyclin D1 positivity excludes a diagnosis of CLL/SLL and B-cell prolymphocytic leukemia (B-PLL); proliferation centers in CLL/SLL may be weakly cyclin D1-positive
- Proliferation centers in lymph node sections are a reasonably specific feature of CLL/SLL, even if some nuclear irregularity

is noted; proliferation centers are less commonly noted in bone marrow core biopsy sections

- Expanded, highly proliferative proliferation centers are an adverse feature in lymph nodes involved by accelerated CLL/SLL
- Prognostic assessment is essential in CLL and requires integration of CD49d/CD38 status by flow cytometry with multiple cytogenetic/molecular features
- Genetic prognostic factors are linked to clonal transformation
- CLL cases can acquire additional genetic mutations during the disease course
- Full genetic risk assessment is optimally performed at the time that the patient requires therapy
- CLL can undergo transformation to large B-cell lymphoma which is usually genetically associated with the underlying CLL—so-called “Richter transformation” (RT)
- Many adverse genetic features of the underlying CLL are linked to RT

Pitfalls

- In blood, bone marrow, and lymph node, it is critical to distinguish CLL/SLL from MCL
- Leukemic, non-nodal MCL can show substantial immunophenotypic overlap with CLL; consequently, FISH testing for t(11;14) should be considered in all cases in conjunction with the CLL FISH panel

- Leukemic MCL cases may be CD23 positive, CD200 positive, and SOX11 negative
- CLL and leukemic non-nodal MCL can also show significant morphologic overlap in blood and bone marrow
- Proliferation centers in CLL/SLL may be cyclin D1 positive
- Rare CLL cases with admixed Hodgkin (Reed-Sternberg) cells in tissue sections should be distinguished from overt Hodgkin lymphoma transformation; both of these CLL morphologic subtypes with Hodgkin (Reed-Sternberg) cells are linked to adverse outcome
- Leukemic, non-nodal MCL and prolymphocytic transformation of CLL must be excluded before a diagnosis of B-PLL is made

DEFINITION OF THE DISEASE

Lymphoplasmacytic lymphoma (LPL) is defined by the 2022 International Consensus Classification (ICC) as a mature small B-cell neoplasm composed of lymphocytes, plasma cells, and plasmacytic lymphocytes that does not meet criteria for any of the other small B-cell lymphomas that may also exhibit plasmacytic differentiation.[1] It typically involves bone marrow (and any amount of marrow involvement by abnormal lymphoplasmacytic aggregates qualifies for the diagnosis), but peripheral blood, lymph nodes, and spleen may also be involved. Waldenström macroglobulinemia (WM) is defined as LPL involving bone marrow associated with an IgM monoclonal paraprotein of any concentration and is found in the majority of patients with LPL. Many studies of LPL are reported as WM. There are LPL, however, that express IgG or IgA heavy chain, but they are less common. Most LPL cases lack expression of a specific immunophenotype related to antigens commonly assessed in the workup of B-cell malignancies, including CD5, CD10, CD23, and CD103.[1,2] Because of this feature and because plasmacytic differentiation may be seen in a number of small B-cell lymphomas, most commonly one of the subtypes of marginal zone lymphoma, a specific diagnosis of LPL may not always be possible, and some cases are best diagnosed as a small B-cell lymphoma with plasmacytic differentiation with a differential diagnosis provided. However, the diagnosis can be established with greater certainty by molecular analysis through the identification of a *MYD88* L265P somatic mutation, a recurrent finding in greater than 90% of LPL/WM and found in only a small proportion of marginal zone lymphomas.[3-5]

SYNONYMS AND RELATED TERMS

WHO revised 4th edition: Lymphoplasmacytic lymphoma
WHO proposed 5th edition: Lymphoplasmacytic lymphoma/Waldenström macroglobulinemia
Both the 2022 ICC and WHO revised 4th edition include Waldenström macroglobulinemia in the classification indented under LPL.

WHO proposed 5th edition: IgM MGUS
2022 International Consensus Classification: Primary cold agglutinin disease
WHO revised 4th edition: Associated B-cell lymphoma classified as LPL in subset of cases
WHO proposed 5th edition: Cold agglutinin disease

EPIDEMIOLOGY

LPL/WM is an uncommon lymphoid neoplasm, representing approximately 2% of non-Hodgkin lymphoma cases diagnosed in the United States between 1988 and 2007 according to Surveillance, Epidemiology and End Results (SEER) registry data.[6] The median age at diagnosis is 73 years with a male predominance.[6-8] The overall age-adjusted incidence is 3.8 per 1 million persons per year and incidence increases sharply with age.[6,7,9] A role for genetic factors in

the pathogenesis of LPL/WM is suggested based on numerous reports of familial occurrence in case-control and larger cohort studies.[10-13] A study from Asia found lower incidence rates in Japan and Taiwan compared with rates reported in the literature for Asians living in the United States, suggesting that both environmental and genetic factors are involved in LPL/WM development.[9] Among environmental factors, chronic antigenic stimulation secondary to various autoimmune diseases or other inflammatory conditions has been implicated.[14] An etiologic role for hepatitis C virus (HCV) has also been suggested; however, this has not been shown in all studies, and a large study with both serologic and molecular genetic methods for HCV detection found no association with LPL/WM.[15]

CLINICAL FEATURES

The clinical manifestations of LPL/WM can be attributed to two main factors: the effects of the monoclonal IgM paraprotein and tissue infiltration by neoplastic cells. The monoclonal IgM paraprotein causes morbidity via several mechanisms related to its biochemical and immunologic properties, non-specific interactions with other proteins, antibody activity, and propensity to deposit in tissues.[16] The high concentration of monoclonal IgM molecules and their tendency to form pentamers can lead to serum hyperviscosity through binding of water and erythrocyte aggregation. Symptomatic hyperviscosity is seen in 10% to 30% of WM patients, and serum viscosity increases sharply at IgM concentrations of greater than 3 g/dL, with most patients manifesting symptoms at levels greater than 5 g/dL. Symptoms of hyperviscosity include headaches, visual disturbances, mental status changes, and, in severe cases,

intracranial hemorrhage.[17-19] Cryoprecipitation of the monoclonal IgM (type I cryoglobulinemia) may be seen in up to 20% of patients, with a minority of such patients exhibiting symptoms of Raynaud phenomenon, acrocyanosis, or, less frequently, renal manifestations.[16,20] In other patients, the monoclonal IgM may behave as a type II cryoglobulin and demonstrate IgG autoantibody activity, leading to symptoms of purpura, arthralgias, renal insufficiency, and peripheral neuropathy.[16,21] Other autoantibody effects of the monoclonal IgM against red blood cell antigens may result in cold agglutinin hemolytic anemia, whereas binding of peripheral nerve constituents may lead to a sensorimotor neuropathy.[22-24] The latter manifestation is relatively common in WM, reported in 25% to nearly 50% of patients in some series.[23-25] Peripheral neuropathy may also be mediated by nonautoimmune effects of the monoclonal IgM protein, secondary to fibrillar or tubular deposits in the endoneurium, amyloid deposition within nerves, or direct infiltration of nerve structures.[16] The monoclonal protein may also deposit in various other tissues as amorphous aggregates leading to dysfunction of affected organs.[16] Deposition of monoclonal light chain in the form of amyloid (primary amyloid light chain [AL] amyloidosis) is much less common in patients with WM, but may lead to similar types of organ dysfunction.[26]

Direct tissue infiltration by neoplastic cells is most common in the bone marrow, leading to peripheral cytopenias. At the time of presentation, the degree of anemia is typically more profound than other cytopenias, because the anemia in WM/LPL is multifactorial in nature and due in large part to increased plasma viscosity leading to inappropriately low erythropoietin production.[27] Other factors

contributing to anemia include hemolysis, plasma volume expansion, and gastrointestinal blood loss in patients with involvement of that site.[16] Nodal and splenic involvement may be present, but bulky lymphadenopathy is uncommon and splenomegaly, if present, is typically mild to moderate in degree. Extramedullary and extranodal sites of disease involvement by LPL that have been reported include lung, soft tissue, skin, gastrointestinal and hepatobiliary tracts, kidney, and central nervous system (CNS).[28-32] Pulmonary involvement, seen in less than 5% of patients, may be in the form of nodules, masses, diffuse infiltrates, or pleural effusions, and results in symptoms of cough (most commonly), dyspnea, and chest pain.[29] Gastrointestinal disease may involve the stomach, duodenum, or small intestine, resulting in malabsorption, bleeding, or obstruction, whereas cutaneous involvement may result in chronic urticaria or in the formation of plaques or nodules.[16] Direct infiltration of the CNS, known as *Bing-Neel syndrome*, is a rare complication of LPL/WM that is characterized clinically by a variety of neurologic signs and symptoms, including mental status changes, headache, motor dysfunction, vertigo, impaired hearing, and, in some cases, coma.[16,29] Unlike in multiple myeloma, lytic bone lesions are not seen, and hypercalcemia is rare.

MORPHOLOGY

Peripheral Blood

Lymphocytosis may be present, but the absolute lymphocyte count is usually lower than in chronic lymphocytic leukemia (CLL) (**Box 14-1**). Circulating neoplastic cells have plasmacytic features with clumped chromatin, eccentric nuclei, and moderately abundant

basophilic cytoplasm, occasionally with a paranuclear hof (**Fig. 14-1**).[33] Red cell agglutination and rouleaux formation may be present in patients with serum hyperviscosity caused by elevated IgM paraprotein.[34]

Bone Marrow

Bone marrow aspirate smears demonstrate lymphocytosis with a morphologic spectrum that includes small, round lymphocytes with clumped chromatin, plasmacytic lymphocytes, and plasma cells (**Fig. 14-2A–B**). Varying patterns of bone marrow involvement may be observed in core biopsy specimens, with interstitial and nodular infiltrates most commonly reported.[35-37] Less frequently, pure paratrabecular or diffuse patterns of marrow involvement may be seen.[35,36] The lymphoid aggregates are composed mainly of small lymphocytes with variable numbers of plasmacytic lymphocytes and plasma cells (**Fig. 14-2C–E**).[1,2] Plasmacytic differentiation may be reflected by the presence of Russell or Dutcher bodies (**Fig. 14-3**).[33] Increased mast cells are almost always present in association with the lymphoid aggregates, and their identification may be facilitated by tissue Giemsa stain or CD117 immunohistochemistry; however, this finding is not considered specific for the diagnosis of LPL (see Figs. **14-2F** and **14-3B**).[1,2,38]

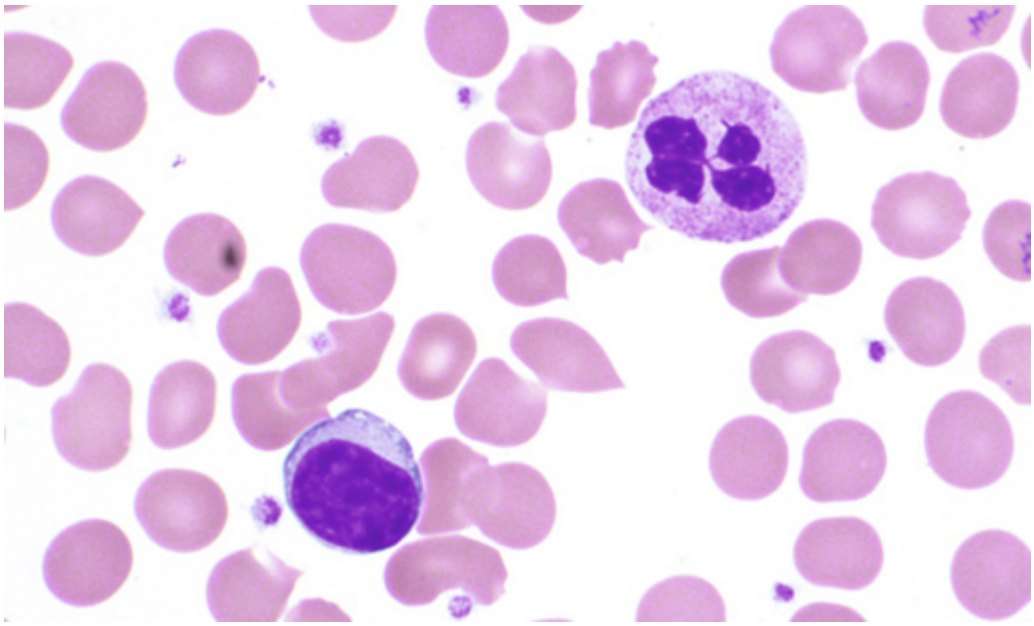

FIGURE 14-1 Peripheral blood findings in lymphoplasmacytic lymphoma.A circulating neoplastic lymphocyte *(bottom left)* shows features of plasmacytic differentiation with clumped chromatin, nuclear eccentricity, and moderately abundant cytoplasm with a paranuclear hof.

Box 14-1 Major Diagnostic Features of Lymphoplasmacytic Lymphoma

Morphology

- Spectrum of small, round lymphocytes with clumped chromatin, lymphoplasmacytic cells, and plasma cells. Russell and Dutcher bodies may be present. Abnormal

lymphoplasmacytic aggregates often associated with increased mast cells.

- Bone marrow: Interstitial and nodular infiltrates; paratrabecular or intrasinusoidal growth patterns rare.
- Peripheral blood: Circulating neoplastic cells have plasmacytic features with clumped chromatin, eccentric nuclei, and moderately abundant basophilic cytoplasm with occasional paranuclear hofs; cytoplasmic projections absent.
- Lymph node: Some cases with interfollicular infiltrates with subtotal architectural effacement and retention of primary or secondary follicles and preserved or dilated sinuses; other cases with complete architectural effacement and vaguely nodular growth occasionally with variable follicular colonization and focal monocytoid or marginal zone-like morphology.

Immunophenotype

- Lymphocytic component: Moderate expression of pan–B-cell antigens and monoclonal surface immunoglobulin.
- Plasmacytic/plasma cell component: Positive for cytoplasmic immunoglobulin and CD19, IRF4/MUM1, and CD138 of variable intensity in all or a subset of cells; negative for CD56.
- Moderate expression of CD200 by flow cytometry; CD25 and CD38 frequently expressed; typically negative for phenotypically distinctive markers of other small B-cell neoplasms, including CD5, CD10, CD23, CD103, LEF1, cyclin D1, SOX11, and DBA.44.

- Rare cases may be positive for CD5 or CD10. CD23 may also be expressed.
- Staining of other cell types: CD117-positive/tryptase-positive mast cells, CD21-positive or CD23-positive follicular dendritic cell aggregates.

Genetics

- *MYD88* L265P mutation most common and characteristic, although not specific for LPL: may be seen with relatively high frequency in other B-cell neoplasms, particularly diffuse large B-cell lymphoma (DLBCL) of immune-privileged sites, but infrequent in other small B-cell neoplasms.
- A minority of bona fide LPL lacks *MYD88* mutations, so its absence does not exclude the diagnosis. However, be more cautious in these cases to exclude other B-cell neoplasms with plasmacytic differentiation, particularly marginal zone lymphomas.
- *CXCR4* nonsense and frameshift mutations identified with relatively high frequency, usually in *MYD88*-mutated cases. *CXCR4* nonsense mutations associated with clinically aggressive disease and lower responsiveness to BTK inhibitors.
- Other commonly mutated genes include *ARID1A, TP53, CD79B, KMT2D,* and *BTK*. *TP53*-mutated cases are associated with clinically aggressive disease and shorter overall survival but remain responsive to ibrutinib. *BTK*-mutated and *MYD88* wild-type cases are less responsive to BTK inhibitors. Wild-

type *MYD88* cases contain mutations downstream of BTK and have a higher risk of transformation to DLBCL.

- Other abnormalities associated with more aggressive disease include chromosome 6q deletion spanning a region that encodes for several regulatory genes involved in B-cell receptor signaling and apoptosis; 17p deletion resulting in *TP53* loss of heterozygosity; and karyotypic complexity.

The extent of marrow involvement by abnormal lymphoplasmacytic aggregates typically exceeds 10% of cellularity; however, in keeping with the diagnostic criteria proposed by the 2nd International Workshop on Waldenström Macroglobulinemia, the diagnosis may be made in cases with *any* amount of abnormal lymphoplasmacytic aggregates in the marrow and evidence of B-cell and plasma cell clonality, because even patients with limited marrow involvement may have symptoms of WM related to the monoclonal paraprotein or bone marrow infiltration.[39]

The pattern of bone marrow involvement may raise the differential diagnosis of other small B-cell neoplasms that more commonly involve the bone marrow, including CLL and follicular lymphoma. Distinction from these entities can be made readily on the basis of the immunophenotype of the neoplastic cells as noted (see "Immunophenotype"). In addition, although nodular aggregates may extend to paratrabecular locations and infrequent LPL cases with predominant paratrabecular patterns of involvement have been described, these paratrabecular aggregates are generally not associated with linear growth along bony trabeculae or fibrosis, as seen in bone marrow involvement by follicular lymphoma (see **Fig. 14-2C**).[35] Bone marrow involvement by marginal zone lymphoma

presents a more challenging distinction, given its shared immunophenotype with LPL. Interstitial involvement is more commonly seen in LPL compared with marginal zone lymphoma.[35] In contrast to bone marrow involvement by splenic marginal zone lymphoma (SMZL), intrasinusoidal involvement is rare in LPL.[35,36] Assessment for the presence of the *MYD88* L265P mutation is helpful in difficult cases.[5] Cases with prominent plasmacytic differentiation may raise the differential diagnosis of multiple myeloma, particularly the small cell variant with lymphoplasmacytic morphology. The latter is distinguishable from LPL on the basis of its CD45-negative, CD19-negative, CD56-positive immunophenotype and frequent cyclin D1 positivity by immunohistochemistry corresponding to an underlying *CCND1* rearrangement detectable by fluorescence in situ hybridization (FISH).[40-43]

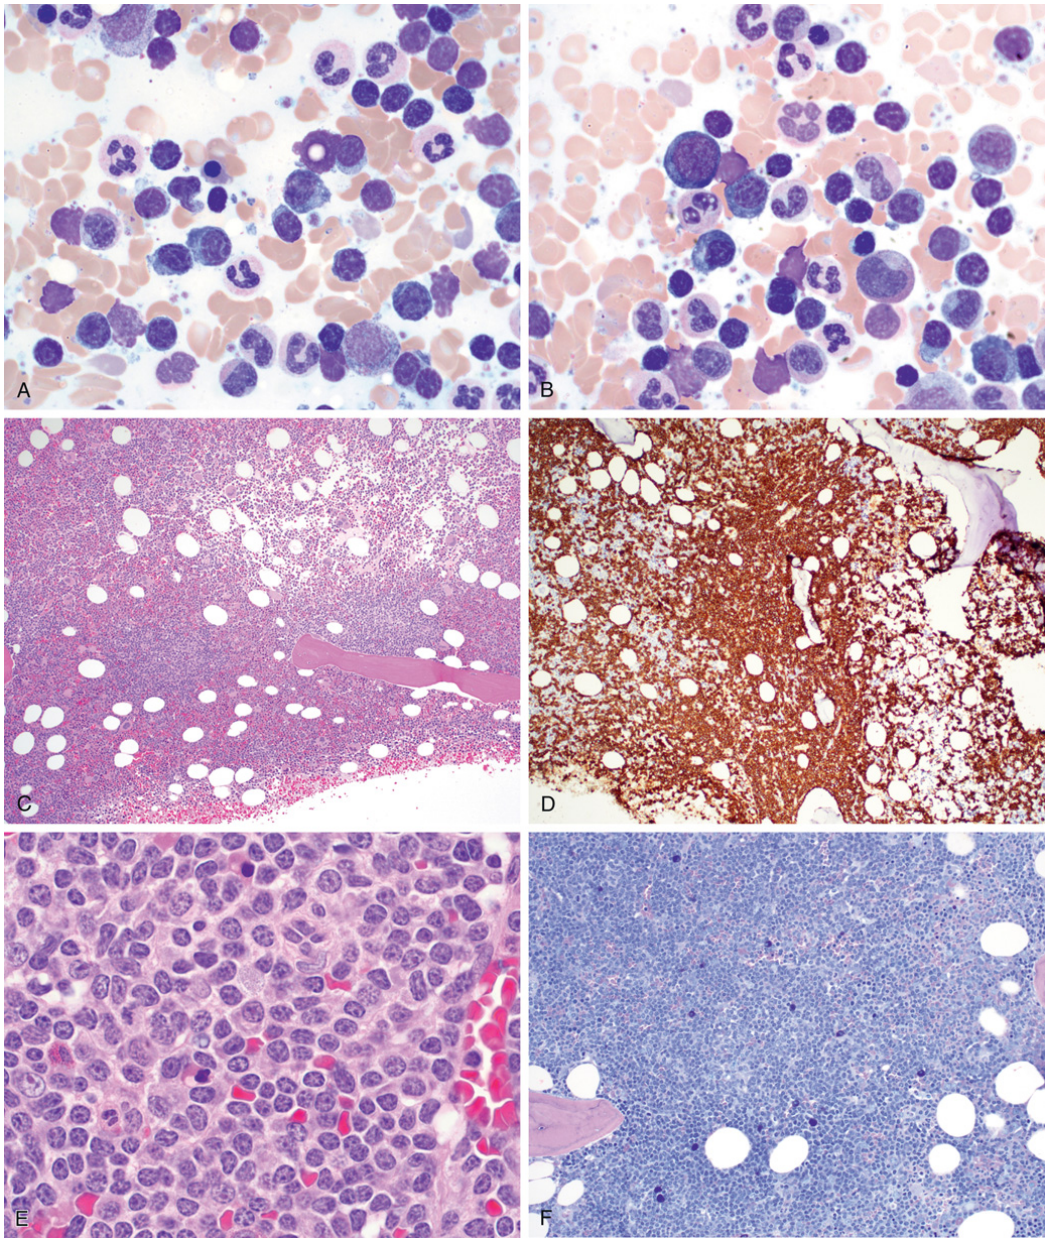

FIGURE 14-2 Bone marrow involvement by lymphoplasmacytic lymphoma.**A** and **B,** Wright-Giemsa–stained bone marrow aspirate smears demonstrate a lymphocytosis consisting of small, mature-appearing lymphocytes with clumped chromatin, including many plasmacytic forms. Rare plasma cells are present. **C,** Low

magnification evaluation of the corresponding core biopsy specimen shows both interstitial and nodular lymphoid infiltrates, including a loose paratrabecular aggregate. **D,** CD20 immunohistochemical stain highlights the variable patterns of bone marrow involvement, as well as the extent of marrow disease in this case. **E,** Higher magnification demonstrates small lymphocytes with clumped chromatin, occasional plasmacytic lymphocytes, and rare plasma cells. **F,** Increased numbers of mast cells are highlighted by this Giemsa stain.

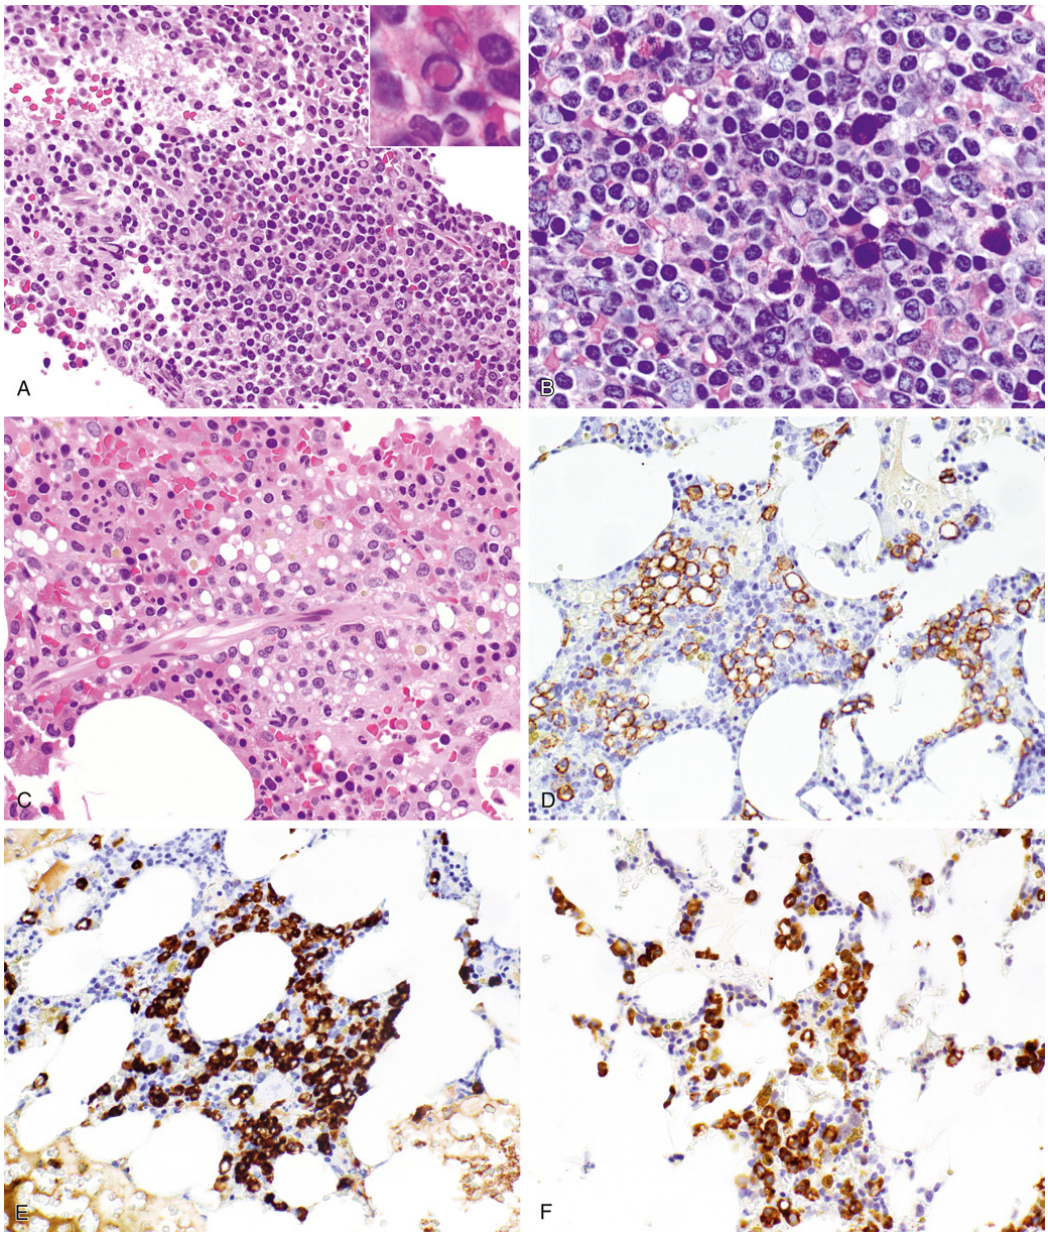

FIGURE 14-3 Examples of lymphoplasmacytic lymphoma with conspicuous plasmacytic differentiation.**A,** H&E-stained bone marrow core biopsy specimen of a case of lymphoplasmacytic lymphoma with noticeable immunoglobin pseudoinclusions overlying lymphocyte nuclei; these Dutcher bodies are positive on periodic

acid–Schiff (PAS) stain (**A,** *inset*). **B,** Giemsa-stained bone marrow biopsy highlights frequent eccentric nuclei with paranuclear hofs and conspicuous mast cells. **C,** A different case of lymphoplasmacytic lymphoma with prominent clear cytoplasmic immunoglobulin deposits (Russell bodies) imparting a signet-ring appearance to the neoplastic cells. The lymphoplasmacytic cells were positive for CD138 **(D)**, IgM **(E)**, and kappa light chain **(F)**, and were negative for lambda light chain (not shown).

Lymph Nodes

In the classic pattern of nodal involvement, there is subtotal architectural effacement with retention of small primary or enlarged reactive follicles and patent or dilated sinuses (**Fig. 14-4A**).[2,4,28,33,37,44] The interfollicular areas contain a relatively monomorphic infiltrate of small lymphocytes, plasmacytic lymphocytes, and plasma cells, generally without prominent follicular colonization (**Fig. 14-4B**).

Following the identification of *MYD88* L265P mutation as being characteristic of LPL, mutational analysis in nodal lymphomas initially diagnosed as LPL, nodal marginal zone lymphoma (NMZL), and small B-cell lymphoma with plasmacytic differentiation have helped to refine the morphologic spectrum of nodal LPL. These studies show that some *MYD88* L265P–mutated cases demonstrate complete nodal architectural effacement, a vaguely nodular growth pattern, variably prominent follicular colonization, or focal areas

containing pale monocytoid or marginal zone B cells (see **Fig. 14-4C–F**).[4,45] Cases harboring the *MYD88* L265P mutation had significantly more common bone marrow involvement, elevated serum IgM levels, and presence of a serum M component, suggesting that they represent true LPL cases despite the presence of morphologic features previously thought to be more characteristic of NMZL.[4,45]

In both the classic and effaced patterns, Dutcher bodies, increased numbers of mast cells, or hemosiderin deposition may be present. Only rare large transformed cells resembling immunoblasts are typically seen; these may be more numerous in some cases, but should not form large aggregates or sheets, in which case a diagnosis of transformation to diffuse large B-cell lymphoma (DLBCL) should be considered.[46] Other possible morphologic findings include the presence of extracellular deposits of immunoglobulin, in the form of amyloid or, more commonly, amorphous Congo red–negative amyloid-like material, or crystal-storing histiocytes. Pseudofollicles or proliferation centers, as seen in CLL/small lymphocytic lymphoma (SLL), are not a typical feature.

Spleen and Other Tissues

Splenic involvement by LPL has not been well described, but older published series and illustrated reviews support the presence of nodular and diffuse infiltrates of lymphoplasmacytic cells involving the red pulp, in a similar distribution to other small B-cell neoplasms with a leukemic pattern of dissemination.[28,47-49] The morphologic spectrum of the lymphoma cells, including small lymphocytes, plasma cells, and intermediate forms, is analogous to that seen in

bone marrow and lymph node specimens (**Fig. 14-5**). This cytologic appearance may give rise to the differential diagnosis of SMZL, which may demonstrate plasmacytic differentiation in some cases. Pathologic features favoring a diagnosis of LPL over SMZL include relative sparing of the white pulp with absence of a marginal zone growth pattern, absence of monocytoid or marginal zone–type cytology, and conspicuous plasmacytic differentiation that is usually readily apparent by both morphology and on immunohistochemical or in situ hybridization studies of tissue sections (see **Fig. 14-5B–E**).[48] In addition, LPL patients typically have higher IgM paraproteinemia and more extensive disease involving the bone marrow or lymph nodes, with secondary splenic involvement resulting in a milder degree of splenic enlargement compared with SMZL. Other small B-cell lymphoma entities with diffuse red pulp involvement that may enter into this differential diagnosis include hairy cell leukemia (HCL) and splenic diffuse red pulp small B-cell lymphoma (SDRPSBL). Distinction between LPL and HCL is usually straightforward on clinical, morphologic, and immunophenotypic grounds.[50] Although SDRPSBL cases may show subtle plasmacytic features, they usually lack strong features of plasmacytic differentiation such as cytoplasmic immunoglobulin deposition by immunohistochemistry or in situ hybridization.[51]

Common sites of extramedullary and extranodal disease were described (see “Clinical Features” above). Among the few histologic descriptions in the literature, LPL involving extramedullary sites may show some features that overlap with extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (EMZL), including the presence of nodular and diffuse infiltrates of lymphoplasmacytic

cells, focal clusters of monocytoid B cells, and presence of Dutcher bodies.[28,30] However, in gastrointestinal sites such as the stomach and colon, lymphoepithelial lesions and colonization of preexisting follicles have not been described.[28,30] Skin biopsies have been reported to show interstitial, nodular, or diffuse dermal infiltration by lymphoplasmacytic cells with perinodal and periadnexal accentuation; focal epidermal ulceration may be present in rare cases.[28,52,53] Hepatic involvement, reported most often in cases with splenic disease, shows expansion of portal tracts and sinusoids by small plasmacytic lymphocytes (**Fig. 14-6**).[28] In cases of CNS involvement (Bing-Neel syndrome), cytologic evaluation of cerebrospinal fluid (CSF) specimens may show a lymphocytic pleocytosis consisting of plasmacytic lymphocytes and plasma cells, similar to the spectrum of cell populations seen in other tissues (**Fig. 14-7A–B**). Laboratory evaluation of such specimens via flow cytometry, electrophoresis, immunofixation, and *MYD88* L265P mutation analysis may help confirm the diagnosis (see **Fig. 14-7C–F**).[32,54,55] In some cases, however, the paucity or absence of neoplastic cells in CSF specimens, as in other subtypes of lymphoma involving the CNS, may preclude a definitive diagnosis, requiring brain biopsy.

IMMUNOPHENOTYPE

The lymphocytic component of LPL expresses moderate levels of pan–B-cell antigens, including CD19, CD20, CD22, CD79a, PAX5, and FMC7, as well as monotypic surface light chain (see Figs. **14-2D** and **14-6D**). The plasmacytic component of the tumor expresses cytoplasmic immunoglobulin and other markers of plasma cell

differentiation, including CD138 (variable) and IRF4/MUM1 (see **Fig. 14-8C**). There is moderate expression of CD200 by flow cytometry.[56] Unlike the neoplastic plasma cells of multiple myeloma, CD19 expression is usually retained on the plasmacytic component and CD56 is negative. CD25 and CD38 are frequently, although not always, expressed, and neoplastic cells are typically negative for other phenotypically distinctive markers, including CD5, CD10, CD23, CD103, and DBA.44. Occasional CD5-positive cases have been reported, which can generally be distinguished from CLL/SLL and mantle cell lymphoma by the presence of strong cytoplasmic immunoglobulin expression in a significant subset of cells and the absence of LEF1 or cyclin D1 and SOX11 expression. Similarly, rare CD10-positive cases can be distinguished from follicular lymphoma based on the degree of plasmacytic differentiation, absence of other germinal-center–associated antigens such as BCL6 and LMO2, and pattern of staining with follicular dendritic cell antigens (CD21 or CD23). CD23 may also be positive in some LPL but other features will help exclude CLL/SLL.

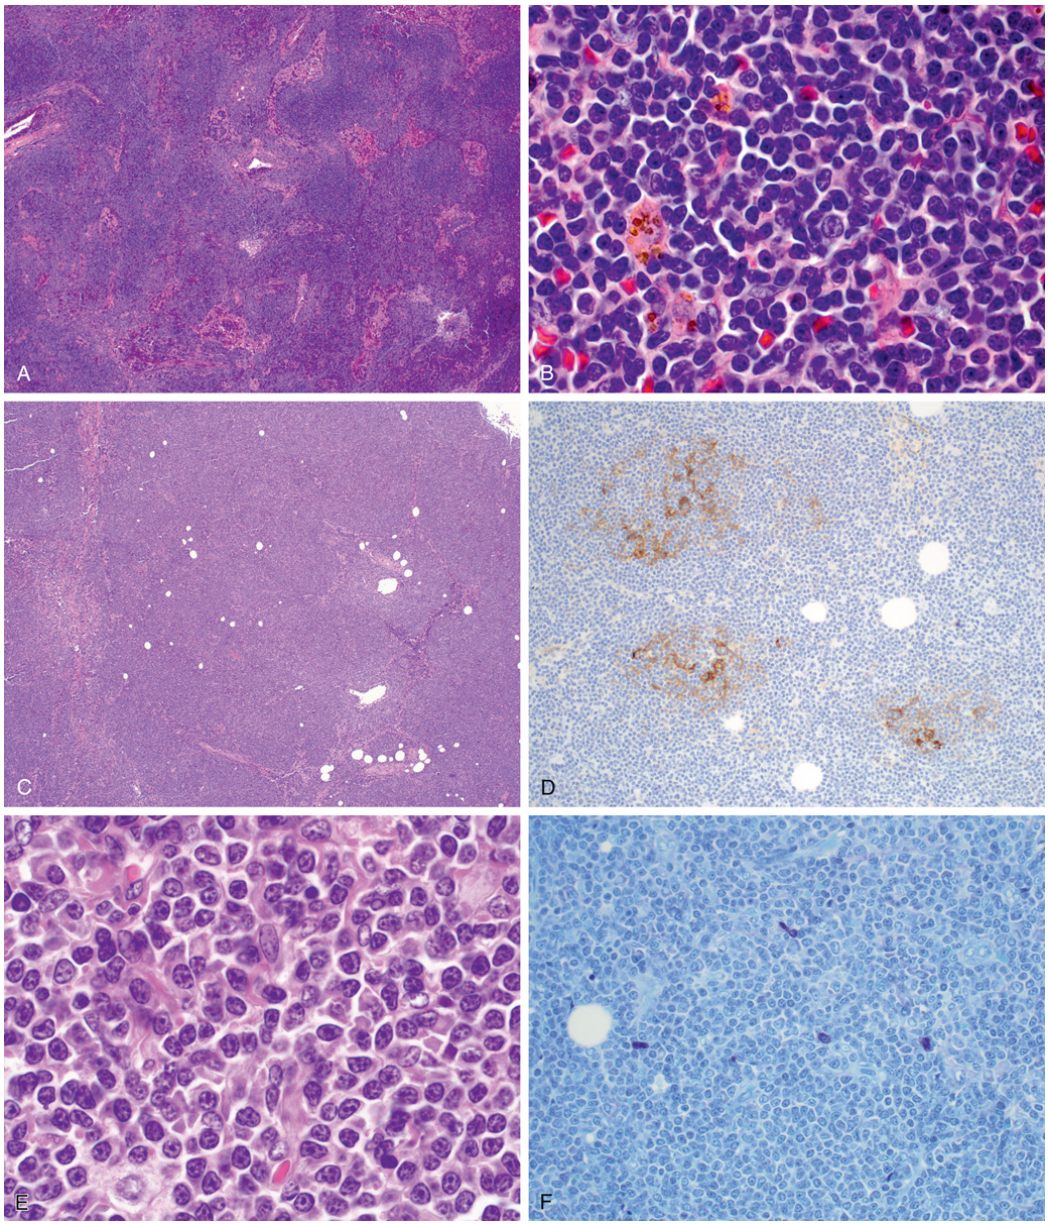

FIGURE 14-4 Spectrum of nodal involvement by lymphoplasmacytic lymphoma.**A** and **B,** Case illustrating the "classic" pattern of nodal involvement with subtotal architectural effacement and patent sinuses on low magnification **(A),** and an interfollicular infiltrate of monomorphic small cells with clumped chromatin associated with extracellular

hemosiderin deposition on high magnification **(B). C–F,** A case demonstrating more complete nodal architectural effacement **(C)** associated with colonized follicles as shown on CD21 stain **(D).** Plasmacytic differentiation is appreciated on high magnification **(E),** and scattered mast cells are present, as highlighted by Giemsa stain **(F).** Both cases were positive for the *MYD88* L265P mutation on molecular genetic analysis.

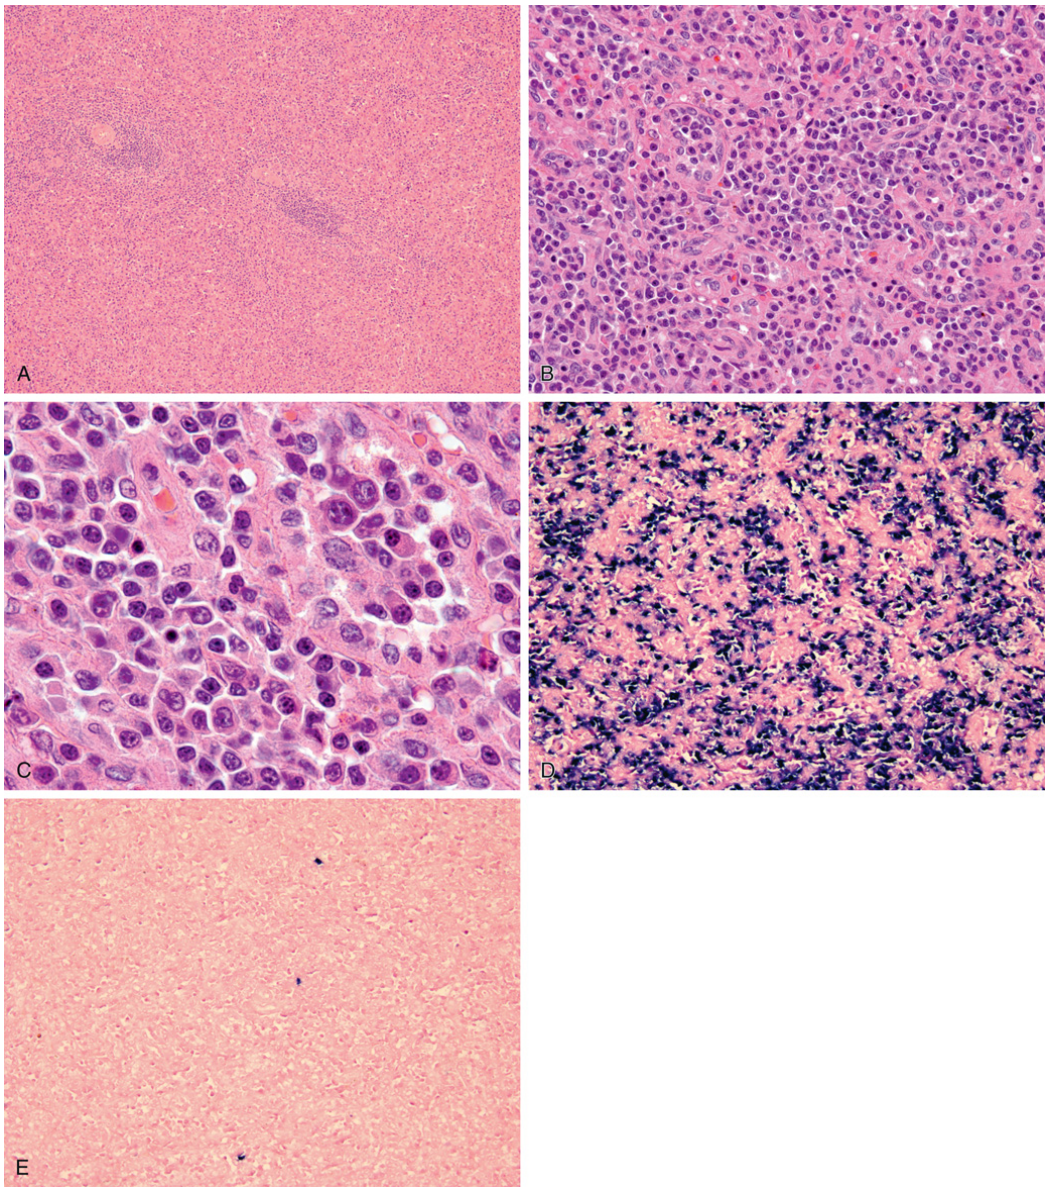

FIGURE 14-5 Splenic involvement by lymphoplasmacytic lymphoma.The spleen was mildly enlarged, weighing 260 grams. **A,** The lymphoma predominantly involves the red pulp, whereas the white pulp is spared and appears atrophic, as seen at low magnification. **B** and **C,** Red pulp sinuses contain small lymphocytes and conspicuous mature plasma cells, as well as many

intermediate forms. **D** and **E,** Plasmacytic differentiation is further evidenced by in situ hybridization demonstrating marked kappa light chain **(D)** predominance over lambda **(E).** A–C Used with permission from Sohani AR, Zukerberg LR. Lymphomas of the spleen. In: Ferry JA, ed. Extranodal Lymphomas. Philadelphia: Elsevier, 2011. p. 204, Fig. 6.6.

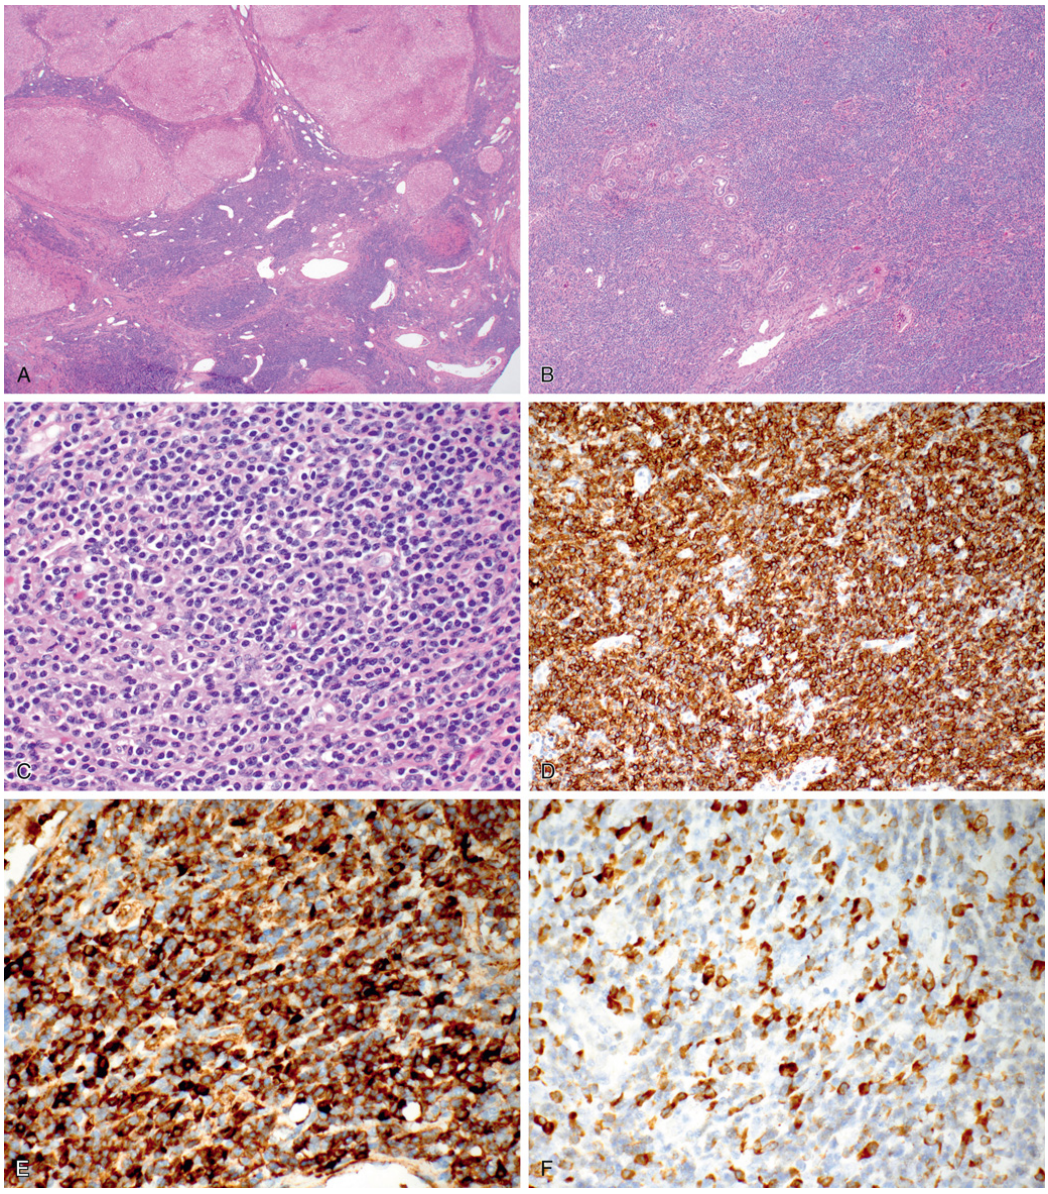

FIGURE 14-6 Hepatic involvement by lymphoplasmacytic lymphoma.**A,** Low-magnification view of a cirrhotic explanted liver in a patient with a history of *MYD88*-mutated lymphoplasmacytic lymphoma shows marked expansion of portal tracts by dense collections of lymphocytes surrounding residual bile ducts, but without evident lymphoepithelial lesions **(B)**. **C,**

On high magnification, the lymphocytes exhibit characteristic features of lymphoplasmacytic lymphoma with a spectrum of small lymphocytes with clumped chromatin and occasional plasmacytic forms with eccentric nuclei. Note, however, that occasional cells have moderate clear cytoplasm reminiscent of monocytoid B cells. **D,** The lymphoma cells are strongly and diffusely positive for CD20 with restricted expression of IgM heavy chain **(E)** and kappa light chain **(F)**, and negative staining for lambda light chain (not shown).

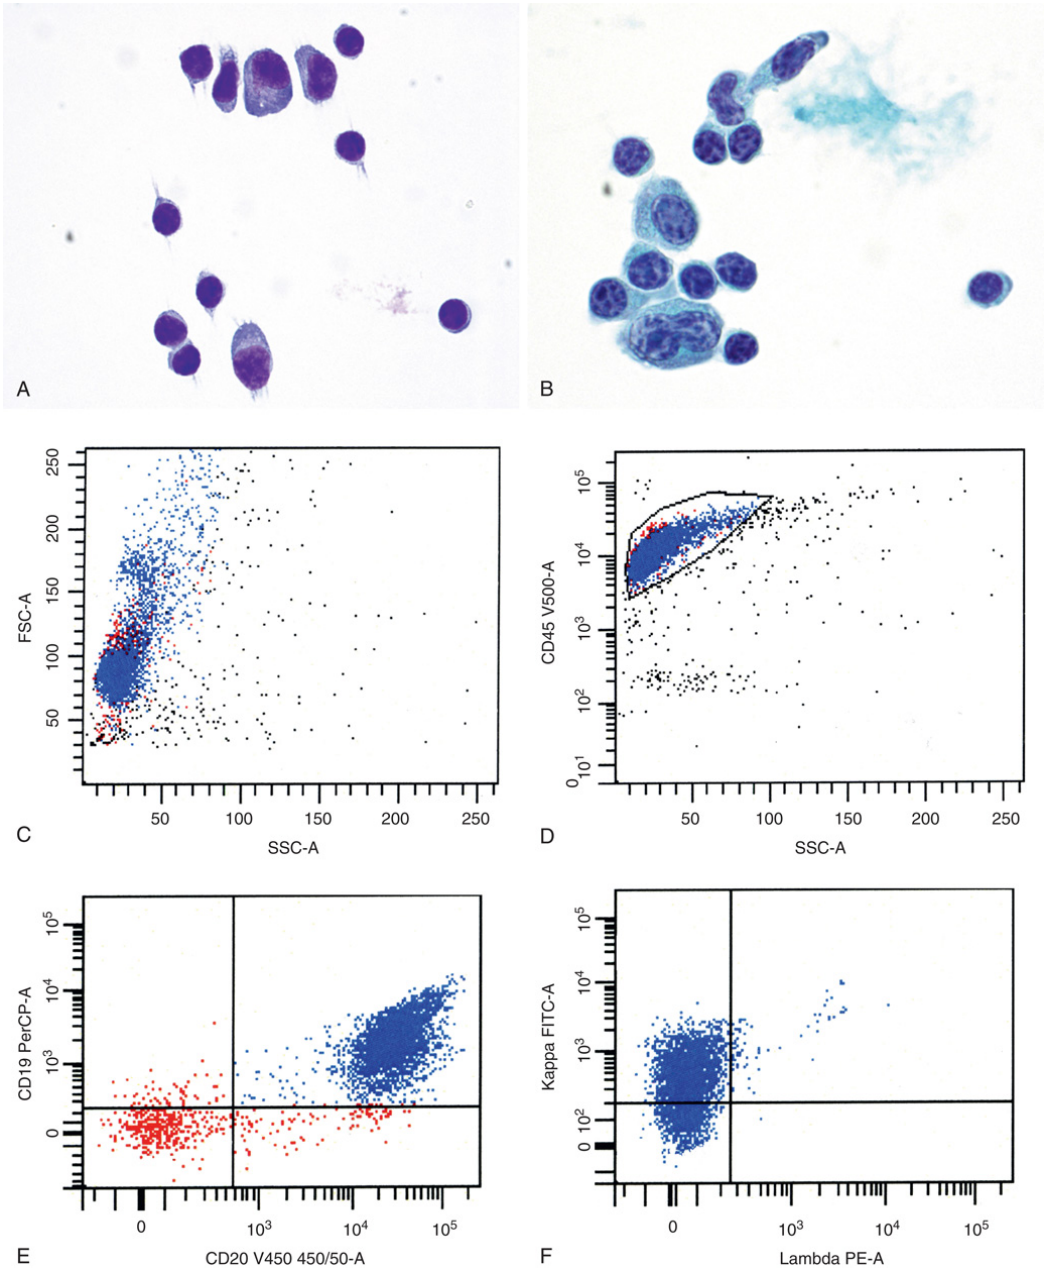

FIGURE 14-7 Cerebrospinal fluid (CSF) involvement by lymphoplasmacytic lymphoma (Bing-Neel syndrome).Diff-Quik **(A)** and Papanicolaou **(B)** stains show a population of small lymphocytes with condensed or clumped chromatin and larger plasmacytic forms. **C–F,** CSF flow-cytometric analysis confirms the

presence of a CD45-positive, CD19-positive, CD20-positive B-cell population with kappa light chain restriction *(blue)*. By light-scatter analysis **(C),** a subset of the clonal B cells shows high forward scatter, corresponding to the larger plasmacytic and plasma cells.

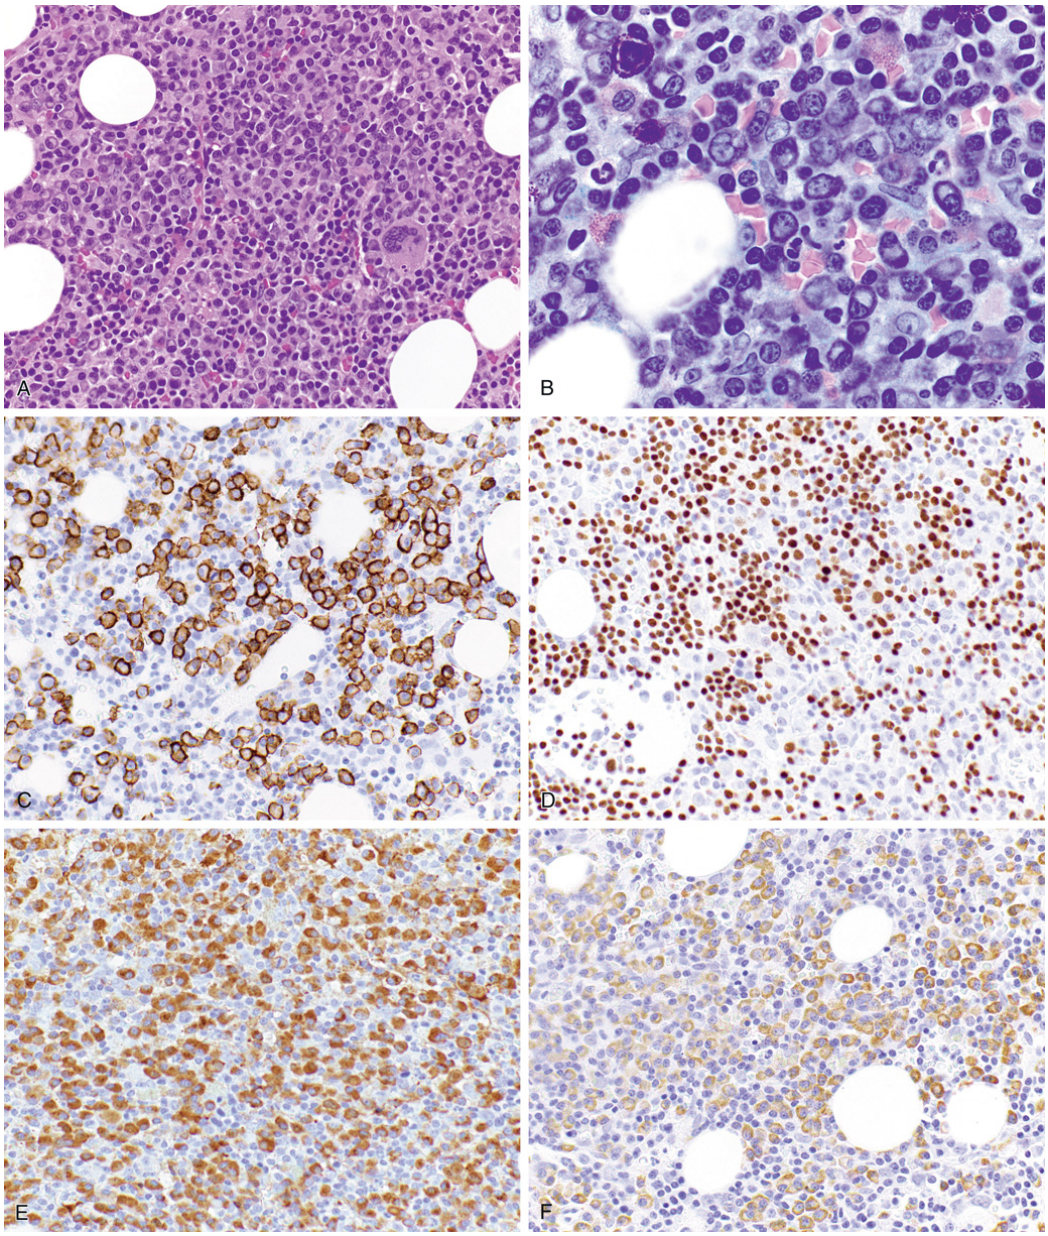

FIGURE 14-8 IgG-positive lymphoplasmacytic lymphoma with *MYD88* L265P mutation.H&E-stained **(A)** and Giemsa-stained **(B)** bone marrow core biopsy specimen shows a dense lymphoid infiltrate with marked plasmacytic differentiation, as confirmed by CD138 immunohistochemical stain **(C)**. **D,** A stain for

PAX5 indicates the presence of many small B cells. The lymphoplasmacytic cells express IgG heavy chain **(E)** and lambda light chain **(F)** and were negative for IgM and kappa light chain (not shown).

MOLECULAR GENETIC FINDINGS

MYD88 L265P Mutation

In 2012, whole-genome sequencing studies of bone marrow lymphoplasmacytic cells in LPL/WM patients identified a somatic T to C point mutation in the myeloid differentiation primary response 88 gene *(MYD88)* on chromosome 3p22.2 that predicted a leucine-to-proline amino acid change at position 265.[3] In the initial study, the *MYD88* L265P point mutation was verified by Sanger sequencing and found to be present in 91% of LPL/WM patients,[3] and in subsequent studies by various groups it was confirmed to be present in up to 95% to 97% of IgM-secreting LPL/WM cases.[5,57-62] Up to 80% of non-IgM LPL cases, including those with extensive plasmacytic differentiation, harbor the *MYD88* L265P mutation (**Fig. 14-8**).[63,64] Compared with IgM LPL patients, non-IgM LPL patients have lower rates of neuropathy and hyperviscosity, more frequent extramedullary involvement, and a shorter median time to treatment, but similar overall survival.[63,65] The mutation has been identified in 50% to 90% of cases of IgM monoclonal gammopathy of undetermined significance (MGUS), supporting it to be an early genetic event in LPL pathogenesis.[57,58,60,64,66-68] The functional significance of the mutation in the pathogenesis of LPL/WM is

discussed in greater detail (see “Postulated Normal Counterpart and Pathogenesis” below).

The high prevalence of *MYD88* L265P in LPL has led to its routine incorporation in the diagnostic workup of small B-cell lymphomas with the development of allele-specific polymerase chain reaction (PCR)-based assays in molecular genetic laboratory settings for use in bone marrow, paraffin-embedded tissue biopsy, and peripheral blood specimens.[4,5,60,69] Assessment of *MYD88* mutational status has been incorporated into multigene high-throughput sequencing panels. However, such targeted next-generation sequencing strategies may fail to detect *MYD88* mutations in up to one-third of patients, particularly those with low bone marrow disease burden.[70] Therefore, testing via allele-specific PCR or, where available, digital droplet PCR is recommended to optimize sensitivity.[64,70,71] It is also important to note that the *MYD88* L265P mutation is not specific to LPL and has been described in other B-cell neoplasms, such as activated B-cell (ABC)-type DLBCL as defined by gene-expression profiling,[72,73] DLBCL of non–germinal-center origin as defined by immunohistochemistry,[74] other subtypes of DLBCL of immune-privileged sites including primary DLBCL of the CNS,[75-77] primary DLBCL of the testis,[76,78] and primary cutaneous DLBCL, leg type,[79,80] as well as rare cases of CLL and marginal zone lymphomas. Despite a reported prevalence of 40% to 90% in various DLBCL subtypes, the presence of this mutation generally does not pose a diagnostic issue in DLBCL cases, which are readily distinguishable from LPL on histologic grounds. The mutation is found in less than 5% of CLL cases, which are reported to have distinct clinicopathologic features, including younger age at

diagnosis, mutated IGHV, and lack of CD38 and ZAP70 expression.[58,81,82] In addition, *MYD88* L265P–positive CLL cases do not typically exhibit plasmacytic differentiation, and only a minority (approximately 10% in one series) are reported to have a small M component.[81] *MYD88* L265P has been identified in a minority of small B-cell lymphomas with plasmacytic differentiation other than LPL that often enter into the differential diagnosis of LPL, including EMZL (7% of cases), SMZL (0% to 10% of cases), and NMZL (0% to 24% of cases).[3,4,45,57,58,83,84] Such cases have been shown to have higher serum IgM levels, and there is additional evidence in some of these reports that they exhibit clinical and laboratory features more akin to LPL, suggesting that they may have been misdiagnosed as marginal zone lymphoma based on standard histopathologic criteria.[3,4,45,83] The mutation has not been identified in multiple myeloma, including cyclin D1–positive cases and rare IgM-positive cases, or in cases of IgG or IgA MGUS.[3,5,58,68,85]

Other Somatic Mutations

Other somatic mutations that have been identified with a relatively high frequency in LPL/WM include C-X-C motif chemokine receptor 4 *(CXCR4)* nonsense and frameshift mutations, found in 30% to 40% of LPL patients.[61,62,86,87] AT-rich interaction domain 1A *(ARID1A)* mutations have been identified in 17% of patients, and additional less common somatically mutated genes include *TP53, CD79B, KMT2D, MYBBP1A, BTK,* and *PLCG2*.[3,62,86] Among these, *CXCR4* mutations have been studied in other B-cell lymphomas: they are rare in SMZL and DLBCL, and absent in CLL, HCL, multiple myeloma, and IgG or

IgA MGUS.[87] However, given that *CXCR4* mutations occur almost exclusively in tumors that also harbor the *MYD88* L265P mutation, the diagnostic utility of *CXCR4* mutations in discriminating LPL from other entities in the differential diagnosis is limited.[61] The functional, prognostic, and predictive significance of these various mutations in LPL/WM is discussed in greater detail (see "Postulated Normal Counterpart and Pathogenesis" and "Clinical Course, Treatment, and Prognosis").

Cytogenetic Abnormalities

A number of numerical and structural aberrations have been observed. Most common among these are deletions involving the long arm of chromosome 6 in the 6q21-22 region, identified in 40% to 60% of cases,[88-93] although its prevalence appears to be much lower when analysis is restricted to nodal LPL.[44,94] A commonly deleted gene in this region includes *ARID1B,* which is thought to participate in p53 signaling and which, interestingly, is found in patients both with and without visible 6q loss.[86] This region of chromosome 6 also encodes for a number of regulatory genes whose targets are involved B-cell receptor signaling, including Bruton tyrosine kinase (BTK) and nuclear factor (NF)-κB, and apoptosis, including BCL2 and FOXO1.[95] Numerical aberrations that have been identified include gains of chromosomes 3, 4, 5, 12, and 18, and losses of chromosomes 8, 16, 18 to 22, X, and Y.[16,44,90,91,96-101] A study demonstrating a significantly greater frequency of certain copy number abnormalities, including +4, del(6q23.3-6q25.3), +12, and +18q11-18q23, in symptomatic WM versus IgM MGUS, suggests a multistep transformation process that involves specific cytogenetic

lesions.[102] Importantly, however, many of these cytogenetic abnormalities are not specific to LPL and have been reported in marginal zone lymphomas of extranodal, nodal, and splenic subtypes.[88] Early reports identified t(9;14)(p13;q32)/*IGH*::*PAX5* as a common recurrent translocation in LPL,[103,104] but this association was not substantiated in subsequent studies showing rearrangements involving the IGH locus to be infrequent in this neoplasm.[44,89,91,105,106]

POSTULATED NORMAL COUNTERPART AND PATHOGENESIS

The lymphocytes of LPL are post–germinal-center B cells capable of spontaneous differentiation to plasma cells in vitro.[107] Molecular genetic analyses of LPL/WM and IgM MGUS have demonstrated the presence of extensive somatic hypermutation within the IGH gene, consistent with derivation from a post–germinal center B cell. There is little evidence of intraclonal variation, and most reports indicate that the tumor cells have failed to undergo heavy chain class switching, with some suggestion that they may be defective in this capacity. These findings suggest that the tumor derives from an IgM-positive memory B cell whose normal counterpart localizes in the bone marrow to mature to an IgM-secreting plasma cell, and that the transformation event occurs after affinity maturation prior to isotype switching.[108-114] Mast cells, which are often increased in tissues involved by LPL, are thought to play a permissive role in LPL development via the elaboration of inflammatory cytokines and CD40 ligand–dependent signaling.[115,116]

Studies unearthing the genetic landscape of LPL/WM have helped to shed further light on its molecular pathogenesis and identify targeted therapeutic approaches. *MYD88* encodes a protein involved in toll-like receptor and interleukin-1 receptor signaling that undergoes homodimerization upon receptor activation. It mediates downstream signaling via BTK and a complex of interleukin-1 receptor–associated kinases (IRAKs), ultimately leading to phosphorylation of IκBα and release and activation of NF-κB.[3] L265P is a gain-of-function mutation that promotes cell survival by

allowing spontaneous MYD88 homodimerization, BTK activation, and IRAK complex assembly, leading to constitutive NF-κB activation.[72,117,118] Inhibition of MYD88 signaling has been shown to decrease NF-κB nuclear translocation and activity in both *MYD88* L265P–mutated ABC-type DLBCL and WM cell lines.[3,72] Blockade of IκBα by proteasome inhibitors is associated with high response rates in WM patients.[119-123] Ibrutinib, a selective BTK inhibitor, showed high activity in *MYD88* L265P–mutated cell lines,[117] and has emerged as a preferred first-line treatment option in symptomatic patients with a *MYD88* mutation, the presence of which is predictive for a therapeutic response.[123] The second-most-commonly mutated gene in LPL/WM, *CXCR4,* is implicated in LPL pathogenesis through AKT activation and mitogen-activated protein (MAP) kinase signaling, which facilitates WM cell migration, adhesion, and homing.[86,124] Loss-of-function *CXCR4* mutations result in impaired receptor internalization and have an activating role in WM, as shown by tumor growth, extramedullary dissemination, and decreased survival in transfected mouse models, effects that were abrogated after use of an anti-CXCR4 monoclonal antibody.[87,125] *ARID1A,* the third-most-common single nucleotide variant in LPL/WM, encodes for a chromatin-remodeling protein, and its family member, *ARID1B,* resides on chromosome 6q and is frequently lost LPL/WM.[86] Both *ARID1A* and *ARID1B* mutations have been described in other malignancies, and are thought to exert their effects via p53 and cyclin-dependent kinase inhibitor 1A (CDKN1A) regulation, important mediators in cell-cycle control and DNA damage response.[126-128] *TP53* itself has been found to be mutated in approximately 7% of LPL/WM cases.[86,129] Clonal 6q deletions also

result in loss of negative regulators of BTK *(IBTK)*, BCL2 *(BCLAF1)*, and NF-κB *(HIVEP2, TNFAIP3)*.[94] Together, these findings imply that multiple somatic point mutations and deletions exist in LPL/WM that cooperate to promote lymphomagenesis via a variety of mechanisms, including NF-κB–dependent prosurvival signaling, BCL2-dependent antiapoptotic signaling, cell migration and homing, and cell-cycle dysregulation.

CLINICAL COURSE, TREATMENT, AND PROGNOSIS

Like most other low-grade B-cell lymphomas, the clinical course in LPL/WM is generally indolent, with most patients experiencing slowly progressive disease and treatment refractoriness.[16] The median overall survival in large series ranges from 5 to 10 years, with variability in outcome reported based on a number of clinical and laboratory prognostic factors.[130,131] An International Prognostic Scoring System for WM has been developed that takes into account the following five adverse characteristics in determining prognosis and optimizing initial therapy: age greater than 65 years, hemoglobin less than or equal to 11.5 g/dL, platelet count less than or equal to 100×10^9/L, β_2-microglobulin greater than 3 mg/L, and serum monoclonal protein concentration greater than 7.0 g/dL.[130] Five-year survival for low-risk patients aged less than or equal to 65 years and with zero or one adverse characteristic is 87% versus 36% for high-risk patients with more than two adverse characteristics.[130] The remaining patients with two adverse characteristics or age greater than 65 years belong to an intermediate-risk group with a 5-year overall survival of 68%.[130]

Large-scale genomic approaches have identified somatic mutations in addition to *MYD88* L265P important for prognosis in LPL/WM.[3,61,86] For example, patients whose tumors harbor both *MYD88* L265P and *CXCR4* nonsense mutations show a more aggressive disease course, with significantly greater bone marrow involvement, higher serum IgM levels, more symptomatic disease (including hyperviscosity syndrome) with shorter time to treatment, lower response and shorter progression-free survival on the BTK inhibitor ibrutinib, and shorter overall survival compared with patients with *MYD88* L265P and wild-type *CXCR4*.[61,132,133] The type of *CXCR4* mutation (nonsense versus frameshift) affects prognosis, as patients with *CXCR4* frameshift mutations have similar outcomes to those with wild-type *CXCR4*.[61,132] Patients with both *MYD88* L265P and *ARID1A* mutations have a significantly greater degree of bone marrow involvement, anemia, and thrombocytopenia than patients with *MYD88* L265P alone.[3] Patients with *MYD88* wild-type tumors have a lower degree of bone marrow involvement but shorter overall survival, decreased response/progression-free survival on ibrutinib, and higher risk of transformation to DLBCL compared with patients with *MYD88* L265P–mutated tumors; these associations appear to be related to the presence of multiple somatic mutations that activate NF-κB signaling downstream of BTK and IRAK and that overlap with somatic alterations in DLBCL.[61,134] Besides *CXCR4* nonsense mutations and wild-type *MYD88,* other alterations associated with diminished response to ibrutinib include mutations involving *PLCG2* and *BTK,* including acquired *BTK* mutations in patients with disease progression on ibrutinib.[62,133-135] Conversely, though *TP53* mutations in LPL/WM are strongly

associated with 17p deletion, higher genomic complexity, and shorter overall survival, tumors with *TP53* alterations remain responsive to ibrutinib.[129,136] Patients with high-risk or ibrutinib-resistant mutations may be candidates for novel treatment approaches, including second-generation BTK inhibitors and BCL2 antagonists (see discussion regarding therapy).

Other pathologic characteristics important in determining prognosis include presence of complex karyotype or cytogenetic 6q deletion, each associated with adverse prognosis in various reports,[90,137] whereas some studies have not found a worse outcome in cases harboring a 6q deletion.[92,93] Transformation to DLBCL has been reported in 13% of cases in one series and is associated with an aggressive clinical course and poor prognosis.[46,90]

Current consensus criteria for initiation of therapy and treatment recommendations are based on a number of International Workshops on WM (IWWM) that have convened over the last two decades.[122,138-141] These guidelines were updated in 2020 based on results of several phase 2 studies.[123] Initiation of therapy is appropriate in patients with constitutional symptoms, progressive symptomatic lymphadenopathy or splenomegaly, severe cytopenias secondary to marrow infiltration, or symptomatic complications of disease, such as hyperviscosity, peripheral neuropathy, amyloidosis, renal insufficiency, or cryoglobulinemia.[138] The decision to initiate therapy is not based solely on serum IgM level, which may not correlate with symptom severity.[16] Besides the patient's symptoms, choice of therapy is guided by their neoplasm's genetic profile and drug availability. The updated consensus guidelines endorse use of alkylating agents such as bendamustine or cyclophosphamide, and

proteasome inhibitors such as bortezomib, carfilzomib, or ixazomib, in combination with rituximab, and the BTK inhibitor ibrutinib, alone or in combination with rituximab, as preferred first-line treatment options for symptomatic WM patients.[123] Emerging treatment strategies include novel BTK inhibitors, such as acalabrutinib, zanubrutinib, and tirabrutinib, and the BCL2 antagonist venetoclax. Limiting exposure to alkylating agents is recommended in younger patients because of complications of myelosuppression and increased risk for secondary therapy-related myeloid neoplasms.[16,142]

DIFFERENTIAL DIAGNOSIS

Neoplastic Conditions

The main neoplastic entities in the differential diagnosis of LPL include other small B-cell lymphomas with plasmacytic differentiation, particularly the various subtypes of marginal zone lymphoma that, like LPL, lack a distinct immunophenotype (**Box 14-2**). EMZL and SMZL have clinical presentations and disease distributions different from LPL/WM and can usually be distinguished from LPL on this basis. In addition, LPL has been shown to lack translocations involving *MALT1* and *BCL10* that are frequently detected in EMZL involving the stomach and lung.[30] The distinction between NMZL and nodal involvement by LPL is perhaps the most challenging, particularly on small biopsy specimens. NMZL may exhibit significant plasmacytic differentiation, whereas some LPL cases contain focal monocytoid or marginal zone cytology and prominent follicular colonization.[4,45] The presence of increased mast cells and dilated sinuses has traditionally been thought to favor LPL,

but these features are not present in all cases.[45] Studies of nodal LPL have highlighted the utility of *MYD88* L265P mutation analysis performed on formalin-fixed, paraffin-embedded tissue in helping to establish the diagnosis of LPL in nodal biopsy specimens.[4,45] Because the presence of this mutation is neither entirely sensitive nor specific to LPL, correlation with other clinical, laboratory, and pathologic features is still necessary to help establish a diagnosis of LPL. In cases lacking *MYD88* L265P or other LPL-associated mutations for which supporting clinical and laboratory data are limited (e.g., cases without a recent or concurrent bone marrow biopsy, corroborating serum immunoglobulin levels, or serum protein and immunofixation electrophoresis studies), a diagnosis of small B-cell lymphoma with plasmacytic differentiation with provision of a differential diagnosis is most appropriate.

Another neoplastic entity that may enter into the differential diagnosis of LPL is gamma heavy chain disease, a very rare B-cell lymphoproliferative disorder characterized by secretion of an abnormal truncated gamma heavy chain that is unable to bind light chains.[143] The median age of presentation ranges from 51 to 68 years, and a substantial proportion of patients have an underlying autoimmune disease, most commonly rheumatoid arthritis, which may precede the onset of lymphoma by several years.[144] The associated lymphoma typically involves bone marrow, lymph nodes, and spleen, but patients may also present with localized extranodal disease involving the skin, thyroid, salivary glands, gastrointestinal tract, and conjunctiva. Examination of involved tissues usually demonstrates a mixed population of lymphocytes, plasmacytic lymphocytes, and plasma cells that may resemble LPL, though some

cases demonstrate clinicopathologic features of other small B-cell neoplasms, including EMZL, SMZL, or other splenic lymphomas.[145] Because of the clinical and morphologic overlap with LPL in many cases, gamma heavy chain disease was previously considered a variant of LPL but has since been shown to lack the *MYD88* L265P mutation.[146] It can usually be readily distinguished from LPL on the basis of its immunophenotype, demonstrating positivity for IgG heavy chain with absent staining for light chains by immunohistochemistry or in situ hybridization. Moreover, the neoplastic infiltrate of gamma heavy chain disease is often more polymorphous than that typically seen in LPL, with variable numbers of immunoblasts, including occasional Reed-Sternberg–like forms, eosinophils, histiocytes, and background hypervascularity.[145]

Box 14-2 Main Entities in the Differential Diagnosis

Other Small B-Cell Lymphomas With Plasmacytic Differentiation (i.e., Marginal Zone Lymphomas)

- No or rare *MYD88* mutations.
- Monocytoid or marginal zone morphology more common.
- Increased mast cells not typically seen.
- Clinical features: Localized extranodal, splenic, or nodal disease.
- Laboratory findings: Lower serum IgM and paraproteinemia.

IgM Monoclonal Gammopathy of Undetermined Significance (MGUS), Not Otherwise Specified (NOS)

- IgM monoclonal paraproteinemia without abnormal bone marrow lymphoplasmacytic infiltrates diagnostic of LPL.
- High prevalence of *MYD88* L265P and *CXCR4* mutations; therefore, these cannot be used to distinguish IgM MGUS from LPL/WM. However, presence of these mutations is helpful in making early or minimal marrow involvement by another small B-cell neoplasm unlikely.
- Monotypic or monoclonal B-cell population may be detectable by flow cytometry or IGH gene rearrangement studies.

IgM Multiple Myeloma

- Typical clinical presentation of multiple myeloma despite rarity of IgM heavy chain subtype (i.e., hypercalcemia, lytic bone lesions); no peripheral lymphadenopathy or splenomegaly. (Note: Anemia and renal insufficiency may be seen with both IgM multiple myeloma and LPL/WM, so cannot be used as clinically distinguishing features.)
- Monoclonal plasma cell component *without* monoclonal B-cell component. Plasma cell immunophenotype similar to IgG or IgA multiple myeloma, including negative staining for CD19 and strong staining for CD56.
- Multiple myeloma–associated cytogenetic abnormalities, including IGH rearrangements and hyperdiploidy of odd-numbered chromosomes; no *MYD88* L265P mutation.

Primary Cold Agglutinin Disease

- Hemolytic anemia associated with the presence of monoclonal IgM kappa paraprotein and cold agglutinins.
- Absence of overt lymphoma by clinical or radiologic evaluation.
- Limited bone marrow lymphoid infiltrates may show B-cell clonality; however, they are often positive for CD5 (approximately 40% of cases), lack plasmacytic differentiation and expression of IRF4/MUM1, and are not associated with increased mast cells.
- Frequent *KMT2D* and *CARD11* mutations and trisomy 3, 12, or 18; no *MYD88* L265P mutation.

Gamma Heavy Chain Disease

- Polymorphous neoplastic infiltrate that includes small lymphocytes and plasma cells, but also immunoblasts, eosinophils, histiocytes, and background hypervascularity.
- Positivity for IgG heavy chain usually with negative staining for kappa or lambda immunoglobulin light chains by immunohistochemistry/in situ hybridization of tissue sections or by flow cytometry.
- Serum or urine immunofixation electrophoresis shows monoclonal IgG heavy chain without associated light chain; however, rare cases may have monotypic light chain secretion.
- Negative for *MYD88* L265P mutation.

IgM Monoclonal Gammopathy of Undetermined Significance

The differential diagnosis of LPL/WM includes disorders in which the presence of a serum IgM paraprotein is a key disease manifestation, including IgM MGUS. Such patients have less than 10% bone marrow plasma cells and absent or equivocal lymphoplasmacytic infiltrates that are insufficient for a diagnosis of LPL.[1] The 2022 International Consensus Classification recognizes two subtypes of IgM MGUS: plasma cell type and not otherwise specified (NOS).[1]

IgM MGUS, Plasma Cell Type and IgM Multiple Myeloma

IgM MGUS, plasma cell type represents a precursor of IgM-secreting multiple myeloma; both are exceedingly rare. The diagnosis of IgM MGUS, plasma cell type can be established in the absence of findings diagnostic of myeloma and in the presence of clonal IgM-expressing plasma cells without a detectable B-cell component and with wild-type *MYD88*. This diagnosis is also warranted in the setting of t(11;14)(q13;q32) or other cytogenetic abnormalities characteristic of multiple myeloma.[1]

IgM multiple myeloma accounts for approximately 1% of multiple myeloma cases, and affected patients often present with hypercalcemia and lytic bone lesions, symptoms typical of non-IgM multiple myeloma and not seen in LPL/WM.[1,47] However, because not all patients with multiple myeloma have these symptoms at presentation and because multiple myeloma and LPL/WM share some clinical features, such as anemia and renal insufficiency, the

diagnosis of IgM-expressing multiple myeloma should be made only after carefully excluding the presence of peripheral lymphadenopathy, splenomegaly, or a monoclonal B-cell component by histopathologic examination or by flow cytometry.[147] The CD19-negative, CD56-positive immunophenotype of clonal plasma cells in myeloma may be an additional clue to the diagnosis, as the plasmacytic component of LPL should show the opposite pattern of staining.

IgM MGUS, Not Otherwise Specified

Most patients with IgM MGUS fall into this category, defined by the presence of *MYD88* mutation or detectable B-cell clonality by flow cytometry or clonal IGH gene rearrangement studies, but without abnormal bone marrow lymphoplasmacytic infiltrates sufficient for a diagnosis of LPL.[1] As previously discussed, the diagnosis of LPL may now be made in the setting of less than 10% bone marrow lymphoplasmacytic infiltrates (see criteria in "Morphology: Bone Marrow"), so that some cases previously considered IgM MGUS are now to be diagnosed as LPL.[39] The diagnosis requires exclusion of minimal or early marrow involvement by other small B-cell neoplasms. *MYD88* mutational analysis, FISH studies, and targeted sequencing studies can help identify cases more likely to progress to multiple myeloma or a small B-cell lymphoma other than LPL.

The presence or absence of a *MYD88* L265P mutation analysis is not helpful in the distinction between IgM MGUS, NOS and LPL/WM because the mutation has been identified in more than half of IgM MGUS, NOS cases.[57,58,60,64,66-68] IgM MGUS, NOS patients with the *MYD88* L265P mutation have a higher risk for progression

to LPL/WM independent of serum M protein concentration, pointing to the importance of *MYD88* L265P as a marker of prognosis and disease progression in patients with IgM MGUS.[66] *CXCR4* mutations have also been identified in 10% to 20% of IgM MGUS, NOS patients.[57,64,148,149] Patients with smoldering or asymptomatic WM have histopathologic evidence of marrow involvement by LPL, but lack symptoms of WM or evidence of end organ damage (i.e., anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly).[121,150] Therefore, the distinction between asymptomatic and symptomatic LPL/WM requires clinical correlation. IgM MGUS and asymptomatic WM patients need to be followed but do not require treatment until symptoms develop.[122,150] IgM MGUS patients have an elevated long-term risk for progression to LPL/WM or, to a lesser extent, CLL or primary AL amyloidosis over time, with a cumulative incidence of progression of 10% at 5 years, whereas the risk for progression to symptomatic disease is significantly greater for asymptomatic WM patients, the majority of whom develop symptoms requiring treatment at 5 years or more of follow-up.[150,151]

Primary Cold Agglutinin Disease

Primary cold agglutinin disease, recognized by the 2022 International Consensus Classification as a new diagnostic entity distinct from LPL/WM and IgM MGUS, is an autoimmune hemolytic anemia mediated by the binding of complement-fixing monoclonal IgM kappa cold agglutinins to the I antigen on the surfaces of red blood cells.[152,153] Diagnostic criteria are based on clinical and laboratory findings of chronic hemolysis, the cold agglutinin titer,

characteristic abnormalities on direct Coombs testing, and the absence of overt lymphoma by clinical or radiologic assessment.[152] Despite the latter feature, lymphoid aggregates are frequently identified on pathologic examination of bone marrow specimens, and clonal B cells may be detected by flow cytometry of peripheral blood or bone marrow, leading to a diagnosis of an associated B-cell lymphoma in approximately 75% of cases that has often been classified as LPL/WM in prior studies.[152] However, detailed analyses of bone marrow and molecular findings in patients with primary cold agglutinin disease have revealed several key differences from LPL/WM, including relatively limited bone marrow infiltration by monomorphic B cells without lymphoplasmacytic morphology or increased mast cells, expression of CD5 in a significant subset of cases, lack of expression of plasma cell–associated markers such as IRF4/MUM1, frequent mutations in *KMT2D* and *CARD11* and trisomies of chromosomes 3, 12, and 18, and absence of the *MYD88* L265P mutation.[153-155]

Rare IgM-Secreting Disorders

Rare cases of primary AL amyloidosis associated with a monoclonal IgM paraprotein have been described. These patients appear to have distinct clinicopathologic features, including older age at diagnosis, more frequent kappa light chain production, and less severe organ dysfunction.[156]

Mu heavy chain disease, the rarest of the three heavy chain diseases with only 30 to 40 cases described in the literature, is a lymphoid neoplasm often reported to resemble CLL/SLL and associated with splenomegaly, lymphadenopathy, lytic bone lesions,

and kappa Bence Jones proteinuria.[143] Review of the literature, however, indicates that unlike CLL, most cases lack a significant lymphocytosis.[157] Serum immunofixation studies show monoclonal IgM without associated light chains, and examination of bone marrow aspirate specimens reveals small, round lymphocytes and admixed plasma cells containing prominent cytoplasmic vacuoles.[143] Several cases have been reported to harbor *MYD88* L265P mutations, which, along with the lymphoplasmacytic morphology, suggests that at least a subset of mu heavy chain disease is biologically related to LPL and that rare cases of LPL manifest clinically as mu heavy chain disease.[157,158]

Other Conditions

The presence of residual reactive follicles, patent sinuses, and a significant interfollicular plasma cell component in nodal LPL may give rise to the differential diagnosis of the plasma cell variant of Castleman disease. The distinction may be challenging, as some cases of plasma cell Castleman disease, particularly those associated with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes), may contain clonal plasma cells. The diagnosis of LPL can usually be established on the basis of clinical and laboratory features supporting LPL/WM, as well as the immunophenotype of the plasmacytic component, because the clonal plasma cells in POEMS syndrome-associated Castleman disease, when present, are almost always IgG or IgA lambda restricted.[159,160]

Among non-neoplastic conditions, the findings of nodal LPL may mimic lymph nodes biopsied in the setting of rheumatoid arthritis or

syphilitic (luetic) lymphadenitis because of overlapping features of follicular hyperplasia and increased interfollicular plasma cells.[161] In addition, lymphadenopathy associated with IgG4-related disease may show features that overlap with LPL.[162-164] The diagnosis of rheumatoid arthritis, syphilis, or IgG4-related disease can be readily established on the basis of clinical and laboratory features and by demonstration of polytypia of the plasmacytic component by stains for immunoglobulin light chains. In addition, LPL lacks the inflamed vasculature seen in syphilis, in which spirochetes can be identified with special histochemical stains or antitreponemal immunohistochemistry.[165]

Pearls and Pitfalls

Pearls

- The diagnosis of LPL/WM requires integration of morphologic, immunophenotypic, molecular, laboratory, and clinical features, with genetic features playing an imperative role in supporting the diagnosis, particularly in cases that show morphologic and immunophenotypic overlap with other small B-cell lymphomas with plasmacytic differentiation.
- The *MYD88* L265P mutation is the most frequent somatic change in LPL/WM, present in up to 95% to 97% of cases, and it is uncommon in other small B-cell lymphomas, including those exhibiting plasmacytic differentiation.

- Other genetic markers of importance in LPL/WM include *CXCR4* loss-of-function mutations, wild type *MYD88, TP53* mutations, *BTK* mutations (which may be acquired on BTK inhibitors), and certain cytogenetic abnormalities including deletion 6q, deletion 17p, and complex karyotype.
- The histopathologic diagnosis of LPL is most often established on a bone marrow specimen, in which interstitial and nodular lymphoplasmacytic infiltrates are most common. Patterns of marrow involvement seen in other small B-cell lymphomas, including intrasinusoidal, pure paratrabecular, or diffuse patterns, are rare.
- In classic cases of nodal involvement by LPL, there is subtotal architectural effacement with preservation of sinuses and follicles and an interfollicular lymphoplasmacytic infiltrate, without evidence of proliferation centers. However, many cases show more extensive nodal involvement with complete architectural effacement and obliteration of sinuses; colonization of underlying reactive follicles may be present and does not exclude the diagnosis.

Pitfalls

- The *MYD88* L265P mutation is neither sensitive nor specific for LPL/WM, as up to 10% of cases lack the mutation. It is relatively common in certain subtypes of DLBCL and has been reported at lower frequency in cases of CLL and marginal zone lymphoma of all three types.
- Cases of nodal LPL may show variable morphology with complete architectural effacement, colonization of follicles, or

focal monocytoid or marginal zone morphology.

- The diagnosis of LPL outside the bone marrow or lymph nodes, where the histopathology is less well-known, requires correlation with clinical features, laboratory features, and *MYD88* mutation status.
- *MYD88* wild-type cases that lack supporting clinical and laboratory data for the diagnosis of LPL are best classified as small B-cell lymphoma with plasmacytic differentiation with a differential diagnosis given, until further clinical and laboratory supporting data are available to establish a more specific diagnosis.
- The differential diagnosis of LPL/WM includes other IgM-secreting disorders, such as IgM MGUS, rare cases of IgM-positive multiple myeloma, primary AL amyloidosis, primary cold agglutinin disease, and occasional non-neoplastic inflammatory conditions. These can usually be resolved on the basis of immunophenotypic analyses and correlation with other laboratory and clinical data.

PROGNOSTIC AND PREDICTIVE FACTORS

DEFINITION OF DISEASE AND NOMENCLATURE

Hairy cell leukemia (HCL) is a mature B-cell neoplasm that involves primarily the blood, bone marrow, and splenic red pulp.[1] The neoplastic lymphocytes have surface "hairy" projections and express the B-cell–associated antigens CD19, CD20, and CD22; characteristically, they are also positive for CD103, CD25, CD11c, CD200, CD123, and annexin A1. The vast majority of HCL cases have a recurrent activating point mutation in the *BRAF* oncogene.[2] The long, slender cell surface projections identified on smear preparations and shown most exquisitely by scanning and electron microscopy gave the disease its vivid descriptive name.[3,4]

EPIDEMIOLOGY

HCL is rare, with only about 600 to 1000 cases per year diagnosed in the United States and accounting for only 2% of all leukemias.[5] It affects predominantly middle-aged men and does not occur in children. In the largest published series on HCL patients, the mean age was 54 years (range 23 to 85 years) and the male-to-female ratio was 4:1.[6]

ETIOLOGY

HCL is not associated with Epstein-Barr virus or other infectious pathogens.[7] Several reports of HCL occurring in family members have raised the possibility of a genetic predisposition for the disease.[8-10] In many families, the cases were linked to an HLA A1, B7 haplotype, and association with other HLA haplotypes such as HLA-DRB*11 has also been reported.[9-11] Some studies have suggested exposure to organic solvents and petroleum products as risk factors.[12] Nevertheless, the vast majority of HCL cases appear to be sporadic, arising from an activated memory B cell via acquisition of a somatic *BRAF* V600E mutation.[2]

CLINICAL FEATURES

Symptoms and Signs

Patients with HCL present most often with clinical sequelae related to one or more cytopenias. In one large series, infections (29%) and weakness or fatigue (27%) were the most common initial symptoms. In about one quarter of patients, HCL is diagnosed incidentally as a

result of routine hematologic screening in patients lacking symptoms attributable to HCL.[13]

Abnormalities found on physical examination and in laboratory studies in HCL patients at presentation are summarized in **Table 15-1**.[6,14-16] HCL is characterized by a leukopenic rather than a leukemic presentation: about half of patients are markedly neutropenic at diagnosis (absolute neutrophil count $<0.5 \times 10^9$/L), and half are pancytopenic.[17] An elevated white blood cell count ($>10 \times 10^9$/L) characterizes only 10% to 15% of cases.[6] Marked leukocytosis with numerous circulating neoplastic cells is rare in HCL and, if present, raises the possibility of the so-called *HCL variant* (HCLv, see the section on variants) or another lymphoma subtype showing a leukemic spread. Notably, monocytopenia is seen in almost all HCL cases and is considered to be one of the most sensitive markers of disease. Leukoerythroblastosis is usually not seen, despite the common presence of bone marrow fibrosis (see the Morphology section below).[18] Palpable splenomegaly is present at diagnosis in 72% to 90% of patients, whereas peripheral lymphadenopathy is uncommon.[6,13,19] Polyclonal hypergammaglobulinemia may be present in about 20% of patients, but a monoclonal paraprotein is usually not seen.[13]

Table 15-1

Clinical and Laboratory Findings of Hairy Cell Leukemia at Presentation

Finding	% of Patients With Finding	Comments
Splenomegaly	86–96	Massive in 25% of patients
Hepatomegaly	73	If biopsied at presentation, the liver is nearly always involved[12]
Lymphadenopathy	13	Mostly abdominal and retroperitoneal; peripheral lymphadenopathy is uncommon[13,14]
Anemia (hemoglobin <12.0 g/dL)	77	
Neutropenia (<1.5 × 10^9/L)	79	
Monocytopenia (<0.15 × 10^9/L)	90	

Finding	% of Patients With Finding	Comments
Thrombocytopenia (<100 × 10^9/L)	73	
Hairy cells detected on peripheral smear examination	85	Often few in number; identification may require careful examination by an experienced observer

Infections represent a major cause of morbidity in HCL patients[20,21] and include both bacterial infections and infections by opportunistic organisms such as *Pneumocystis* species and fungi. This striking susceptibility to infections likely reflects both the reduced number of circulating granulocytes and monocytes and disrupted function of immune effector cells, including defective interferon gamma production.[22,23] Uncommon disease manifestations include lytic bone lesions; involvement of extranodal organs such as lung, stomach, and esophagus; and bulky abdominal lymphadenopathy.[24-26] Autoimmune manifestations, including arthritis, vasculitis, and antibody-mediated hemolysis or thrombocytopenia have been reported to occur in up to 25% of HCL patients.[27-30] HCL also appears to have an association with concurrent or subsequent other B-cell lymphomas or plasma cell myeloma that is greater than would be expected by chance, being seen in about 5% of patients.[31] When HCL co-occurs with chronic

lymphocytic leukemia (CLL), it often is the predominant population in the bone marrow biopsy despite the prevalence of CLL cells in the blood.[32]

Imaging Studies

Retroperitoneal lymphadenopathy is detected by computed tomography (CT) in about 15% of patients at presentation and in up to 56% of patients later during the course of the disease.[15,33] Massive abdominal lymphadenopathy has been associated with a poorer response to therapy, leading some to suggest the use of abdominal CT scans to stage HCL.[15,33] However, CT imaging to stage HCL is not common practice in the current era. Skeletal involvement is rare (3% of cases), occurs mostly in advanced disease, and most commonly manifests as lytic lesions of the femoral head and neck.[34]

Table 15-2

Major Diagnostic Features of Hairy Cell Leukemia

Study	Findings
Morphology of hairy cells	Oval or indented nuclei and abundant pale blue cytoplasm Absent or inconspicuous nucleoli Circumferential cell surface "ruffled" projections
Bone marrow biopsy morphology	Diffuse or interstitial bone marrow infiltration, without discrete nodular aggregates Clear cells with "fried egg" or spindled appearance Reticulin fibrosis
Flow cytometry	Clonal B cells expressing CD103, CD25, CD200, and CD11c and lacking CD5 expression
Immunohistochemistry	Positive for DBA.44, TRAP, annexin A1, and BRAF V600E
Molecular genetics	*BRAF* V600E mutation

Diagnostic Procedures

Although a diagnosis of HCL can be based on peripheral blood morphology and immunophenotype, examination of bone marrow is recommended in all newly diagnosed cases to assess the extent of marrow involvement and provide a baseline for assessing response to treatment. The pattern of HCL in bone marrow is highly characteristic and is distinct from other small B-cell lymphomas.[35] The key diagnostic features of HCL are summarized in **Table 15-2**. A good-quality bone marrow core biopsy is essential, because the bone marrow aspirate is often poorly cellular or unobtainable because of marrow fibrosis.[36] If an aspirate cannot be obtained, the diagnostic HCL immunophenotype can usually be demonstrated by flow cytometry of the peripheral blood, as circulating neoplastic cells are present in almost all patients, even when they are difficult to identify on smears.[12]

MORPHOLOGY

Cell Morphology on Smear Preparations

HCL morphology is ideally represented on well-prepared Wright-Giemsa–stained peripheral blood smears. Hairy cells are 1.5 to 2 times the size of small lymphocytes and are characterized by oval to bean-shaped nuclei, dispersed granular chromatin with features intermediate between a mature lymphocyte and a blast, and absent or inconspicuous, small nucleoli. Hairy cell cytoplasm is moderately abundant, pale blue, and often flocculent, with ill-defined or ruffled borders exhibiting thin circumferential surface projections (**Fig. 15-1A–C**).[37,38] Occasional cytoplasmic granules or small rod-shaped structures may be evident. These correspond to the ribosome-lamellar complexes frequently seen in hairy cells by electron

microscopy.[39] Hairy projections are best seen in thin areas of the smears and, when well demonstrated, are present all around the cell membrane. Poorly prepared or thick smears (particularly from bone marrow aspirations) may cause artifactual hairlike projections or cytoplasmic ruffling in other cell types, mimicking hairy cells. Moreover, the cell trauma associated with preparing the bone marrow aspirate renders the characteristic hairy cell cytomorphology more difficult to appreciate in aspirate smears or touch preparations than in peripheral smears.[18]

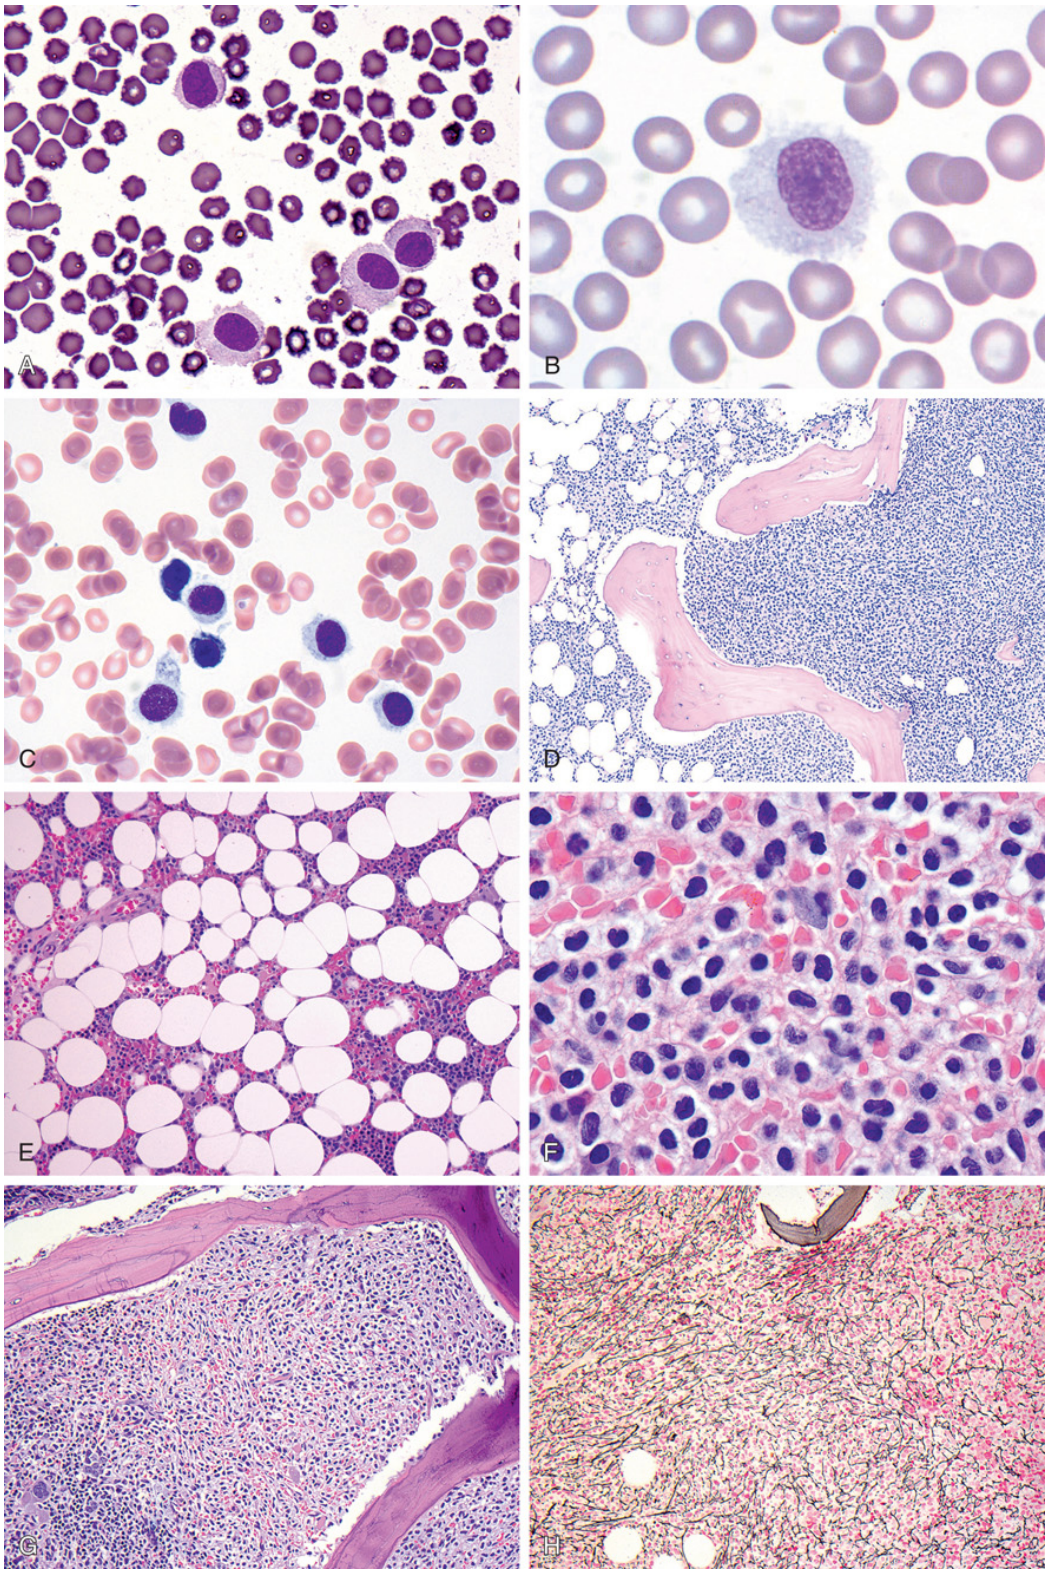

FIGURE 15-1 **A,** Hairy cells on peripheral blood smear. The nuclei are oval to indented

(kidney- or bean-shaped), with slightly dispersed chromatin, and the cytoplasm is pale blue with a ruffled border showing discrete hairy projections. **B,** Hairy cell on peripheral blood smear. The cytoplasmic border may appear ragged with hard-to-appreciate surface projections. Small nucleoli may be present. **C,** Hairy cells are often poorly preserved in bone marrow aspirate smears, with stripped or relatively scant cytoplasm. **D,** Hairy cell leukemia (HCL) in bone marrow biopsy section (low power), illustrating characteristic diffuse and interstitial infiltration patterns. **E,** Early subtle involvement by HCL in bone marrow biopsy section, in which hairy cells insinuating between the hematopoietic elements are difficult to appreciate and may be easily missed. **F,** HCL in bone marrow biopsy section (high power), illustrating wide spacing of the folded and bean-shaped nuclei. Depending on the fixation and processing method, the cytoplasm may appear clear or pale pink. **G,** Extensive bone marrow involvement in some HCL cases may exhibit a spindled appearance, potentially mimicking a non-hematologic neoplasm. **H,** HCL in bone marrow biopsy (reticulin silver stain). Reticulin is increased in almost all HCL cases, often resulting in a poor or failed aspirate.

Cell Morphology and Histologic Features in Bone Marrow Sections

At low power, the bone marrow infiltrate in HCL is interstitial or diffuse and does not form well-defined nodular aggregates that characterize most other small B-cell lymphomas (see **Fig. 15-1D**). At diagnosis, the bone marrow is hypercellular in most cases, with diffuse sheets of hairy cells.[37] However, in early stages of the disease the bone marrow may be hypocellular or may have a subtle interstitial infiltrate that is not readily apparent on routine histologic stains (**Fig. 15-1E**).[40] At higher power, the hairy cells appear round and monotonous, with oval to indented and occasionally convoluted nuclei set in an abundant clear cytoplasm that holds the nuclei equidistant and imparts the characteristic "fried egg" appearance; large lymphoid cells are virtually absent.[18,41] Depending on the fixation and processing method, the cytoplasm may appear clear, uniformly pale pink, or flocculent on hematoxylin and eosin (H&E) stain (see **Fig. 15-1F**). The spaced appearance of hairy cells in tissue sections appears to be caused by pericellular deposition of fibronectin.[42] The hairy projections are usually not evident on routine histologic stains, although these may be visualized with DBA.44 immunohistochemistry.[43] Immunohistochemical stains for CD20 or DBA.44 reveal an intrasinusoidal component to the infiltrate in up to 70% of cases.[44,45] In some cases, particularly when there is extensive involvement, the neoplastic cell infiltrate may appear spindled (**Fig. 15-1G**).[41] The so-called hairy cell index, representing the proportion of bone marrow space occupied by hairy cells,[46] can be useful in comparing bone marrow samples before and after treatment.

The amount of residual hematopoiesis is variable, but there is often a reduction in normal hematopoietic cells, particularly of the myeloid lineage.[47,48] Not infrequently, there is a modest increase in the number of plasma cells and mast cells.[49] Hematopoietic elements may manifest morphologic dysplasia, potentially mimicking a myelodysplastic syndrome,[48,50] and in some cases the marrow may appear hypoplastic, mimicking aplastic anemia.[40] These observations have suggested that HCL may actively suppress hematopoiesis beyond a mere space-occupying effect, possibly by disrupting the bone marrow microenvironment and by the abnormal release of cytokines such as transforming growth factor-β.[51,52] However, a study revealing that the *BRAF* V600E mutation is present in primitive hematopoietic stem cells from HCL patients (see the Genetics and Molecular Findings section below) raises the possibility that the cytopenias may result at least in part from an inherent defect in hematopoiesis.[53]

Significant reticulin fibrosis, likely mediated by the deposition of pericellular fibronectin, is found in almost all cases of HCL at diagnosis, and this is the presumed cause of poor aspirate smears or the inability to aspirate marrow (**Fig. 15-1H**).[42] Collagen fibrosis demonstrated by trichrome staining is uncommon.[54] The bone marrow fibrosis resolves after effective therapy for HCL.[55]

Spleen and Other Organs

HCL almost always involves the spleen, although splenomegaly may be absent early in the course of disease. In contrast to most other B-cell lymphomas (including splenic marginal zone lymphoma [SMZL]), HCL preferentially involves the splenic red pulp rather

than the white pulp. On gross examination, the spleen is massively enlarged (median weight, 1300 g) and exhibits inconspicuous white pulp (**Fig. 15-2A**).[46] Microscopically, the hairy cells in the spleen appear similar to those in involved bone marrow sections.[41,56] Areas of hemorrhage (so-called pseudosinuses or blood lakes) are characteristic but not specific for HCL and result from hairy cell adhesion and damage to sinus endothelial cells.[41,57] Extramedullary hematopoiesis is infrequently observed.[18] Owing to advances in HCL diagnosis and therapy, pathologists now only rarely encounter splenectomy specimens from HCL patients.

HCL also almost always involves the liver at presentation and commonly causes modest hepatomegaly, although the liver is usually not biopsied. In liver biopsies, the hairy cells are located in small clusters in the sinuses and portal tracts. As in the spleen, there may be associated hemorrhage, which in the liver may mimic peliosis hepatis.[16]

HCL commonly involves abdominal and retroperitoneal lymph nodes, particularly after splenectomy or in patients with long-standing disease. In lymph nodes, HCL shows a paracortical and medullary distribution and may surround germinal centers in a pattern mimicking nodal marginal zone lymphoma (MZL) (see **Fig. 15-2B**).[35,56] Examination of the peripheral blood and bone marrow (including immunophenotyping) is helpful in accurately separating MZL from HCL involving lymph nodes. In HCL patients with lymphadenopathy, the HCL cells in the involved lymph nodes may appear larger and the disease may be refractory to therapy, suggesting transformation to a higher-grade disease biology.[26,58]

However, transformation of HCL to bona fide diffuse large B-cell lymphoma is rare.[56]

Although 10% to 12% of HCL patients may develop cutaneous lesions during the disease course, these are mostly secondary to infectious, autoimmune, or drug manifestations. True cutaneous involvement by HCL is rare; it may present as a localized lesion or as generalized cutaneous involvement and appears to respond to purine analogue therapy.[59]

PHENOTYPE

Flow Cytometry

Flow-cytometric demonstration of the characteristic hairy cell immunophenotype, in combination with morphology, is a cornerstone of HCL diagnosis. HCL expresses CD45 (at bright intensity) and the B-cell markers CD19, CD20 (at bright intensity), FMC-7, CD22 (at bright intensity), and CD79a, and it is usually negative for CD5, CD10, and CD79b.[60,61] CD10 can be positive in 10% to 26% of otherwise classical HCL cases and CD23 is positive in 17% to 21% of cases, whereas CD5 is positive in less than 10% of cases.[62-64] HCL expresses monotypic surface immunoglobulin at high intensity in all cases.[65] Bright expression of CD11c, CD25, CD103, and CD200 is characteristic of HCL,[61,65] and these markers are typically included in the flow cytometry immunophenotyping panel when HCL is suspected. In addition, the alpha chain of the IL-3 receptor, CD123, is expressed in 95% of cases of HCL but not in HCLv, SMZL, or most other B-cell lymphomas with the exception of a subset of splenic diffuse red pulp lymphoma.[66-68] Thus CD123 may be helpful in distinguishing other diseases with “hairy” or “villous”

morphology from HCL.[69,70] HCL shares with CLL characteristic bright expression of CD200, in contrast to other small B-cell lymphoms, which are dim or negative for CD200.[71] If the characteristic but often elusive hairy cells are not recognized on examination of the peripheral smear, the typical high forward and side light-scatter qualities of hairy cells on flow cytometry may be helpful clues (**Fig. 15-3A**). Care must be taken when performing flow-cytometry studies as hairy cells often fall within the monocyte gate, outside of the usual lymphocyte region.[72]

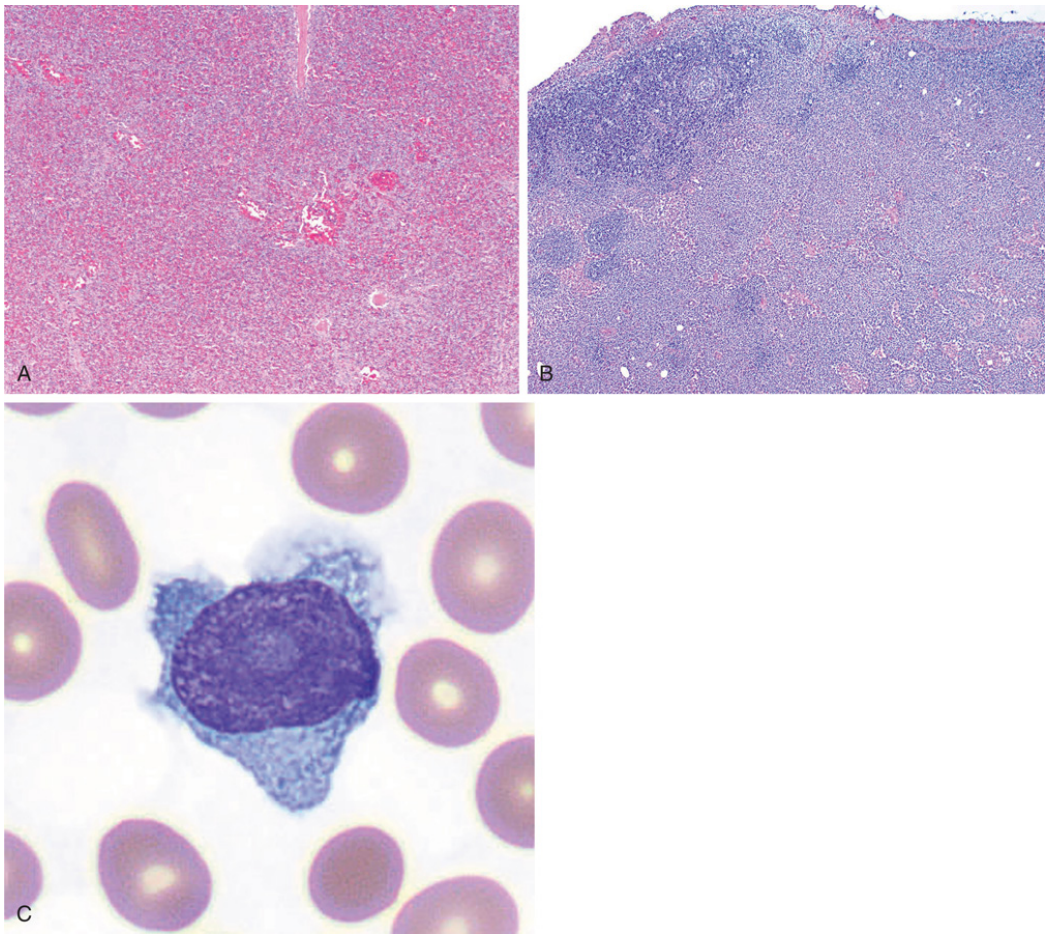

FIGURE 15-2 **A,** Hairy cell leukemia (HCL) involving the spleen. The red pulp is diffusely infiltrated with scattered pseudosinuses (small blood lakes lined by neoplastic hairy cells). **B,** HCL involving an intraabdominal lymph node. Hairy cells fill the lymph node sinuses and paracortex, with only a few residual follicles. **C,** Hairy cell leukemia variant (HCLv) on peripheral blood smear. The cell has a higher nuclear-to-cytoplasmic ratio than in classical HCL, and has a prominent nucleolus. The cytoplasmic border is ruffled, as in classical HCL and unlike in

prolymphocytic leukemia. The cells had a phenotype of CD20bright+, CD10−, CD5−, CD23−, CD103+, CD11c+, CD25−, and CD200−. Genetic testing showed no *BRAF* mutation, but did show a *CREBBP* mutation.

There is no absolutely specific immunophenotypic marker for HCL; the pathologist should evaluate the overall immunophenotype in the context of the morphologic and clinical findings. The vast majority of HCL cases—and only very rare cases of other B-cell lymphomas—express at least three of the four characteristic HCL markers (CD11c, CD103, CD25, and CD123), and most express all four of these markers.[66,73-75] Cases with some atypical immunophenotypic features, such as CD10 or CD5 expression or lack of CD103 or CD25 expression, may still be diagnosed as HCL if the clinical features, marrow infiltration pattern, and cytomorphology are otherwise typical, particularly if a *BRAF* V600E mutation is confirmed.[62] In particular, low or absent CD103 expression may rarely occur in about 5% of cases; these patients otherwise have a typical HCL immunophenotype and respond similarly to HCL therapies.[65]

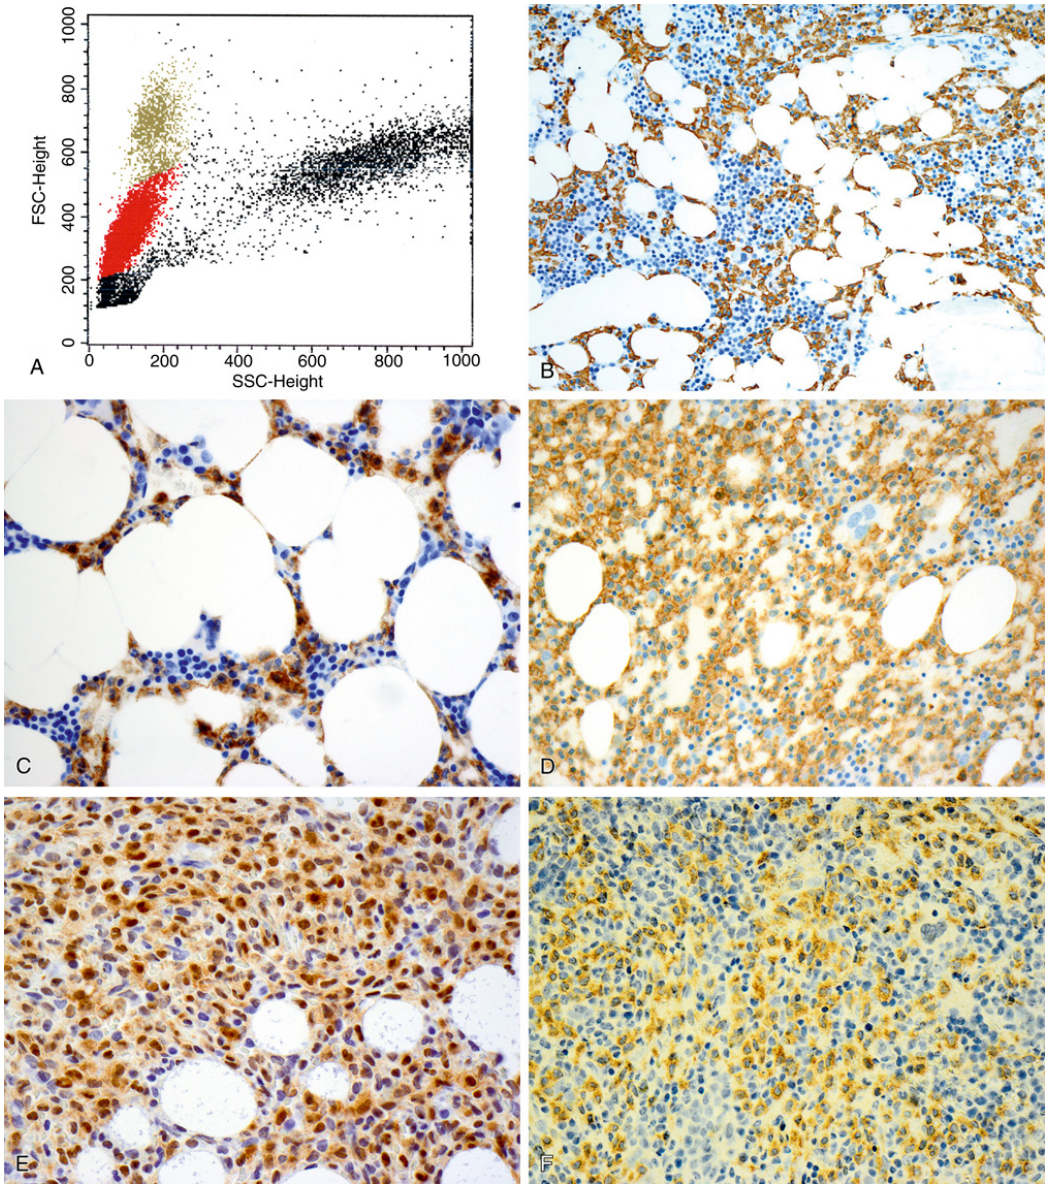

FIGURE 15-3 **A,** Light-scatter characteristics of hairy cell leukemia (HCL) in peripheral blood (flow cytometry). The hairy cells *(green)* have higher forward light scatter (FSC, *vertical axis*) and slightly higher side light scatter (SSC, *horizontal axis*) than the normal lymphocytes *(red)*. Also note the absence of monocytes, which would be located between the red lymphocytes

and the black granulocytes. **B,** CD20 immunostain of a subtle case of HCL in the bone marrow in which the hairy cells occur in an interstitial pattern and do not form confluent sheets. **C,** CD25 immunostaining of hairy cells in the bone marrow. **D,** Annexin A1 stains hairy cells in the bone marrow. **E,** Cyclin D1 stain shows the weak, variable nuclear expression typically seen in HCL. **F,** Immunostaining of HCL in bone marrow with a mutation-specific antibody to BRAF V600E.

Immunohistochemistry and Cytochemistry

If the characteristic HCL immunophenotype can be demonstrated by flow cytometry of peripheral blood or bone marrow aspirate, paraffin section immunohistochemistry on biopsy samples is usually unnecessary except to help quantify involvement in morphologically subtle or treated cases. Hairy cells can be readily identified in tissue sections by routine B-cell markers such as CD20, PAX5, and CD79a, and these markers often reveal far more hairy cells than are suspected on routine stains (see **Fig. 15-3B–C**). DBA.44 is a widely used marker, but it does not stain all the neoplastic cells and is expressed in other neoplasms.[76] Hairy cells are nearly unique among lymphocytes in that their acid phosphatase enzyme maintains its function after the addition of tartrate (tartrate-resistant acid phosphatase [TRAP]). This feature can be used to detect HCL relatively specifically in air-dried smears with cytochemical staining for TRAP, but this is now seldom used in HCL diagnosis.

Immunohistochemistry for the TRAP enzyme is available[77] but it stains other B-cell neoplasms and is less specific than TRAP cytochemistry.[78] An antibody to a fixation-resistant epitope of CD11c (5D11) is a sensitive marker for HCL in paraffin-embedded bone marrow sections.[79] The annexin A1 gene *(ANXA1)* is markedly upregulated in HCL, and antibody to annexin A1 is a sensitive and specific marker for HCL, being expressed in a cell membrane pattern in 74% to 97% of HCL and uniformly negative in other B-cell lymphomas (see **Fig. 15-3D**).[35,80,81] However, annexin A1 also stains myeloid elements, macrophages, and T cells and is thus not optimal for the detection of small amounts of bone marrow disease after therapy.[82] By immunohistochemistry, CD123 is expressed in over half of HCL cases (and in 95% by flow cytometry) and is not expressed in most other B-cell lymphomas, but is expressed in some myeloid leukemias, plasmacytoid dendritic cells, and neoplastic mast cells.[35] Cyclin D1 is overexpressed in most HCL cases and can be detected by immunohistochemistry in paraffin sections; the staining is weaker and more variable in intensity compared with the strong, diffuse staining seen in mantle cell lymphoma (see **Fig. 15-3E**).[35,83] Of note, SOX11 can also be expressed in a subset of HCL cases,[84] and thus the combination of SOX11 and cyclin D1 positivity does not necessarily prove a diagnosis of mantle cell lymphoma. Although small subsets of HCL show expression of CD10 and, to a lesser extent, CD5 by flow cytometry, these stains are almost always negative by immunostaining of HCL in tissue sections.[35]

A monoclonal antibody that recognizes the mutated protein product of *BRAF* V600E (VE1) is applicable to paraffin-embedded decalcified bone marrow material (see **Fig. 15-3F**). The BRAF

V600E antibody is a highly sensitive and specific marker of HCL in bone marrow trephine sections[85] and correlates with the presence of the *BRAF* V600E mutation detected by molecular genetic methods.[86] **Table 15-3** summarizes key immunophenotypic, flow cytometric, and cytochemical findings commonly used to diagnose HCL.[43,64,75,77,87-92]

Table 15-3

AML, Acute myeloid leukemia; *B-PLL,* B-cell prolymphocytic leukemia; *CC,* cytochemical stain; *CLL,* chronic lymphocytic leukemia; *FC,* flow cytometry; *HCLv,* hairy cell leukemia variant; *IHC,* immunohistochemistry; *SMZL,* splenic marginal zone lymphoma; *TRAP,* tartrate-resistant acid phosphatase.

GENETICS AND MOLECULAR FINDINGS

The identification in 2011 of a *BRAF* point mutation in the vast majority of HCL and its negativity in other small B-cell lymphomas has validated HCL as a discrete and unique entity. *BRAF* is a proto-oncogene located at chromosome 7q24. In HCL, a point mutation occurs in exon 15 at codon 600, leading to a substitution of glutamate (E) for valine (V), termed the *V600E mutation*.[2] The *BRAF* V600E mutation can be detected in bone marrow aspirates or peripheral blood by Sanger sequencing, allele-specific polymerase chain reaction (PCR), or next-generation sequencing technologies. Rarely, alternative *BRAF* mutations may occur in exon 11.[93] Cases of bona fide HCL that express IGH VH4-34 (about 10% of cases; see the Variants section below) lack *BRAF* mutations altogether. The *BRAF*

V600E mutation causes constitutive activation of the MAP kinase signaling pathway, a hallmark of HCL.[94] Additional gene mutations are found in about one-third of HCL cases, and include *CDKN1B, KLF2, KMT2C, NOTCH1,* and *ARID1B*.[95,96] Interestingly, although the *BRAF* V600E mutation in HCL is thought to originate in a hematopoietic stem cell and is shared with histiocytic/dendritic cell–derived neoplasms such as Langerhans cell histiocytosis and Erdheim-Chester disease, in HCL the V600E mutation is restricted to the B-cell compartment in mature cells, while in histiocytic/dendritic neoplasms it occurs in myeloid cells and monocytes.[53,97]

Routine cytogenetic analysis of HCL is generally not indicated; the low proliferation of HCL renders karyotyping difficult, the diagnosis can usually be made on morphologic and immunophenotypic grounds, and no prognostic cytogenetic markers have been identified.[98] Karyotypes obtained by stimulation with mitogens or cytokines have revealed clonal abnormalities in up to 67% of cases.[98] These include trisomy 5 and inversions and interstitial deletions involving 5q13 (which are only rarely seen in other B-cell lymphomas), and structural and numerical aberrations of chromosomes 7 and 14, including loss of the wild-type *BRAF* allele at the 7q34 locus through del(7q).[94,95,98-100] Notably, despite the fact that HCL cells express activation-induced cytidine deaminase that has been implicated in the chromosomal translocations of B-cell neoplasms, recurrent chromosomal translocations involving immunoglobulin genes are lacking in HCL.[101,102] Although cyclin D1 expression is detected by immunohistochemistry in a high

proportion of HCL cases,[83] translocations involving the *CCND1* locus do not occur in HCL.[103,104]

HCL has a homogeneous gene-expression profile.[82] The expression profile for genes regulating proliferation and apoptosis is similar to that of normal B cells, but exhibits deficient expression of genes related to lymph node homing (*CCR7* and *CXCR5*); overexpression of genes whose products interact with actins *(GAS7)* and promote B-cell adhesion to fibronectin (*IL3RA* and *FLT3*); and marked upregulation of *ANXA1,* the gene encoding annexin A1. These findings help explain the disease distribution, cellular morphology, and bone marrow fibrosis characteristic of HCL.[82] Interestingly, BRAF and MEK inhibitors that induce MEK/ERK dephosphorylation specifically in HCL cells (but not HCL-like normal B cells) were shown to cause silencing of the BRAF-MEK-ERK pathway transcriptional output and loss of the HCL-specific gene-expression signature.[105] These changes were also associated with smoothing of the surface of the hairy cells and, ultimately, apoptosis.

POSTULATED CELL OF ORIGIN AND NORMAL COUNTERPART

Analysis of HCL immunoglobulin gene mutational status has revealed that HCL cells have experienced immunoglobulin heavy chain variable region (IGHV) somatic hypermutation but do not display ongoing mutation, features typically associated with the post–germinal-center B cell.[106] Gene-expression profiling has shown that HCL cells are closely related to memory B cells[82] and that they additionally express the junctional adhesion-molecule C protein that

is found in post–germinal-center circulating memory B cells.[107] In spite of these similarities, HCL cells display notable differences from normal memory B cells in terms of their gene-expression profile of cytokines, chemokine receptors, and adhesion molecules; in addition, unlike most memory B cells, HCL cells are CD27 negative.[101,102] The identification of the *BRAF* V600E mutation in hematopoietic stems cells in HCL patients intriguingly suggests that the initial steps of HCL development may occur in a hematopoietic precursor cell; presumably, the acquisition of additional (as yet unidentified) mutations during differentiation create the full HCL disease phenotype that manifests in post–germinal-center B cells.[53] Such a stem cell origin may explain the increased risk for other B-cell and plasma-cell malignancies observed in HCL patients.

VARIANTS

About 10% of patients with otherwise typical HCL have IGH gene rearrangement using the VH4-34 region. These cases tend to have more advanced disease at presentation, poorer response to purine analogue therapy, and shorter survival compared with other HCL cases. VH4-34-positive HCLs have been reported to lack the *BRAF* V600E mutation,[108] and a subset have been reported to harbor *MAP2K1* gene mutations,[96,109] a feature shared with HCLv. The nature of these HCL cases and their relationship to HCLv and splenic diffuse red pulp small B-cell lymphoma still remains controversial.[108]

The disease known as hairy cell variant (HCLv) is rare, and it is only about 10% as frequent as HCL, which is already a rare disease. These cases display significant morphologic, immunophenotypic,

and clinical differences from HCL and also show a profile of genetic aberrations that is distinct from HCL.[110] HCLv is not actually considered as a “true variant” of HCL, but is rather a separate provisional disease entity in the revised WHO 4th ed. and in the 2022 International Consensus Classification (ICC) of Mature Lymphoid Neoplasms.[44,102,111-113] In the proposed WHO 5th ed.,[114] HCLv has been renamed *splenic B-cell lymphoma/leukemia with prominent nucleoli,* a designation that also includes some cases of B-cell prolymphocytic leukemia (a disease no longer recognized by the proposed WHO 5th ed.).

HCLv patients tend to be older than HCL patients, with a median age of 71 years. In contrast to HCL, there is usually marked leukocytosis with a white blood cell count that is greater than 30 × 10^9/L because of the presence of numerous circulating leukemic cells.[89,115] These resemble hairy cells in terms of having abundant cytoplasm and surface projections, but also have prominent central nucleoli that are not typically seen in HCL and are reminiscent of prolymphocytes (see **Fig. 15-2C**).[89] Unlike in classical HCL, monocytopenia does not occur. The pattern of bone marrow and splenic red pulp infiltration is largely similar in the two entities, although HCLv often shows sinusoidal infiltration of marrow, which is typically not as prominent in classical HCL. Moreover, in HCLv bone marrow fibrosis, if present at all, tends to be patchy.[89] Immunophenotypically, HCLv shares some similarities with HCL in that it expresses CD11c, DBA.44 (by immunohistochemistry), and often CD103, but it is negative for CD123, cyclin D1, CD200, annexin A1, and CD25.[35,69,115,116] CD43 expression is brighter in HCL compared with HCLv, while CD81 expression is brighter in HCLv.[116]

More than half of HCLv cases express immunoglobulin G (IgG) heavy chain, often in combination with other heavy chains—an unusual feature shared with HCL.[89] But unlike HCL, the IGHV gene status is unmutated. HCLv lacks *BRAF* mutations and about 40% show VH4-34 family usage, similar to a small subset of classical HCL as discussed above. It has been shown that 30% to 50% of HCLv cases bear activating mutations in the mitogen-activated protein kinase 1 *(MAP2K1)* gene.[109,117] Activating *ARID1A, KMD6A, CREBBP, CCND3,* and *U2AF1* mutations have also been reported.[95,96] A high proportion of HCLv cases show 17p *TP53* locus deletion by fluorescence in situ hybridization (FISH),[118] and *TP53* mutations are seen in up to 38% of cases.[95,119] Like HCL, chromosome 7q deletions may also be present.

The clinical course of HCLv is more aggressive than that of HCL, with a median survival of 7 to 9 years in one study, significantly shorter than that of HCL; about 50% of patients are resistant to treatment with purine analogues[89,115,120-124] and the responses are of shorter duration than seen in HCL. HCLv may respond to ibrutinib and some reports suggest that adding rituximab to purine analogue regimens or using anti-CD22 immunotoxin improves outcome.[125-130]

DIFFERENTIAL DIAGNOSIS

The clinical differential diagnosis of pancytopenia, splenomegaly, and a poor or dry aspirate because of bone marrow fibrosis includes myeloid disorders such as myelodysplastic syndromes, myelodysplastic/myeloproliferative neoplasms, primary myelofibrosis, acute myeloid leukemia, and systemic mast cell

disease. The spindled appearance of the HCL cells may mimic a sarcoma involving the bone marrow. Diligent review of smear material to identify hairy cells is helpful to exclude these entities and elicit appropriate immunophenotypic studies to confirm the HCL diagnosis; monocytopenia is an additional clue that points to the possibility of HCL in such cases. The relative erythroid hyperplasia and reactive dysplastic changes in hematopoietic elements in bone marrow subtly involved by HCL may lead to an erroneous diagnosis of myelodysplastic syndrome or, in hypoplastic cases, aplastic anemia.[40] Immunostaining on bone marrow biopsy with a B-cell marker such as CD20 is recommended when myelodysplastic syndrome or aplastic anemia is considered but HCL remains a possibility. Mastocytosis and monocytic leukemias on biopsy sections, and large granular lymphocytic leukemia on smear preparations, may morphologically mimic HCL, but can readily be distinguished by their expression of lineage-specific markers and negativity for B-cell markers. In difficult cases, evaluation for the presence of a *BRAF* V600E mutation with molecular genetic techniques or immunostaining may be helpful.

Upon identification of a clonal B-cell population in bone marrow or blood, the unique therapy for HCL requires that this entity be correctly classified; a diagnosis of “low-grade B-cell lymphoma,” although appropriate in some instances, should not be rendered if HCL remains a diagnostic possibility. SMZL is the most common differential diagnostic consideration. A nodular and intrasinusoidal (rather than interstitial and diffuse) bone marrow infiltration pattern is a helpful morphologic clue to SMZL. In the peripheral blood, circulating SMZL cells have less prominent and blunter hairy

projections that are often “polarized” to one aspect of the cell surface, unlike the encircling hairy projections of HCL.[131] Immunophenotypically, although SMZL cells are also negative for CD5 and CD10, they do not typically manifest the CD103-positive, CD25-positive, CD11c-positive, CD200-bright phenotype characteristic of HCL. In addition, they are CD123 negative and are negative for annexin A1 and cyclin D1 by immunohistochemistry. Splenic diffuse red pulp small B-cell lymphoma (SDRPSBL) is a provisional entity recognized in the revised WHO 4th ed. and in the ICC and is also an entity in the proposed WHO 5th ed. It displays a splenic infiltration pattern similar to HCL and bone marrow intrasinusoidal involvement similar to SMZL. The immunophenotype appears to be more similar to SMZL, although it shares with HCL the expression of DBA.44 and in some cases, expression of CD11c, CD123, and CD103.[111,132-134] There is also some overlap between this entity and HCLv in that they both lack CD25 expression.[44] Useful features in the differential diagnosis of HCL and other lymphoproliferative disorders are summarized in **Table 15-4**.[61,133-137]

CLINICAL COURSE AND TREATMENT

About 90% of HCL patients will require treatment for symptoms related to recurrent infections, symptomatic splenomegaly, progressive fatigue, or cytopenia (hemoglobin <11 g/dL, platelets <100 × 10^9/L, or absolute neutrophil count <1.0 × 10^9/L).[138,139] The clinical course of HCL has changed dramatically owing to major advances in therapy.[140] The purine analogues 2-chlorodeoxyadenosine (2-CdA) and deoxycoformycin (pentostatin,

DCF) represent highly effective therapies for HCL, with similar efficacies, and have replaced interferon-α and splenectomy as the first-line therapy.[141-143] The long-term survival of HCL treated with 2-CdA is excellent (96% at 13 years), and death caused by HCL is now uncommon; patients can be expected to experience a normal or near-normal life expectancy.[141,144,145] Although late relapses are relatively common (ranging from 24% at 5 years to nearly 50% at 10 years), relapsed disease usually responds to retreatment with purine analogues.[146] Monoclonal antibodies such as rituximab and anti-CD22 immunotoxin (moxetumomab pasudotox) have proved effective in purine analogue–resistant HCL; rituximab also may be used in combination with purine analogues as first-line therapy.[147-151]

Vemurafenib, a low–molecular-weight inhibitor of BRAF, has been used as a single agent or combined with rituximab to effectively treat HCL cases that are resistant to other therapies.[152-155] Of note, purine analogues and rituximab have been associated with profound immunosuppression and increased risk for severe COVID infection; thus active surveillance or less immunosuppressive agents were used more frequently in HCL patients during the COVID pandemic.[156]

Conventional chemotherapies used to treat other B-cell neoplasms are less helpful in HCL. Splenectomy, which is helpful in the management of SMZL, alleviates symptoms and palliates HCL but does not alter the disease course.[138,157] Thus accurate diagnosis of HCL and distinction from other types of B-cell lymphoma (especially SMZL) are critical in ensuring that patients receive disease-appropriate therapy.

PROGNOSTIC AND PREDICTIVE FACTORS

There are no known morphologic, immunophenotypic, or genetic markers of disease behavior in HCL. Unusual immunophenotypic features such as CD23 or CD10 expression in cases otherwise classic for HCL do not appear to confer an adverse prognosis.[62] The subset of cases using the VH4-34 IGH region and lacking somatic IGHV hypermutation has an inferior prognosis.

Patients are considered to achieve complete remission (CR) if there is near normalization of blood counts (hemoglobin >11 g/dL, platelets >100 × 10^9/L, absolute neutrophil count >1.5 × 10^9/L) without transfusion, regression of any splenomegaly on physical exam, and absence of morphologic evidence of HCL on both peripheral blood and bone marrow examination.[139] Measurable residual disease (MRD) after therapy can be detected by in a subset of patients who are in CR. A consensus opinion suggested that MRD in HCL can be established by identifying hairy cells by bone marrow immunostaining, flow cytometry, or molecular assays to detect a clonal IGH rearrangement or *BRAF* V600E mutation.[158] Immunohistochemical detection of HCL cells in the bone marrow biopsy specimen is particularly valuable given the often hemodilute nature of the aspirate smears in HCL. One study suggested that the presence of low-level HCL in the biopsy can be confirmed by any of the following: CD20-positive cells being more frequent than CD3-positive T cells; more than 50% of CD20 positive cells showing HCL morphology; or the presence of any TRAP-positive cells with HCL morphology.[159] Other investigators have used immunohistochemistry for DBA.44,[20,43,88] CD11c, or an antibody to

the T-cell–associated transcription factor T-bet to detect MRD.[78,160] The mutation-specific BRAF V600E antibody is also a sensitive method to reveal MRD in bone marrow trephine sections, and it effectively detects small amounts of disease after therapy.[86,161]

* In Wright-Giemsa–stained smear preparations.

Flow cytometry[162,163] and molecular genetic methods that detect a specific IGH gene rearrangement[164] or quantitative real-time PCR that detects the *BRAF* V600E mutation[165,166] can also be used to identify MRD in HCL. Flow cytometry can be used to quantify very low levels of HCL cells in the peripheral blood and to follow changes in these levels with therapy.[167,168] Most studies have shown that detectable MRD correlates with disease relapse in HCL after purine analogue therapy,[20,146,169] whereas patients with no detectable MRD (to the level of 10^{-4}) have a much lower risk for relapse.[170] However, patients with detectable MRD may remain in clinical remission for several years,[88] and MRD detection does not generally guide therapy for HCL patients in clinical remission.[18] Conversely, highly sensitive droplet digital PCR (ddPCR) for the *BRAF* V600E mutation can be used to detect MRD in HCL patients in morphologic

remission, and patients with undetectable *BRAF* V600E mutation can be considered to have a complete molecular response.

Pearls and Pitfalls

- Consider performing CD20 immunohistochemistry on bone marrow biopsies to evaluate for subtle hairy cell leukemia (HCL) in patients presenting with an unusual myelodysplastic syndrome–like picture, unexplained infections or fever, or aplastic anemia.
- Look carefully for characteristic HCL morphology in thin areas of well-prepared blood smears to avoid missing hairy cells or overcalling hairy cells owing to smear artifact.
- Consider adding CD103, CD25, CD11c, and CD200 to the flow-cytometry workup of cytopenic patients if any of the following is present:
    - Monocytopenia
    - Splenomegaly (which is unusual in myelodysplastic syndrome)
    - Cells that are suspicious for HCL are detected on review of the peripheral blood or bone marrow smears (especially if lymphocytes with high forward and side scatter on flow cytometry are present).
- Avoid making a general diagnosis of “low-grade B-cell lymphoma” if HCL remains in the differential diagnosis.

Hairy Cell Leukemia Variant

DEFINITION

The term *splenic marginal zone lymphoma* (SMZL) was coined by Schmid and colleagues[1] in 1992 for a B-cell lymphoma involving the spleen and bone marrow characterized by a micronodular tumoral infiltration that replaces the preexisting lymphoid follicles and shows marginal zone differentiation as a characteristic finding. SMZL is defined in the *World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues* as a B-cell neoplasm comprising small lymphocytes that surround and replace the splenic white pulp germinal centers, efface the follicle mantle, and merge with a peripheral (marginal) zone of larger cells, including scattered transformed blasts; both small and larger cells infiltrate the red pulp.[1,2]

A large majority of the cases have a fairly typical clinical presentation characterized by prominent splenomegaly and bone marrow and peripheral blood infiltration. Cells in peripheral blood

can frequently be recognized by the villous cytology; this and other findings confirm that SMZL and splenic lymphoma with villous lymphocytes are the same entity.[3,4]

The term splenic marginal zone B-cell lymphoma has prevailed to emphasize the morphologic and molecular features supporting marginal zone differentiation. Despite the name, the clinical, immunophenotypic, and molecular features of SMZL differ from those found in other marginal zone lymphomas (MZLs), indicating SMZL is a distinct clinicopathologic entity unrelated to mucosa-associated lymphoid tissue (MALT) or nodal MZL.

Nowadays, splenectomy is rarely performed, because the diagnosis of splenic low-grade B-cell lymphoma is usually established with the morphologic, immunophenotypic, and molecular findings of bone marrow and peripheral blood samples, integrated with clinical findings.

SYNONYMS AND RELATED TERMS

The WHO 5th edition uses the same terms, with the only exception the hairy cell leukemia variant (HCL_v), for which the term *splenic B-cell lymphoma/leukemia with prominent nucleoli* has been proposed.

The term *splenic lymphoma with villous lymphocytes* is quite generic and includes different disorders.

EPIDEMIOLOGY

The incidence of SMZL may be underestimated because, until recently, the diagnosis was typically made on splenectomy specimens; because splenectomy is not performed in many cases of

low-grade lymphoma, it is difficult to compare the incidence of this disease with that of other B-cell lymphomas. Nevertheless, SMZL appears to account for about 1% to 2% of all lymphomas.[2,4,5]

The median age at diagnosis is around 65 years, with a range from 30 to 90 years. A female predominance has been found in different series.[6,7]

ETIOLOGY

Analysis of the immunoglobulin (Ig) genes in SMZL shows biased use of selected VH1 genes *(VH1.2),* suggesting a role of unknown antigens in the promotion of tumor cell growth.[8] Interestingly, a small fraction of patients with SMZL harbor hepatitis C virus, and the therapy directed against hepatitis C seems to influence control of the tumor load in these patients, suggesting infectious agents play a role in the pathogenesis of SMZL.[9] This role of infectious agents is supported by the similarities between SMZL and so-called "hyperreactive malarial splenomegaly."[10]

CLINICAL FEATURES

SMZL is a disorder of older adults, with a median age of around 65 years. Most patients are asymptomatic, and usually the disease runs an indolent course. Splenomegaly is the most common sign, observed in 75% of patients; anemia, thrombocytopenia, or leukocytosis is reported in 25% of patients. Autoimmune hemolytic anemia is found in 10% to 15% of patients.[5,11,12] SMZL is infrequently diagnosed incidentally on routine examination, but monoclonal B-lymphocytosis with a marginal zone phenotype has

been recognized and could precede some of these marginal zone lymphomas.[13]

Almost without exception, SMZL involves the bone marrow at diagnosis, and roughly 33% of patients have liver involvement. Tumor involvement of peripheral blood (defined as the presence of absolute lymphocytosis or >5% tumor lymphocytes in peripheral blood) was detected in 68% of cases by Chacon's group[11] and in 57% by Berger's.[12] Abdominal lymphadenopathy was observed in 25%; peripheral lymphadenopathy was observed more rarely (17%). Because of the high frequency of bone marrow or liver involvement, most patients are diagnosed at Ann Arbor stage IV at diagnosis. Serum paraproteinemia (usually a small monoclonal IgM) band is observed in 10% to 28% of cases.[5,11,12]

Although the diagnostic criteria were initially based on splenic morphology, the conjunction of clinical features, immunophenotype, and morphology allows a diagnosis with a reasonably high level of confidence on bone marrow biopsy specimens.

MORPHOLOGY

Splenic involvement in SMZL is the rule, and some cases may even show a massive splenomegaly, rarely seen in other B-cell lymphoma disorders, with the exception of HCL. Histologic studies display a micronodular lymphoid infiltrate in which white pulp follicles are increased in both size and number, with a variable degree of red pulp involvement always present (**Fig. 16-1**). The neoplastic follicles typically have a biphasic appearance, with the presence of both a small-cell and a peripheral marginal cell component. The cells in the center of the follicles are small lymphocytes with generally round

nuclei and scant cytoplasm, and the cells in the marginal zones have irregular nuclear contours and moderately abundant pale cytoplasm. In addition, most cases contain scattered proliferating large B cells resembling centroblasts or immunoblasts; in the spleen, these appear in the marginal zone and red pulp, but they can also be seen in the bone marrow and lymph nodes.[14] Residual or colonized germinal centers may be seen in the centers of some nodules (as in the bone marrow), sometimes highlighted by follicular dendritic cell staining. Neoplastic plasma cells may be present within the germinal centers, forming clusters in rare cases, and in the splenic red pulp, surrounding small arterioles. The cellular composition of the tumor follicles may plausibly reflect the capacity of marginal zone B cells to induce germinal-center development through the transport of immune complexes to the follicular dendritic cells[15]; thus, tissue infiltration by SMZL in the bone marrow or other locations is frequently accompanied by the presence of induced lymphoid follicles with reactive/colonized germinal centers.

In contrast with the organoid pattern of involvement of the white pulp, mimicking the architecture of normal splenic lymphoid follicles, the red pulp more frequently shows a diffuse pattern of involvement, with infiltration of both the cords and the sinuses. The cells in the red pulp include both small lymphocytes and large centroblasts or immunoblasts. Epithelioid histiocytes may be present in some cases, sometimes surrounding neoplastic follicles.

Splenic hilar lymph nodes are commonly involved in SMZL (**Fig. 16-2**), but peripheral lymph node involvement is rarely seen at diagnosis. In these SMZL-involved lymph nodes, a marginal zone pattern is only rarely observed. The pattern is typically

micronodular, and the cells are predominantly small; sinuses may be dilated.[16] The variability of the cellular composition of the tumor in various sites suggests the microenvironment is relevant to the pattern of tumor growth.[1,2]

Bone marrow infiltration is the rule in SMZL, although it may be difficult to recognize on routine morphologic sections (**Fig. 16-3**). CD20 staining helps reveal the presence of intertrabecular lymphoid aggregates and intrasinusoidal small tumor cells. The intertrabecular nodules mimic the architecture and cell composition of tumor nodules in the spleen, with occasional reactive germinal centers surrounded by tumor cells. Characteristically, CD20 staining reveals the presence of linear aggregates of intrasinusoidal B cells.[17,18] The intrasinusoidal pattern can be observed in other B-cell lymphomas, including follicular lymphoma (FL), mantle cell lymphoma (MCL), chronic lymphocytic leukemia (CLL), and HCL, but the combination of intertrabecular nodules with intrasinusoidal infiltration is quite characteristic of SMZL. In contrast with lymphoplasmacytic lymphoma (LPL), bone marrow infiltration in SMZL lacks the prominent mast cell component. Differential diagnosis for FL is facilitated by the staining of SMZL cells with antibodies for MNDA or T-bet, negative in the vast majority of FL cases. Also, although SMZL nodules in the bone marrow may show some peritrabecular arrangement, they lack the characteristic paratrabecular pattern (surrounding bone marrow trabeculae) typical in FL cases and occasionally observed in LPL.

Peripheral blood involvement is less frequent than bone marrow infiltration. However, it is relatively common to find a small number of neoplastic B cells in the blood, some of which may have a villous

morphology. This usually takes the form of small cytoplasmic projections at one pole of the rather abundant cytoplasm (**Fig. 16-4**). There are cases that present clinically with monoclonal lymphocytosis, with morphology, phenotype, and molecular findings compatible with SMZL, and that later develop splenomegaly.[13]

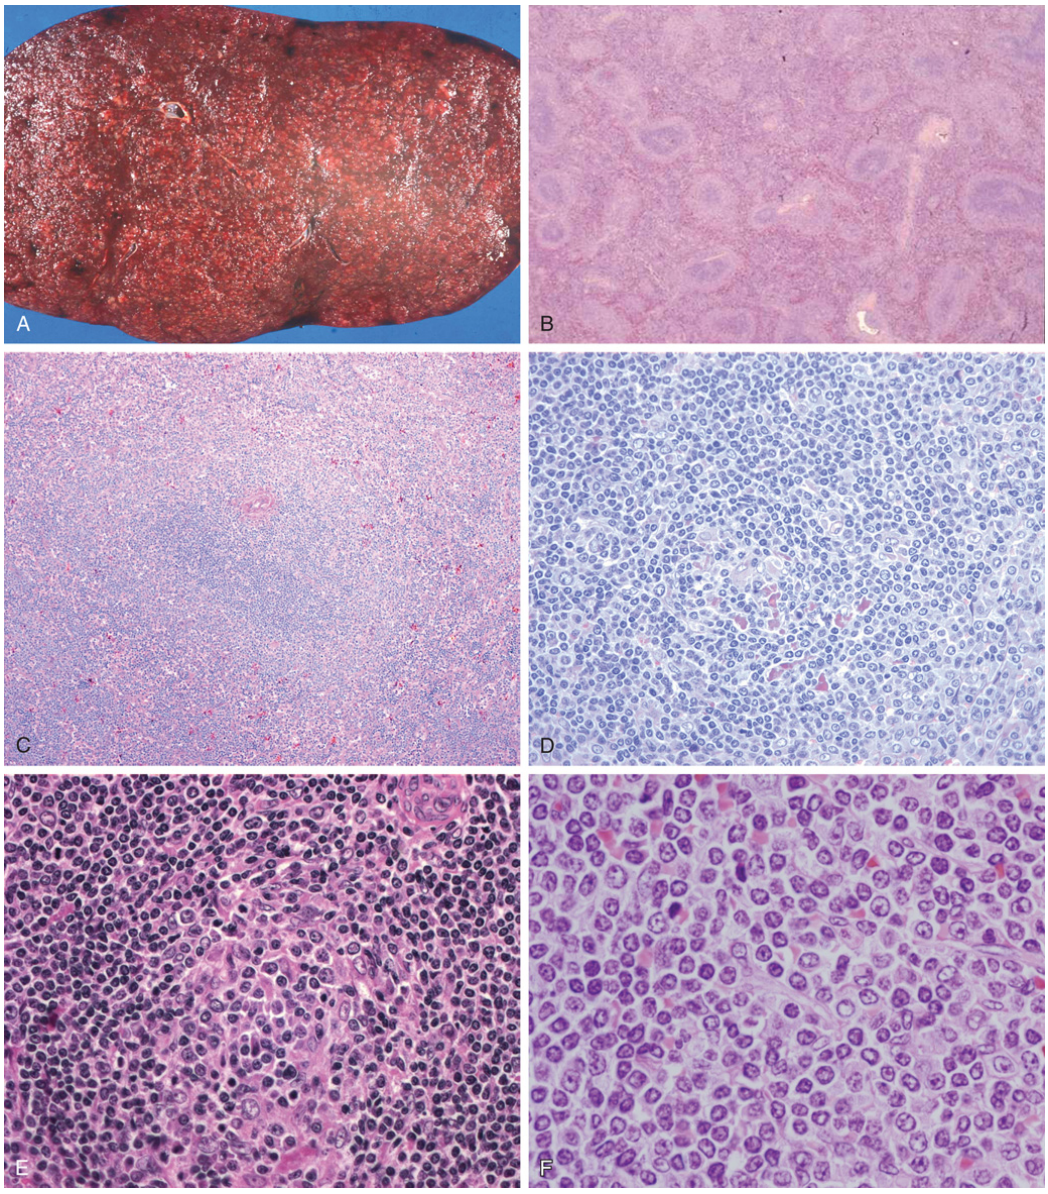

FIGURE 16-1 Splenic marginal zone lymphoma morphology in the spleen.**A,** Gross photograph shows a micronodular homogeneous pattern. **B,** Low magnification shows marginal zone differentiation and biphasic cytology, with pale-staining cells in the marginal zone, darker cells in the interior of the follicle, and occasional pale central areas, indicating residual reactive

germinal centers. **C** and **D,** Replacement of lymphoid follicles by neoplastic cells (Giemsa stain). **E,** Germinal center infiltration by neoplastic cells at a higher magnification; this case shows plasmacytic differentiation within the germinal center. **F,** Cytologic features. Cells in the marginal zone component have slightly enlarged nuclei and abundant pale cytoplasm, which is in contrast to the neoplastic small-cell component in the center of the nodules (Giemsa stain).

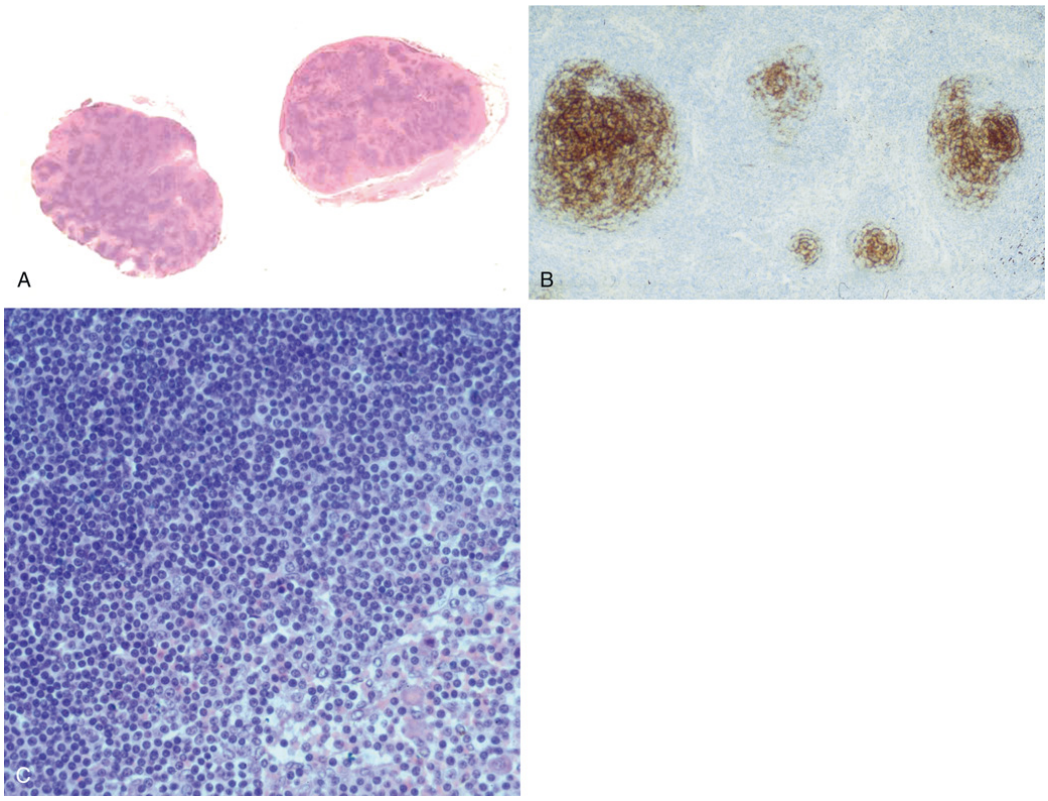

FIGURE 16-2 Lymph node involvement by splenic marginal zone lymphoma.**A,** Low magnification of a splenic hilar lymph node with a micronodular pattern and prominent sinusoidal dilation. **B,** Tumor is centered in lymphoid follicles, highlighted by staining for follicular dendritic cells (immunoperoxidase stain for CD23). **C,** Higher magnification shows small tumor cells in the lymph node, with scant cytoplasm and clumped chromatin and lacking marginal zone differentiation.

An increase in the number of large cells can be seen within the marginal zone rings of the spleen and is definitely associated with large cell transformation,[14,19,20] but a reproducible way of counting

these large cells and a threshold associated with increased risk of large cell transformation has not been defined.

IMMUNOPHENOTYPE

Immunophenotypic features are summarized in **Box 16-1** and shown in **Figure 16-5**. SMZL cells usually express B-cell markers such as CD20, Pax5, and CD79a and IgD and marginal zone markers such as MNDA and T-bet, with staining for DBA44 in at least a proportion of the neoplastic cells.

SMZL lacks the expression of CLL markers (LEF1, CD5, CD23), although CD5 is expressed in 25%[20,21] of SMZL cases and associated with a more tumoral clinical presentation. SMZL cells are negative for FL markers (BCL6, CD10), MCL markers (SOX11, CyclinD1), and HCL markers (AnnexinA1, CyclinD1).

MIB-1 staining shows a distinctive annular pattern, indicating the presence of an increased growth fraction in both the germinal centers and the marginal zones. BCL2 staining helps to distinguish the reactive germinal centers, occasionally infiltrated by BCL2-positive neoplastic cells. MNDA and T-bet staining are definitely useful in the differential diagnosis for FL.[21]

Flow cytometry is also useful in the recognition of SMZL. According to the Matutes CLL score, most SMZL cases have scores ranging from 0 to 2.[3] In the majority of patients, the immunophenotype is CD20+, CD22+, CD24+, CD27+, FMC7+, IgD+, IgM+, and CD79b+, and some of them are DBA44+ (75%), CD11c+ (50%), CD23+ (30%), CD103+ (<10%), CD25+ (25%), and CD5+ (20%).[3]

An inflamed phenotype of splenic marginal zone B-cell lymphomas, with expression of PD-L1 by intratumoral monocytes/macrophages and dendritic cells, has been demonstrated, a finding that could have important conceptual and therapeutic implications.[22]

GENETICS

Genetic Abnormalities

The analysis of chromosome region 7q22-36 demonstrated allelic loss in up to 40% of cases, a frequency higher than that observed in other B-cell neoplasms (8%).[23] A minimal common deleted region has been mapped to a 3-Mb region at 7q32.1-32.2.[24] This region has been shown to contain some potentially relevant genes[25-27] and a cluster of micro-RNA.[25,28]

Other clonal chromosome abnormalities detected in SMZL are gain of 3q (10% to 20%) and involvement of chromosomes 1, 8, and 14. No t(11;14)(q13;q32) or t(14;18)(q21;q32) are seen. Occasional cytogenetic abnormalities involving 14q32, such as t(6;14)(p12;q32) and t(10;14)(q24;q32), or 7q21 (with deregulation of cyclin-dependent kinase 6) are rarely found, but they may distinguish specific clinicopathological variants.[29] Deletion of 17p13 *(TP53)* has been observed in 3% to 17% of cases.[30-33]

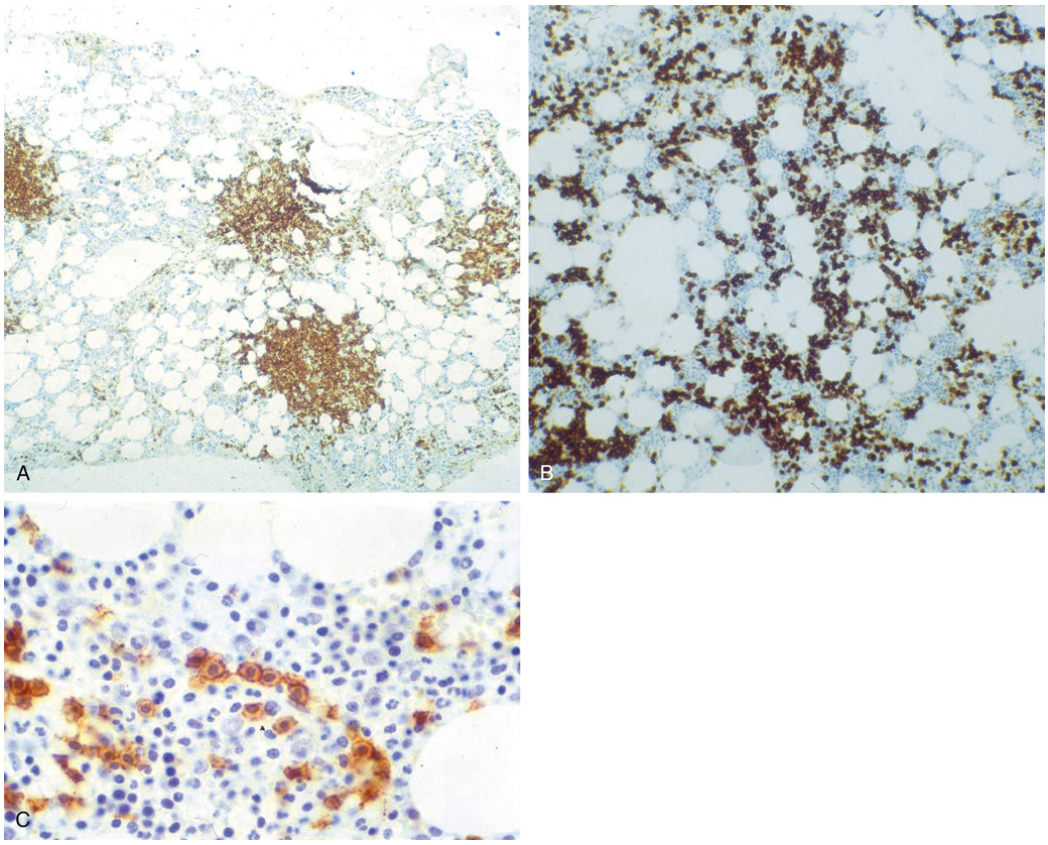

FIGURE 16-3 Bone marrow biopsy specimen shows the characteristic patterns of splenic marginal zone lymphoma with CD20 staining.**A,** Low magnification shows nodular intertrabecular and intrasinusoidal tumor aggregates. **B,** Higher magnification shows diffusely scattered tumor cells. **C,** Intrasinusoidal tumor cells.

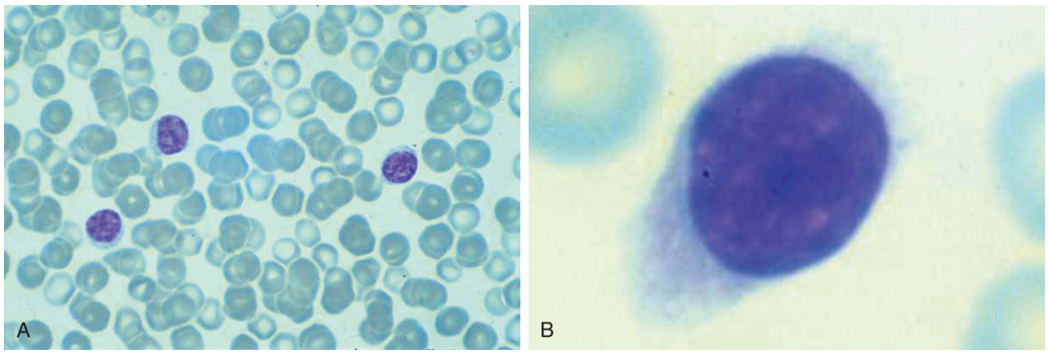

FIGURE 16-4 **A** and **B,** Peripheral blood morphology shows villous lymphocytes. Villi are typically short and are described as polar—that is, they are concentrated at one pole of the cytoplasm, in contrast to the longer, circumferential villi typically seen in hairy cell leukemia. Villi are usually seen in only a subset of cells.

Whole-exome sequencing in SMZL reveals mutations in genes involved in marginal zone differentiation, *NOTCH2* and others. The most frequently mutated gene is *KLF2*, a transcription factor important for B-cell differentiation and NF-κB activation, found in 20% to 42% of SMZL cases.[34,35] All SMZL genetic studies coincide in showing high frequency of mutations in NF-κB pathway genes; specifically, *TNFAIP3, MYD88, TRAF3, CARD11, IKBKB*, and *BIRC3*.[34-38]

The *MYD88* L265P mutation can be found in otherwise typical SMZL cases (4% to 15%)[39,40]; nevertheless, SMZL cases with the *MYD88* mutation should be investigated for the presence of serum paraproteinemia and other findings suggesting LPL.[40,41]

Published data has confirmed the results of previous molecular studies, disclosing two main genetic clusters in SMZL, one termed NNK (58% of cases, harboring NF-κB, NOTCH, and KLF2 modules) and the second denominated as DMT (32% of cases, with DNA-damage response, MAPK, and TLR modules). Both genetic types also differ in survival probability, with inferior survival in NNK-SMZLs. The study also revealed variations in the SMZL immune microenvironments, with two main types denominated as immune-suppressive SMZL (50% of cases, associated with inflammatory cells and immune checkpoint activation) and immune-silent SMZL (50% of cases, associated with an immune-excluded phenotype) with distinct mutational and clinical correlations.[42]

Box 16-1 Major Diagnostic Features of Splenic Marginal Zone Lymphoma

Clinical Features

- Splenomegaly
- Bone marrow involvement
- Lymphocytosis with or without villous cells

Morphologic Features

- Spleen: micronodular pattern; biphasic cytology; follicular replacement; marginal zone differentiation; diffuse, micronodular infiltration of red pulp
- Peripheral blood: villous cells, small lymphocytes

- Bone marrow: intertrabecular nodules, occasionally with a marginal zone pattern and follicular dendritic cell remnants
- Lymph nodes: micronodular pattern, small lymphocytes, scattered blasts, rare marginal zone differentiation

Immunophenotypic Features

- $CD20^+$, IgD^+, $BCL2^+$, $MNDA^+$, $CD3^-$, $CD23^-$, $CD43^-$, $CD5^-$, $CD10^-$, cyclin $D1^-$, $BCL6^-$, annexin A_1^-
- Ki-67 (MIB-1) low (target pattern with higher proliferation in germinal center and marginal zone); residual germinal centers may be $BCL2^-$, $BCL6^+$

Genetic Features

- 7q deletion: 40%
- *TP53* gene alterations: 0% to 20%[32]
- Somatic mutation in *NOTCH2/KLF2* and other marginal zone genes[34,36,38]
- *IgVH* gene somatic mutations: frequent VH1.2 use, low mutational load

of infiltration. Light-chain restriction is revealed by **(I)** the negative cytoplasmic staining for lambda and **(J)** positivity for kappa.

Antigen Receptor Genes

The frequency of Ig heavy-chain variable region (IgVH) somatic mutations has also been investigated in SMZL. The frequency of IGHV1-2 use has been shown to oscillate from 25% to 44% of cases. Most (95%) of these rearrangements were mutated; however, they mostly carried a low mutational load (97% to 99.9% germline identity) of conservative nature and restricted distribution, which supports the presence of antigenic selection in the pathogenesis of SMZL.[8,43-45] Although antigen selection and biased use of Ig genes has been found in different B-cell lymphomas, such as FL, CLL, LPL, and others, the use of IGHV1-2 in SMZL has been confirmed in multiple studies and has allowed the proposition that some SMZL subtypes could derive from B-cell progenitor populations adapted to specific antigenic challenges through selection of VH domain specificities.[43]

Gene-Expression Profiling

Gene-expression profiling studies have revealed potential diagnostic markers and pathogenetic pathways involved in tumor cell survival. Thus, the signature obtained in different studies coincides with upregulation of the following families of genes:

- Genes involved in apoptosis regulation, B-cell receptor and tumor necrosis factor signaling, and nuclear factor-κB

activation, such as *SYK, BTK, BIRC3, TRAF3, TRAF5, CD40,* and *LTB*.

- Genes associated with the splenic microenvironment, such as *SELL* and *LPXN*.
- Lymphoma oncogenes such as *ARHH* and *TCL1*.[46] Increased *TCL1* expression is linked with *AKT1* activation in SMZL, as proposed by Thieblemont and colleagues.[47]
- *AP-1* and *NOTCH2* transcription factors.[48]

Cell of Origin

The debate over the cellular origin of SMZL has been fueled by conflicting morphologic and molecular findings. A large proportion of tumor cells in SMZL are IgD-positive small lymphocytes in which marginal zone differentiation is produced only in the microenvironment provided by the splenic marginal zone. The presence of somatic mutations in genes (*NOTCH2, KLF2,* and others) involved in marginal zone differentiation supports the relationship of the neoplastic cells with the normal marginal zone. Alternatively, the low mutational load of the *IgVH* genes in SMZL cases does not support a close relationship with normal marginal zone B cells, which typically have somatic mutations, indicating passage through the germinal center.[49] These findings favor the existence of a subpopulation of small B cells in the primary lymphoid follicles of the spleen with the potential capacity to differentiate into marginal zone B cells in the appropriate environment and to acquire somatic mutations after exposure to antigens present in the germinal center.

Clinical Course

SMZL is a low-grade tumor with a survival probability of 5 years that varies from 65% (for patients diagnosed with SMZL after splenectomy) to 78% (for patients diagnosed with splenic lymphoma with villous lymphocytes [SLVL] in peripheral blood).[5,11] A large SMZL study found 68.5% overall survival after 10 years follow-up.[42]

The few studies performed on relatively large series show that adverse clinical prognostic factors are related to high tumor burden and poor performance status. The biological parameters associated with adverse outcome are *TP53* mutation or overexpression, 7q deletion, and the absence of somatic mutation in *IgVH* genes. SMZL therefore seems to behave similarly to CLL, in which an unfavorable clinical course is associated with *TP53* inactivation and unmutated (naïve) *IgVH* genes. Massive high-throughput studies have shown *NOTCH2* and *TP53* gene mutations are independent markers of reduced treatment-free and overall survival.[34,42,50]

Although little information about SMZL is available from clinical trials, some clear points have emerged. These include the lack of efficacy of 2-chlorodeoxyadenoside typically used in HCL,[51] the relatively favorable course for patients treated with splenectomy,[5,52] and the potential efficacy of fludarabine for patients who relapse after splenectomy or are resistant to chlorambucil.[51] Rituximab, with or without splenectomy, has been found to be a very good option for the treatment of SMZL,[53,54] and rituximab monotherapy has been shown to induce prolonged responses.[54] The BRISMA trial has shown that a combination of bendamustine with rituximab is a good option when a chemotherapy combination with rituximab is deemed necessary for symptomatic patients with SMZL.[55] Consistent with the data generated in gene expression profiling studies

demonstrating an activated B-cell receptor signaling pathway in SMZL, durable ibrutinib responses have been shown in relapsed/refractory marginal zone lymphoma cases.[56] Hepatitis C–positive patients seem to benefit from antiviral therapy.[9] Specific recommendations for therapy have been published.[3,57] A simple staging system has also been published and validated, using hemoglobin concentration, platelet count, lactate dehydrogenase (LDH) level, and the presence of extrahilar lymphadenopathy.[58]

Patients with SMZL appear to have a greater frequency of transformation to large B-cell lymphoma (13% of cases with adequate follow-up) than those with CLL (1% to 10%), although the incidence of large cell transformation in SMZL is lower than in follicular lymphoma (25% to 60%). In the cases studied to date, it seems that progression in SMZL could depend on multiple factors, including *TP53* mutations and Epstein-Barr virus (EBV) presence, and is more frequently associated with 7q loss.[14,33,50,59]

Differential Diagnosis

The differential diagnosis of SMZL and other small B-cell lymphomas requires the integration of clinical, morphologic, immunophenotypic, and genetic information (**Table 16-1**). A micronodular pattern of splenic involvement with villous cells in the peripheral blood can be observed in other conditions, particularly in FL, but also in MCL (Figs. **16-6** and **16-7**). Immunophenotyping and genetic features are usually diagnostic; FL is typically CD10 and/or BCL6 positive, though MCL expresses SOX11 and Cyclin D1. The absence of t(14;18)(q32;q21) and t(11;14)(q13;q32) is also helpful in ruling out these entities, respectively.[60] Particularly helpful features

are the intrasinusoidal pattern of involvement in the bone marrow[17,18] and IgD expression by tumor cells. Differential diagnosis with FL is also facilitated by the common expression of MNDA and T-bet by SMZL cells.[21,61]

Distinguishing LPL may be problematic, because SMZL has shown some degree of plasmacytic differentiation with serum monoclonal paraproteinemia in up to 28% of cases in some series. There are no specific immunophenotypic features that distinguish these disorders; however, detection of the characteristic 7q abnormalities favors SMZL. Patients with SMZL rarely have a sufficient serum IgM concentration to result in hyperviscosity syndromes. Bone marrow trephine examination may be useful, because LPL typically produces a subtle, diffuse (sometimes paratrabecular) lymphoplasmacytic infiltrate with striking increase in the proportion of mast cells; if intertrabecular lymphoid aggregates with a marginal zone pattern or intrasinusoidal involvement are recognized, a diagnosis of SMZL should be suspected. Finally, on splenectomy specimens, the pattern of infiltration in LPL is typically diffuse red pulp involvement, in contrast to the nodular involvement of both white and red pulp in SMZL.[62] The presence of a *MYD88* L265P mutation should lead to consideration of a possible LDL diagnosis.[41,63]

Table 16-1

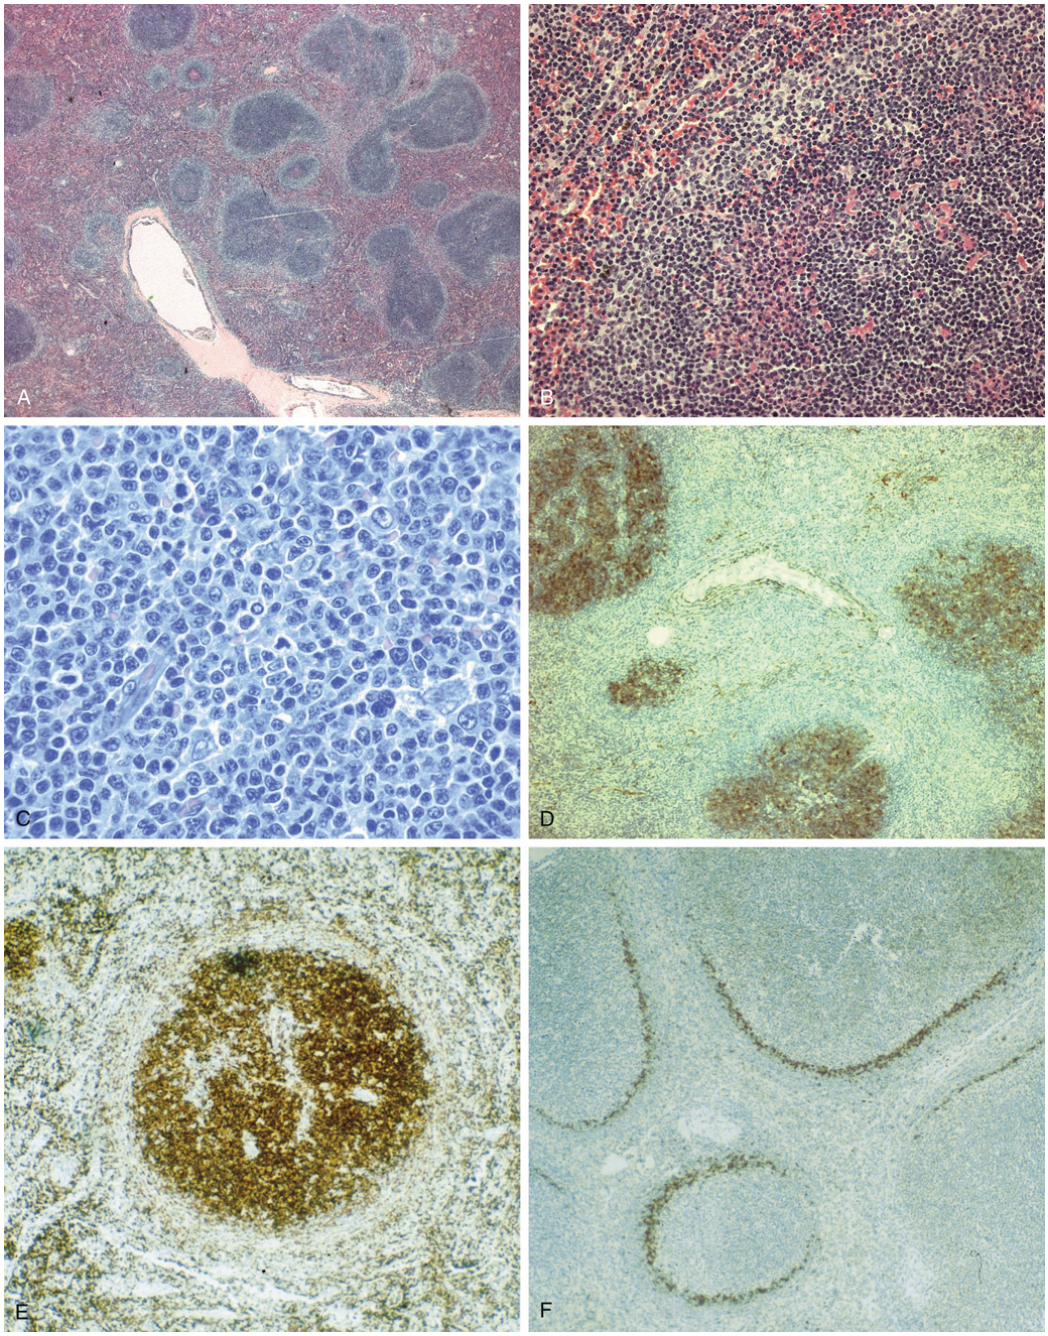

FIGURE 16-6 Follicular lymphoma with splenic infiltration, mimicking splenic marginal zone lymphoma (SMZL).**A** and **B,** Micronodular pattern with marginal zone differentiation. **C,** On higher magnification, the cells in the follicles are a mixture of centrocytes and centroblasts, typical

of germinal-center cells (Giemsa stain). **D,** CD10 staining highlights the entire follicle rather than just a residual germinal center, as would be seen in SMZL. **E,** Homogeneous BCL2 expression within the follicle. **F,** Characteristic immunoglobulin D staining of residual mantle cells; the neoplastic cells are negative.

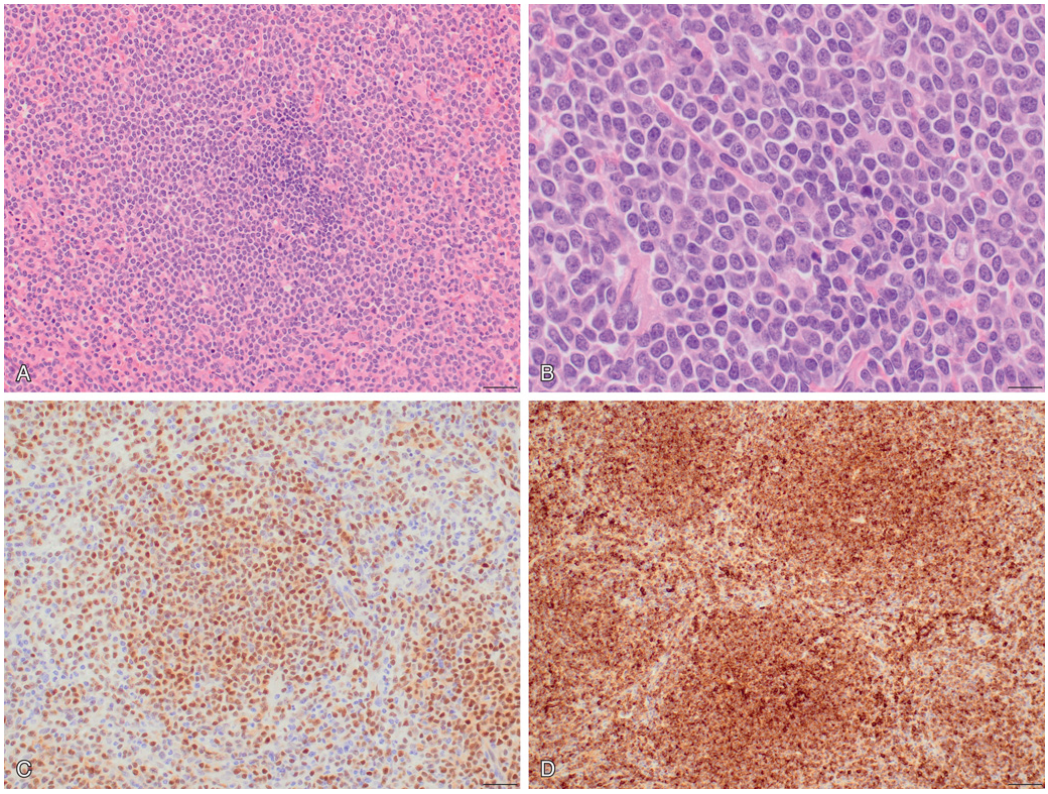

FIGURE 16-7 Mantle cell lymphoma splenic infiltration.Micronodular pattern **(A)**, with monomorphous cytology **(B)**. Tumor cells are Cyclin D1 positive **(C)** and CD5 positive **(D)**.

Rarely, MALT-type MZL may infiltrate the spleen with a micronodular pattern, characteristically involving the splenic marginal zone and thus causing diagnostic problems. Useful distinguishing features are the absence of t(11;18)(q21;q21) typical of MALT-type MZL in SMZL,[64] the presence of 7q abnormalities in SMZL, and the characteristic IgD expression in SMZL, which is only rarely observed in MALT-type MZL.

OTHER SPLENIC B-CELL LYMPHOMAS

Splenic Diffuse Red Pulp Small B-Cell Lymphoma

This lymphoma presents clinically with splenomegaly, bone marrow, and peripheral blood involvement, similar to SMZL. Villous cells and clonal expansions of B cells in peripheral blood with marginal zone phenotype may precede both entities,[13] although they may be more frequent in splenic diffuse red pulp small B-cell lymphoma (SRPL) (**Fig. 16-8**).[65] However, the histopathological findings in the splenectomy specimen are quite different. Instead of the micronodular pattern with biphasic cytology composition presented in SMZL, the spleen features in SRPL show diffuse involvement of the red pulp with infiltration of cords and sinuses, effacement of the white pulp, and monomorphous population of small cells resembling marginal zone B cells. Both SMZL and SRPL show intrasinusoidal infiltration in the bone marrow, but it is usually more striking in SRPL cases, where a pure intrasinusoidal pattern may be frequently observed. The expression of cyclin D3, CD180, and DBA44 is more frequent in SRPL than in SMZL.[66-69]

Cytogenetic findings and molecular data such as 7q deletion, trisomies of chromosomes 3 and 18, and mutations of *KLF2* or *NOTCH2* genes are present in SMZL and rare in SRPL. On the other hand, sequencing studies have shown recurrent mutations in *CCND3* in SRPL.[69]

The sinusoidal pattern of infiltration of the bone marrow is outlined after CD20 staining **(H)**.

Hairy Cell Leukemia Variant

Despite its name, this very unusual low-grade B-cell lymphoma bears no relation to HCL in terms of morphology, immunophenotype, or response to therapy. Cases are characterized by large, prolymphocyte-like cells with prominent nucleoli; absence of annexin A_1, CD25, and CD103; and resistance to conventional HCL therapy.[70] Consequently, the next WHO lymphoma book is proposing the term *splenic B-cell lymphoma/leukemia with prominent nucleoli*. Quite interestingly, HCL_v cases seem to lack the *BRAF* V600 mutation typical of HCL, but activating mutations in the *MAP2K1* gene (encoding MEK1) have been found in 50% of these cases.[71] Some degree of overlap has been found between HCLv and SRPL.[68]

Pearls and Pitfalls

Feature	Comments
Follicular replacement	SMZL grows around preexistent follicles, replacing them. MIB-1/BCL2/MNDA/CD21/CD23 stains illustrate this phenomenon.
IgD staining	IgD is expressed in most SMZL cases. Residual mantle cells are absent from this lymphoma. In FL and MALT-type MZL, preserved IgD-positive mantle cells may be observed.
Bone marrow infiltration	Bone marrow histology is quite characteristic in SMZL, with intertrabecular nodules of small lymphocytes surrounding residual/replaced germinal centers. Intrasinusoidal involvement (demonstrated by CD20 staining) is useful, albeit not diagnostic.
Splenic hilar lymph node morphology	Lymph node involvement by SMZL displays characteristic histologic and immunohistochemical features, with frequent loss of marginal zone differentiation.
7q deletion	7q31-32 loss is a relatively specific genetic marker of SMZL, present in 40% of cases.
***IgVH* somatic**	Stereotyped use of Ig genes indicates the role of antigens in SMZL cell survival.

Feature	Comments
mutations	
Marginal zone pattern	A marginal zone pattern can be observed in other small B-cell lymphomas involving the spleen. Marginal zone differentiation in bone marrow and lymph node involvement by SMZL are usually absent.
Monoclonal B-cell lymphocytosis	Monoclonal B-cell lymphocytosis, non-CLL phenotype may precede both SRPL and SMZL.
Villous cells in peripheral blood	Villous lymphocytes may also be present in SRPL, MCL, FL, B-CLL, and lymphoplasmacytic lymphoma.
MNDA and T-bet	SMZL cells are usually positive for both, in contrast with FL.

Other Small B-Cell Lymphomas

Definition

Follicular lymphoma (FL) is defined as a neoplasm composed of follicle center (germinal-center) B cells (typically both centrocytes and centroblasts) that usually has at least a partially follicular pattern.[1,2] If diffuse areas composed predominantly of large cells are present in any case of FL, a diagnosis of diffuse large B-cell lymphoma (DLBCL) is also made. Lymphomas composed of centrocytes and centroblasts with an entirely diffuse pattern in the sampled tissue may be included in the category of FL. FL is generally clinically indolent and characteristically harbors a translocation between the *BCL2* and immunoglobulin heavy chain (IGH) genes, leading to the characteristic strong overexpression of the BCL2 protein. The major features of FL are listed in **Table 17-1**. Several FL variants that have distinctive clinicopathologic features are defined in the International Consensus Classification (ICC) and World Health Organization (WHO) classifications (**Table 17-2**).

Synonyms and Related Terms

FL has been a distinct entity with classic morphologic and genetic features since the Revised European and American Lymphoma classification in 1998[3] and WHO Classification of Tumours of the Haematopoietic and Lymphoid Tissues, 2nd edition, in 2002. Increasingly, the diversity of clinical presentations and genetic and mutational variability has been recognized, leading to several subtypes and distinct entities. In particular, FL cases presenting in the pediatric age group; confined to the testes, duodenum, or skin; confined to lymphoid follicles (in situ); and those with *IRF4*

rearrangements were described in the WHO 4th edition. A provisional entity including cases lacking *BCL2* gene rearrangements and expressing CD23 has also been described.[1] In addition, new broader groupings of cases based on morphologic features have emerged.[2] These include classic FL (cFL), follicular large B-cell lymphoma (FLBCL), FL with unusual cytologic features (uFL), and FL with predominantly diffuse growth pattern (dFL). See **Table 17-2** on Synonyms and Related Terms. These variants and entities will be further discussed throughout this chapter.

Epidemiology

FL predominantly affects adults, with a median age of 65 years (**Table 17-1**).[3] In contrast to most other hematologic malignancies, it is equally common in women and men. In the United States, it is two-to-three times more common in Whites than in Black and Asian populations.[4] FL is the second most common lymphoma worldwide (after DLBCL), accounting for 20% of all non-Hodgkin lymphomas.[5] It constitutes almost 40% of non-Hodgkin lymphomas in the United States and up to 70% of "low-grade" lymphomas reported in American clinical trials.[5,6] It is less common in other parts of the world, including eastern and southern Europe, Asia, and nonindustrialized countries.[7]

Table 17-1

Major Features of Follicular Lymphoma

Feature	Description
Definition	A lymphoma of germinal-center B cells (centrocytes and centroblasts) with typically at least a partially follicular pattern
Frequency	40% of adult lymphomas in the United States; 20% worldwide
Age	Median, 65 years
Sex	Male = female
Clinical features at presentation	Generalized lymphadenopathy, frequent splenomegaly, often asymptomatic; bone marrow positive in 40%; rare stage I, extranodal or pediatric
Morphology	Pattern: follicular with or without diffuse areas or interfollicular involvement, extracapsular extension, sclerosis, vascular invasion Cytology: centroblasts and centrocytes, follicular dendritic cells, reactive T cells

Feature	Description
Usual immunophenotype	Ig^+, $CD19^+$, $CD20^+$, $CD22^+$, $CD79a^+$, $PAX5^+$, $CD10^+$, $BCL2^+$, $BCL6^+$, $CD43^-$, $CD5^-$; nodular meshworks of $CD21^+$, $CD23^+$ follicular dendritic cells
Genetic features	Immunoglobulin genes rearranged, mutated, intraclonal heterogeneity t(14;18)(q23;q32)/*BCL2*::*IGH*
Postulated normal counterpart	Germinal-center B cells
Clinical course	Indolent, incurable: prognosis based on histologic grade (grade 1 to 2 indolent, grade 3 aggressive), Follicular Lymphoma International Prognostic Index
Treatment	Symptomatic for grade 1 to 2, aggressive for grade 3

Table 17-2

Synonyms and Related Terms

WHO, 4th Edition	ICC	WHO, Proposed 5th Edition
FL, grade 1 to 2, follicular +/− diffuse pattern	FL, grade 1 to 2, follicular +/− diffuse pattern	Classic FL
FL, grade 3A	FL, grade 3A	Classic FL
FL, grade 3B	FL, grade 3B	Follicular large B-cell lymphoma
FL, grade 1 to 2, diffuse pattern	FL, grade 1 to 2, diffuse pattern*	FL with predominantly diffuse growth pattern
N/A	N/A, see text for the ICC approach to these cases	FL with unusual cytologic features, uFL
In situ follicular neoplasia	In situ follicular neoplasia	In situ follicular B-cell neoplasm
Pediatric-type FL	Pediatric-type FL	Pediatric-type FL

WHO, 4th Edition	ICC	WHO, Proposed 5th Edition
Testicular FL	Primary testicular FL	Subtype of cFL
Duodenal-type FL		Duodenal-type FL
	BCL2-R(neg), CD23(+), follicle center cell lymphoma	Cases with diffuse architecture fall into FL with predominantly diffuse growth pattern
Large B-cell lymphoma with *IRF4*-R	Large B-cell lymphoma with *IRF4*-R	Large B-cell lymphoma with *IRF4*-R

cFL, Classic FL; *FL,* follicular lymphoma; *ICC,* International Consensus Classification; *neg,* negative; *R,* rearrangement.

* Many of these cases fulfill criteria for BCL2-R-negative, CD23-positive follicle center lymphoma—see text for ICC criteria for these cases.

The incidence of FL in the United States in the past 20 years has been estimated at 2.7 to 3.0 per 100,000 for White men and women and 0.9 to 1.3 per 100,000 for Black men and women.[5] The annual incidence of FL in Asian countries has been estimated at 0.15 to 0.38

per 100,000—less than 10% that in industrialized Western countries.[8,9]

Ethnic susceptibilities have not been extensively evaluated and are difficult to dissect from socioeconomic factors. In one report from Malaysia, FL accounted for only 12% of 158 adult non-Hodgkin lymphomas; lymphomas in Indian patients were more likely to be follicular (31%) than they were in Malaysian (16%) or Chinese (6%) patients.[10] In a study of Chinese and Japanese residents of the United States, the relative risk of FL was low among those born in Asia (relative risk 0.11 to 0.15 compared to White Americans) and higher among those born in America (relative risk 0.36 to 0.84),[11] suggesting environmental factors may be more important than race.

Clinical Features

Sites of Involvement

Most patients with FL have widespread nodal disease at the time of diagnosis, even though they may feel relatively well.[6] In most studies, up to two-thirds of the patients are in stage III or IV. They infrequently have systemic "B" symptoms (28%); 44% are in the low-risk group (category 0/1) of the International Prognostic Index, and 48% are in the low-intermediate–risk group (category 2/3).

Peripheral, mediastinal, and retroperitoneal nodes are often involved. Large mediastinal masses are rare, but large retroperitoneal and mesenteric masses often occur and may cause ureteral obstruction. Pure extranodal presentations are uncommon—9% in one survey[5]—and extranodal involvement (other than bone marrow) was seen in 20% of cases in another study.[6] The most common sites of stage IV disease are the bone marrow and liver, with

42% of patients having bone marrow involvement.[6] The majority of patients probably have circulating neoplastic cells, and a small proportion are frankly leukemic.[12]

Non-nodal presentations usually involve the spleen, Waldeyer's ring, skin, or gastrointestinal (GI) tract. Within the GI tract, the small bowel and particularly the duodenum are most often involved (see "Related B-Cell Lymphomas and Follicular Proliferations," later).[13,14] Rare cases of FL presenting as lymphomatous polyposis of the intestinal tract have been reported.[15] Primary cutaneous lymphoma of the follicle center type is an important subset of cutaneous B-cell lymphoma and is discussed in **Chapter 19**.[16-20]

Clinical Evaluation and Staging

The diagnosis of FL is best made on an excisional lymph node biopsy, which provides the best opportunity to assess histology and architectural pattern. Patients with peripheral lymph nodes that are accessible for open biopsy should have this procedure done. For patients with deeper, less accessible lymph nodes, FL can be diagnosed on core needle biopsies if adequate material is available for morphologic evaluation and for immunophenotyping (flow cytometry or immunohistochemistry) to document clonality and confirm germinal-center origin.[21] Appropriate grading or subclassification of FL may not be possible with these specimens, and in such cases, excision may be considered. In addition, grade 3B cases may not be distinguishable from DLBCL, but this distinction may not be clinically relevant.

Patients typically undergo abdominal and pelvic computed tomography scanning and bone marrow biopsy for staging, in

addition to measurement of serum lactate dehydrogenase for stratification within the Follicular Lymphoma International Prognostic Index (FLIPI).[22,23]

Morphologic Features

Architectural Patterns

Lymph nodes are typically enlarged, with complete architectural effacement by neoplastic follicles. Follicles are typically uniform in size, closely packed, and evenly distributed throughout the lymph node, obliterating sinuses and extending outside the capsule (**Fig. 17-1A**). Neoplastic follicles typically lack a starry-sky pattern and polarization. They may range in size from no larger than a primary follicle to much larger than the average reactive follicle; although usually round, they may be irregular and serpiginous (**Fig. 17-1B**), mimicking floridly reactive hyperplastic follicles. Within a given tumor, the follicles are likely to be relatively uniform and monotonous, but in some cases there is marked variation in size from one follicle to another. In other cases, the follicles may appear irregularly mottled, resembling progressively transformed germinal centers; this usually occurs in cases with increased large cells and has been called the *floral variant* of FL (**Fig. 17-1C**).[24,25]

Neoplastic follicles usually lack mantle zones, but in some cases, partial or complete mantle zones may be present around all or some of the follicles (**Fig. 17-1B**).[26] In some FLs, the outer cells of the follicles may resemble marginal zone or monocytoid B cells with nuclei similar to those of centrocytes but with more abundant, pale cytoplasm (**Fig. 17-2**). These cells may form partial or complete "marginal zones" around some or most of the follicles in a given case,

and they may have an interfollicular and perisinusoidal distribution, resembling nodal involvement by extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue or nodal marginal zone lymphoma. This phenomenon should not be regarded as a "composite lymphoma" with follicular and monocytoid B-cell lymphoma, as has been suggested by some authors[27,28]; rather, it should be considered evidence of intratumoral differentiation.[29] Marginal zone B cells in cases of FL with marginal zone differentiation share the same genetic abnormalities as the neoplastic follicles.[30] In one study, the presence of significant marginal zone or monocytoid B-cell areas in FL was associated with a significantly poorer prognosis compared with cases lacking this feature.[31]

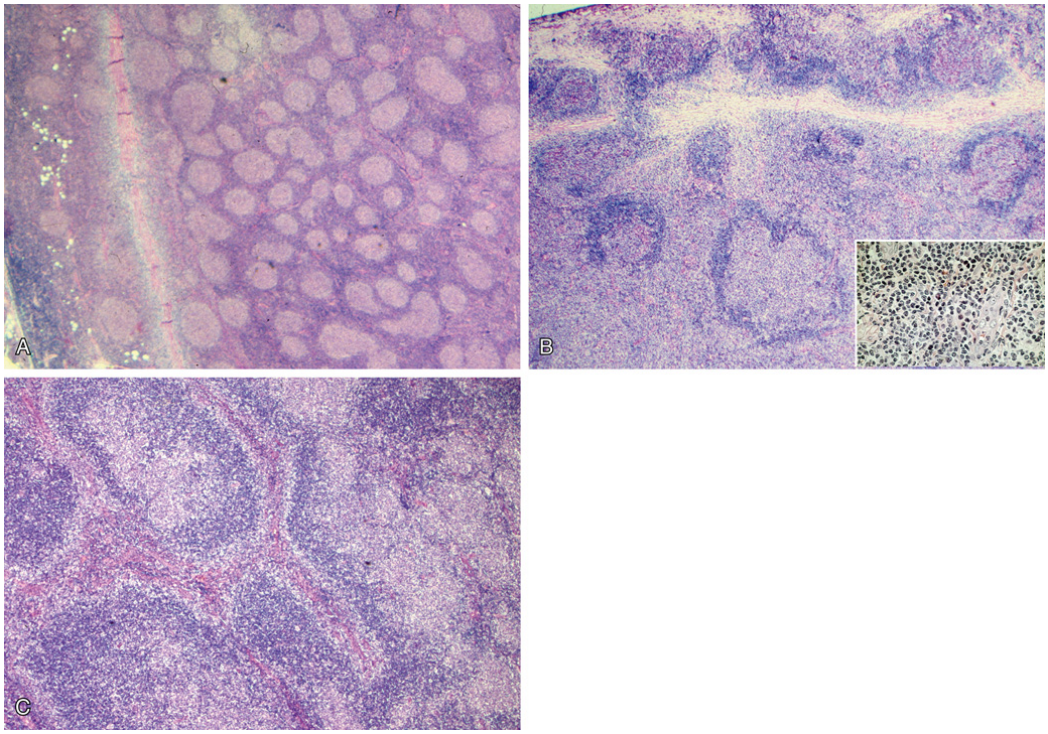

FIGURE 17-1 Morphologic patterns of follicular lymphoma (FL).A, In a typical case, the relatively uniform follicles are slightly larger than most reactive follicles. Note the extension of neoplastic follicles beyond the capsule *(left)*, with concentric bands of fibrosis. **B,** Some cases of FL are composed of irregularly shaped follicles with focally prominent mantle zones. This example has prominent interfollicular involvement, and fibrosis extends beyond the capsule. Interfollicular regions *(inset)* contain predominantly small centrocytes, and high endothelial venules may be numerous. **C,** The floral variant of FL shows broken-up follicles within a mantle zone of small lymphocytes, resembling progressively transformed germinal

centers or nodular lymphocyte-predominant Hodgkin lymphoma.

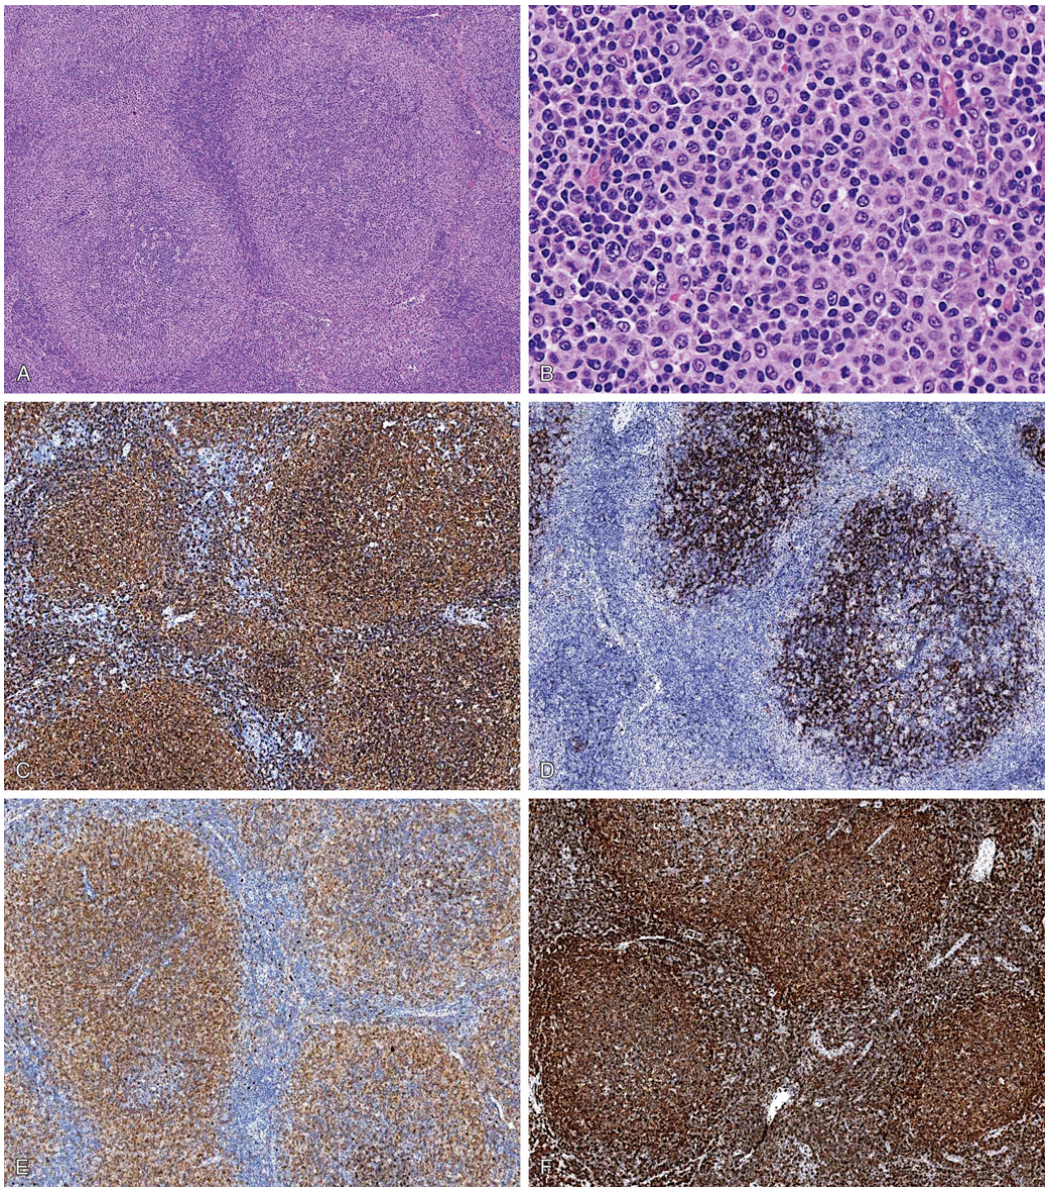

FIGURE 17-2 Follicular lymphoma (FL) with marginal zone differentiation.A, A broad peripheral band of pale-staining cells outside the mantle zone surrounds the follicles, forming a marginal zone. **B,** The cells in the marginal zone have centrocyte-like nuclei but more abundant cytoplasm. The neoplastic follicles are CD20 positive **(C)** and are associated

with CD23-positive FDC meshworks **(D)**. Follicles but not marginal zones are CD10 positive **(E)**. BCL2 **(F)** stains the follicles, including the marginal zones.

Subcapsular and medullary sinuses are typically obliterated, but sinuses may be partially or completely preserved. Extracapsular extension is common but not universal; when it occurs, the capsule may be visible as a band of fibrous tissue within the tumor. Successive levels of extracapsular extension may appear as concentric parallel bands of fibrosis in the extranodal tissue (**Fig. 17-1A**). In most cases, the follicles are closely packed, with absence of the normal T zones. The interfollicular region may contain numerous small blood vessels of the high endothelial venule (HEV) type but is poor in transformed lymphocytes and plasma cells and usually contains neoplastic centrocytes.[26,32] In occasional cases, interfollicular involvement is prominent, leading to widely spaced follicles (**Fig. 17-1B**). This interfollicular involvement is not considered to constitute a diffuse area: a diffuse area is defined as an area completely lacking follicles.

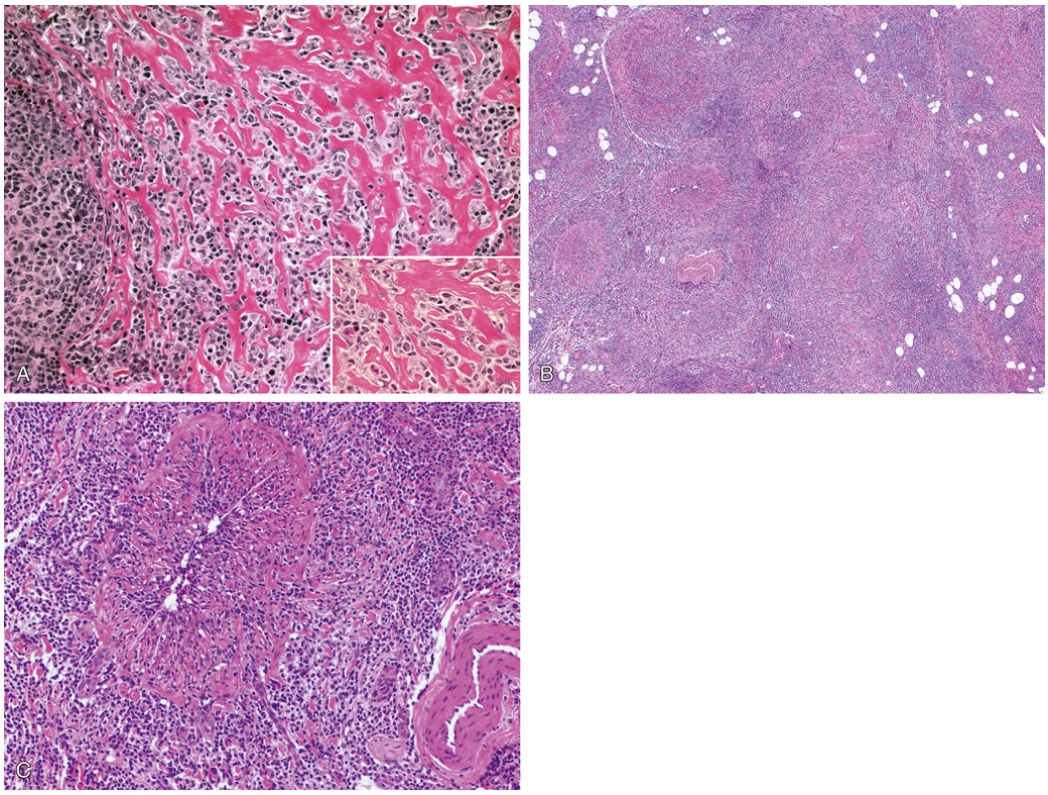

FIGURE 17-3 Additional morphologic patterns of follicular lymphoma (FL).A, The diffuse area in low-grade FL contains prominent sclerosis; the follicle is at *left*. The inset shows a predominance of centrocytes with distorted, elongated nuclei. **B,** prominent infiltration of hilar vessel walls is shown in a lymph node involved by FL. **C,** The neoplastic lymphoid cells infiltrate the wall of a small vein, resulting in obliteration of the lumen; note an intact arteriole *(right)*.

Sclerosis is common and may be present surrounding the follicles, in diffuse areas, or less often, within the follicles.[33] It is more marked in areas in which the infiltrate is diffuse, which can be a useful

feature in distinguishing FL from follicular or diffuse lymphoid hyperplasia. In diffuse areas with sclerosis, the neoplastic centrocytes may be spindle shaped, resembling fibroblasts (**Fig. 17-3A**). Centrocytes are often more numerous in sclerotic areas than in other areas; thus, in difficult cases, careful examination of the cells in areas of sclerosis is useful in establishing the diagnosis.

Occasional cases of FL may have amorphous, eosinophilic, extracellular, periodic acid-Schiff–positive material deposited in an irregular fashion within the follicle centers.[34,35] The nature of this material is not clear; Chittal and colleagues[35] found that, ultrastructurally, it contained membrane fragments, and on immunohistochemistry, it contained many antigens found in and on the neoplastic cells (CD45, CD22, immunoglobulin [Ig]). Others have speculated that it represents the deposition of antigen-antibody complexes on the processes of follicular dendritic cells (FDCs), analogous to the deposits often seen in reactive follicles.[34] However, in reactive follicles, extracellular Ig deposition is rarely massive enough to be conspicuous by light microscopy, whereas in the few lymphomas that exhibit this phenomenon, it may be impressive. Thus, although uncommon and by no means diagnostic, massive extracellular deposition of amorphous material within follicles should raise the question of lymphoma.

Vascular invasion is surprisingly common in FL, both within involved lymph nodes and in pericapsular veins.[36] Centrocytes infiltrate through the walls of small and even larger veins, accumulating within the intima (**Fig. 17-3B and C**). Vascular invasion may be useful in distinguishing FL from hyperplasia. Perhaps as a consequence of this invasion, total infarction of the

lymph node may occur.[36] The diagnosis can be suspected in totally infarcted nodes by careful evaluation of the cells preserved in the extranodal tissue and by reticulin stains, which demonstrate the follicular pattern throughout the infarcted area; molecular genetic analysis can occasionally demonstrate Ig gene rearrangement in infarcted tissue, and immunohistochemistry may be used to document that the cells are CD45 positive and CD20 positive, although non-specific staining of necrotic tissue by these antibodies can be a problem.[37-39]

Diffuse Areas in Follicular Lymphoma

A diffuse area in FL is defined as an area that lacks evidence of neoplastic follicles and contains a mixture of centrocytes and centroblasts similar to those seen within the neoplastic follicles (**Fig. 17-3A**). Involvement of the interfollicular region by neoplastic cells is not considered evidence of a diffuse pattern. Although the prognostic importance of diffuse areas is debatable, the WHO classification has historically recognized three patterns of grade 1 to 2 FL: follicular (>75% follicular), follicular and diffuse (25% to 75% follicular), predominantly diffuse (>25% follicular), and diffuse (0% follicular) (**Table 17-3**). Diffuse areas in low-grade (grade 1 to 2) FL are not prognostically significant. However, diffuse areas composed predominantly of centroblasts (grade 3) are diagnosed as DLBCL (**Table 17-3**).

Diffuse Follicular Lymphoma

Rare lymphomas composed of both centrocytes and centroblasts have a purely diffuse pattern. In some core biopsy samples, it is likely that focal follicular areas are present in the lymphoma and that the

purely diffuse pattern seen in the biopsy is the result of limited sampling. In the ICC classification, diffuse FL is defined as a diffuse lymphoma composed of both centrocytes and centroblasts in which centrocytes predominate (grade 1 to 2, low grade). In the WHO 5th edition classification, these cases are referred to as FL with predominantly diffuse growth pattern (**Table 17-2**). A significant subset of diffuse FL may fall under the new provisional entity defined in the ICC classification as "BCL2-R-negative, CD23+ follicle center lymphoma" that characteristically has CD23 expression, *STAT6* mutations, and absent *BCL2* rearrangement (see section titled "BCL2-R-Negative, CD23-Positive Follicle Center Lymphoma").

The diagnosis of diffuse FL should be made with caution after other diffuse lymphomas have been excluded and when sufficient tissue is available to exclude FL with follicular pattern. Immunophenotyping studies are essential to show that both small and large cells are B cells (to exclude T-cell/histiocyte–rich large B-cell lymphoma [LBCL]) and that the immunophenotype is consistent with FL ($CD10^+$, $BCL6^+$, $CD5^-$, $CD43^-$, cyclin $D1^-$). Molecular genetic or cytogenetic analysis for evidence of *BCL2* rearrangement may be useful to confirm this diagnosis. However, the possibility of BCL2-R-negative, CD23-positive follicle center lymphoma should be considered.[40]

BCL2-R-Negative, CD23-Positive Follicle Center Lymphoma

BCL2-R-negative, CD23-positive follicle center lymphoma is a provisional entity described in the ICC classification characterized by a predominance of centrocytes expressing germinal-center markers

(CD10 and BCL6), usually with CD23 co-expression, the presence of *CREBBP* and *STAT6* or *SOCS1* mutations, recurrent deletions of 1p36 and/or 16p, and characteristic absence of *BCL2* gene rearrangements (**Fig. 17-4**). The majority of cases are associated with purely diffuse growth pattern with scattered microfollicles and interstitial sclerosis (as originally described by Katzenberger et al.[40]), but some cases have been found to retain follicular architecture. Clinically, patients with this disease often present with painless localized (stage I-II) lymphadenopathy, most commonly in the inguinal area (more than 75% of cases), but noninguinal sites can also be involved. This type of FL generally has an excellent prognosis.

Table 17-3

* Grading of FL is considered optional in the 5th edition of World Health Organization classification, and, if performed, the recommended grading system is as described in this table, with the exception of FL grade 3B, which goes under the name of Follicular Large B Cell Lymphoma.

† Among cases of grade 1 to 2 follicular lymphoma with a proliferation fraction, >40% may be reported as “follicular lymphoma grade 1 to 2 with a high proliferation fraction.”

‡ High-power field (hpf) of 0.159 mm^2 (40× objective). If using an 18-mm field-of-view ocular, count 10 hpf and divide by 10; if using a 20-mm field-of-view ocular, count 8 hpf; if using a 22-mm field-of-view ocular, count 7 hpf for an equivalent area and divide by 10 to get the number of centroblasts/0.159 mm^2 hpf.

§ Give approximate percentages in report.

¶ If the biopsy specimen is small, a note should be added that the absence of follicles may reflect sampling error.

Partial Nodal Involvement

In some cases of FL, the nodal architecture may be largely or partially preserved, with residual reactive germinal centers; this phenomenon is reportedly associated with a lower stage at diagnosis.[41] In other cases, there may be widely spaced, monomorphous follicles surrounded by a relatively normal-appearing interfollicular region, without evidence of extrafollicular neoplastic cells (**Fig. 17-5**). This pattern appears to reflect the

homing of neoplastic cells to preexisting reactive follicles, with follicular colonization by tumor cells.[42] This phenomenon may occur in lymph nodes with obvious FL elsewhere in the node, in adjacent nodes, or rarely, in patients without evidence of overt lymphoma (see section titled “In Situ Follicular Neoplasia”).[43,44]

Cellular Composition

The centrocytes and centroblasts of most cases of FL are morphologically similar to those of normal germinal centers (**Fig. 17-6A–F**). The nuclei of centrocytes (**Fig. 17-6C and D**) are usually less than twice the size of small lymphocytes, but they may be almost as large as the nuclei of tissue histiocytes or centroblasts. The nuclei appear irregular or angulated in tissue sections; although the term *cleaved* is used, a distinct nuclear cleft is seldom seen in tissue sections. The chromatin is paler than that of small lymphocytes and is evenly dispersed, giving the nucleus a gray-blue appearance. One or more small nucleoli may be present. The cytoplasm is scant and pale and is usually not visible on H&E (hematoxylin and eosin)-stained or Giemsa-stained sections. In most cases, the centrocytes appear more monomorphous than those of normal follicles, with the majority approximately the same size. The nuclei of centroblasts (**Fig. 17-6B, D–F**) are usually three-to-four times the size of small lymphocytes, similar to or larger than the nuclei of tissue histiocytes; the nuclei are round or oval but may be irregular, indented, or multilobated or may even have a cleft. The nucleus is vesicular, with a clear center and some peripheral condensation of chromatin; there are one-to-three basophilic nucleoli, usually apposed to the nuclear membrane. Centroblasts have a narrow rim of cytoplasm that is

intensely basophilic on Giemsa staining. The proportion of centroblasts may vary somewhat among follicles in a given case; an extreme example is shown in **Figure 17-6G**. Areas of DLBCL may be encountered in FL of any grade (**Fig. 17-6H**). In cases with ill-defined neoplastic follicles, an immunostain for FDCs can be useful in distinguishing follicular and diffuse areas (**Fig. 17-6I**).

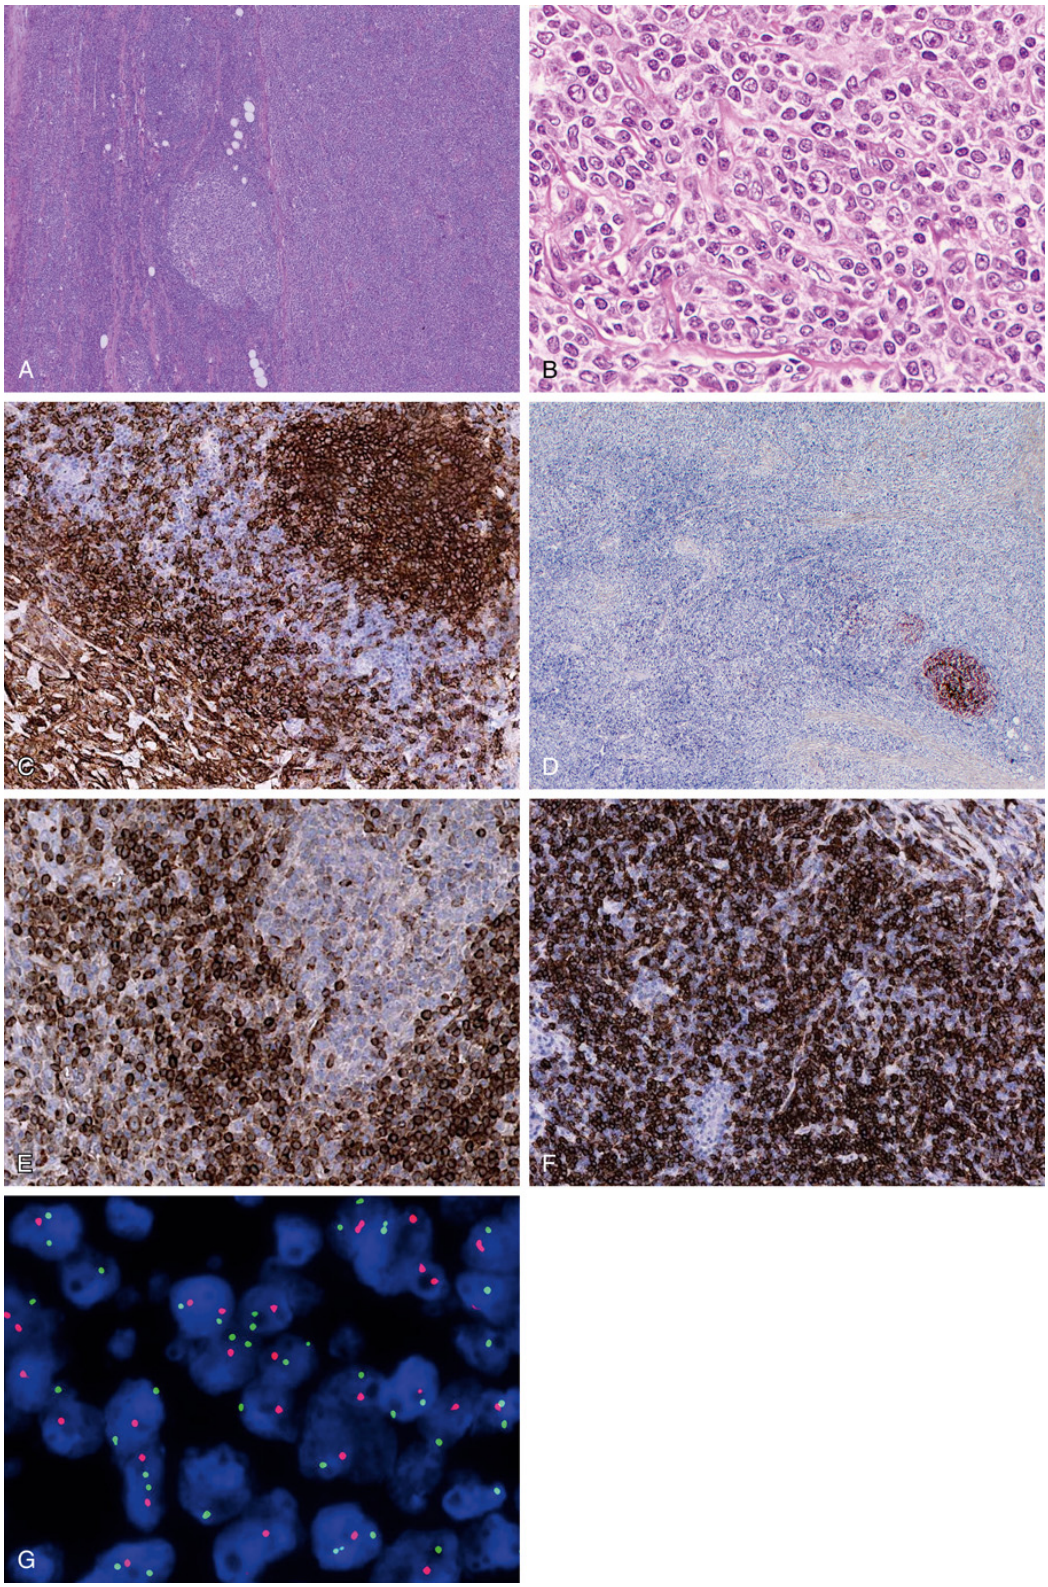

FIGURE 17-4 Follicular lymphoma (FL) with diffuse areas and 1p36 deletion.**A,** This case

presented as a large inguinal lymphadenopathy with massive extension to the surrounding soft tissues; the lymphoma displayed a predominantly diffuse pattern with occasional follicles. **B,** At higher magnification, there was an admixture of centrocytes and scattered centroblasts (<15/high power field) and variably abundant sclerosis. **C,** CD20 stained the majority of the lymphoid cells in a nodular and diffuse pattern. **D,** CD21 immunostaining highlighted focal follicular dendritic cell meshworks. **E,** The B cells in the follicles and in diffuse areas were negative for BCL2, and there was no *BCL2* rearrangement demonstrated by fluorescence in situ hybridization (FISH). **F,** CD23 was strongly expressed by the lymphoma cells. **G,** FISH using Vysis LSI 1p36 SpectrumOrange/1q25 SpectrumGreen probes shows many nuclei with one red and two green signals (1p36 deletion).

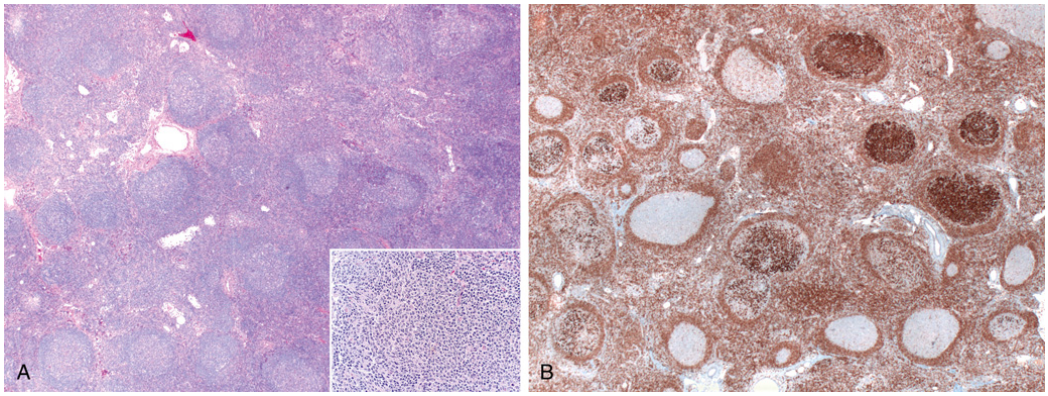

FIGURE 17-5 Partial nodal involvement by follicular lymphoma (FL).A, A lymph node partially involved by FL contains scattered monomorphous-appearing follicles among other typical reactive follicles with preserved mantle zones. A neoplastic follicle at higher magnification shows a monotonous cellular composition *(inset)*. **B,** BCL2 stain shows strongly positive cells in some follicles.

In most cases of FL, the centrocytes are relatively small, and the few centroblasts stand out sharply against the monotonous background of centrocytes. In some cases, however, the centrocytes are larger and may be almost as large as centroblasts. In these cases, the centrocytes may appear more pleomorphic, with more deeply indented or multilobated-appearing nuclei. Centroblasts may also appear atypical, with variable nuclear size and shape, increased heterochromatin, and binucleate or multinucleated forms.

Mitotic activity is low in most cases of FL, and a starry-sky pattern, with phagocytic histiocytes, is absent. However, in cases with increased numbers of centroblasts, mitoses are more numerous, and rarely, phagocytosis of nuclear debris may be seen. Polarization, as

seen in reactive follicles, is rare in FL, although in some cases, centroblasts may be more numerous in one area of the follicle than another, creating an impression of polarization.

In addition to clonal B cells, neoplastic follicles contain FDCs; their nuclei are similar in size to centroblast nuclei but have delicate nuclear membranes and are central, small, and eosinophilic. FDCs are often binucleate, and the two nuclei are typically apposed to each other, with flattening of the adjacent nuclear membranes (**Fig. 17-6C and E**). In contrast to centroblasts, their cytoplasm does not stain blue with Giemsa stain. Small T cells are also present in neoplastic follicles; these are usually less numerous than in reactive germinal centers, but occasionally they may be numerous.

FL rarely contains an appreciable number of plasma cells, which can be useful in its differentiation from reactive hyperplasia; however, a small proportion of FLs have variably extensive plasmacytic differentiation (**Fig. 17-7**).[45] FL of any grade may have plasmacytic differentiation.[45,46] The plasma cells may be found predominantly in the interfollicular area or in an intrafollicular distribution. In cases with interfollicular plasma cells, the plasma cells express class-switched Ig; these cases are CD10 positive and harbor *BCL2* gene rearrangements, *BCL6* gene rearrangements (subset), and mutations in chromatin remodelling genes (e.g., *KMT2D, CREBBP, EZH2*). In contrast, cases with intrafollicular plasma cells often lack CD10 expression, feature IgM-positive plasma cells, have less frequent mutations in chromatin remodeling genes, and lack *BCL2* rearrangements, though they often have extra copies of *BCL2* and *BCL6*. The latter group often lacks the usual composition of centrocytes and centroblasts and can have features

that overlap with nodal marginal zone lymphoma.[47] In rare cases of FL, the neoplastic centrocytes have large cytoplasmic vacuoles, either clear or eosinophilic, giving them the appearance of signet ring cells (**Fig. 17-8A**).[48] In most of these cases, cytoplasmic Ig can be demonstrated in the signet ring cells. Cases with clear cytoplasm typically express cytoplasmic IgG, with a predominance of lambda light chain, whereas those with periodic acid-Schiff–positive eosinophilic globules in the cytoplasm or nucleus more commonly express IgM.[48,49] On ultrastructural examination, the clear inclusions are large, membrane-bound vacuoles containing multiple tiny, coated vesicles, whereas the eosinophilic inclusions consist of dilated rough endoplasmic reticulum filled with electron-dense material, presumably Ig.[50] Clinically, FL with a signet ring cell morphology does not differ from typical FL.

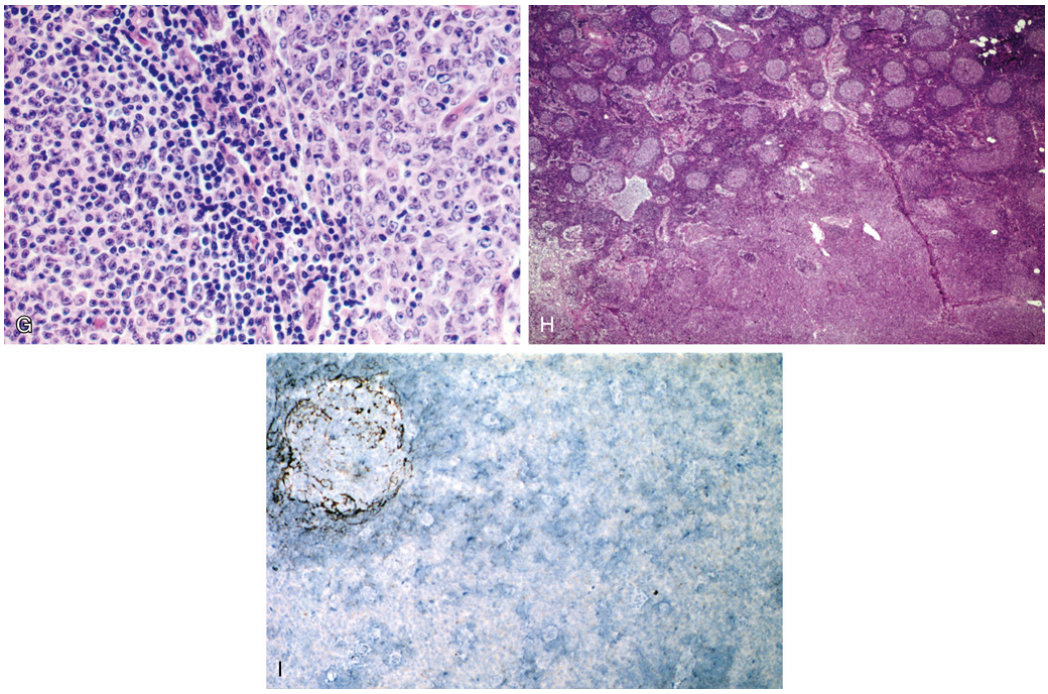

FIGURE 17-6 Cellular composition and grading of follicular lymphoma (FL).A, This reactive germinal center contains normal centrocytes and centroblasts; follicular dendritic cells are often binucleate and identified by their oval-to-round nuclei with pale chromatin and small distinct eosinophilic nucleoli *(arrows)*. **B,** On a Giemsa stain of a reactive germinal center, the centroblasts show a rim of basophilic cytoplasm *(arrows)*. **C,** A neoplastic follicle in low-grade FL contains centroblasts and centrocytes, similar to those in the reactive germinal centers; however, the follicles have a more monomorphous appearance because of the predominance of centrocytes. *Arrows* indicate follicular dendritic cells. **D,** Scattered centroblasts are best demonstrated by a Giemsa

stain in low-grade FL *(arrows)*. **E,** In FL grade 3A, centroblasts are numerous, but centrocytes are still present; note the persistence of follicular dendritic cells *(arrow)*. **F,** In FL grade 3B, there are solid aggregates of centroblasts.**G,** In this FL, a follicle with a predominance of centrocytes (grade 1 to 2, *left*) is adjacent to a follicle with a predominance of centroblasts (grade 3B, *right*). **H,** The bottom of the image shows an area of diffuse large B-cell lymphoma, present in association with a low-grade FL. **I,** CD21 highlights a follicular dendritic cell meshwork associated with a neoplastic follicle *(upper left)*; diffuse areas lack follicular dendritic staining (immunoperoxidase stain for CD21).

Grading and Terminology

The establishment of FL grading was based on the idea that clinical aggressiveness of the lymphoma increased with the number of centroblasts. In particular, early studies had suggested the "cell counting" method of Mann and Berard was more reproducible and better at predicting prognosis than other methods of grading FL.[51-53] In this method, the centroblasts (large nucleolated cells) per 40× microscopic high-power field (hpf) are counted (10 to 20 hpf in different randomly selected follicles). A case with up to five centroblasts/hpf is grade 1, 6 to 15 centroblasts is grade 2, and greater than 15 centroblasts is grade 3 (**Fig. 17-6C–F**).[54] Using a

standard 0.159 mm^2 hpf, the international study of the REAL classification found that a cutoff of 15 centroblasts/hpf significantly predicted overall and disease-free survival in FL.[55] Approximately 80% of FLs are grade 1 (40% to 60%) or grade 2 (25% to 35%). However, interobserver reliability has been questionable, and the prognostic significance of grading has not been reproducible in studies with more current therapies. In fact, because there is no appreciable difference in clinical behavior between grades 1 and 2, the 4th edition of the WHO classification combined them into a "low-grade" category (**Table 17-3**).

Using these numerical cutoffs, the spectrum of grade 3 FL ranges from cases with 16 large cells/hpf to those in which the majority of cells in the follicle are centroblasts.[56] Some studies suggest that cases with solid sheets of centroblasts are biologically distinct from those with a mixture of centrocytes and centroblasts.[46] For this reason, classifications have traditionally recommended subdividing grade 3 FL: grade 3A, with more than 15 centroblasts/hpf, but centrocytes are still present; and grade 3B, with solid sheets of centroblasts (**Fig. 17-6E and F**). Grade 3B cases are often associated with areas of DLBCL. The relative proportion of centrocytes and centroblasts may vary from one follicle to another in a given case. Examination of multiple sections is often required. The proportion of large cells is estimated based on a representative sample of follicles. Rarely, individual follicles or parts of the node may show an abrupt transition from a predominance of centrocytes (grade 1 to 2) to a predominance of centroblasts (grade 3) (**Fig. 17-6G**). In such cases, it is appropriate to give the predominant grade (grade 1 to 2) with a separate diagnosis of grade 3 (A or B), giving the

relative proportions of each. For some higher-grade lesions, it is difficult to make the critical distinction between grades 3A and 3B. The ICC proposed that the presence of *BCL2* rearrangements (*BCL2*-R) and CD10 positivity (detectable by fluorescence in situ hybridization [FISH]) favor FL 3A.

Areas of DLBCL may also be found in lymph nodes showing FL (**Fig. 17-6H**); this is more common in grade 3B cases but can occur in other grades. Although there are no established quantitative criteria, the presence of large confluent sheets of large cells is usually accepted as representative of transformation. In such cases, the primary diagnosis of DLBCL should be reported, followed by addition of the term "transformed from follicular lymphoma" (**Table 17-2**). An estimate of the proportion of DLBCL and FL can be included. Occasional patients with FL have divergent histologic features in lymph nodes taken simultaneously from different sites, showing variation in grade or progression to DLBCL.[57]

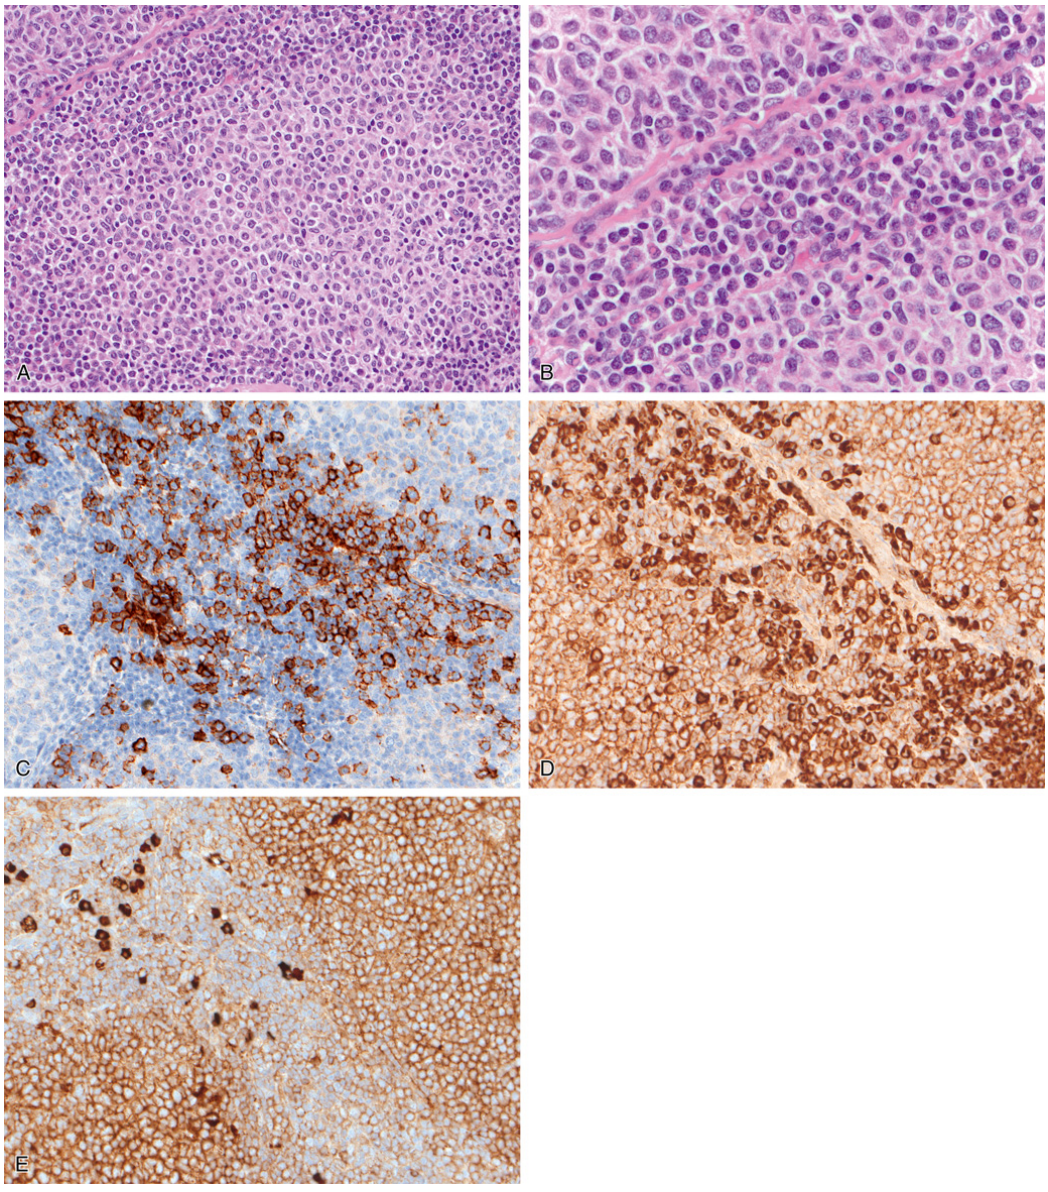

FIGURE 17-7 Follicular lymphoma (FL) with plasmacytic differentiation.A, FL is shown with a follicular growth pattern, involving a large proportion of centroblasts and a subset of cells with cytologic evidence of plasma cell differentiation, within the follicles and at their periphery. **B,** The periphery of the follicles and the interfollicular zones contain numerous cells

with plasmacytic differentiation in the form of cytoplasmic inclusions and/or eosinophilic nuclear pseudoinclusions (Dutcher bodies) of immunoglobulin. **C,** The plasma cell component is highlighted by CD138 immunostaining. There is monotypic expression of κ light chains by the lymphoma cells and the plasma cells **(D)**, but only rare plasma cells appear to express γ light chains **(E)**.

Infrequently, FL is composed predominantly of large centrocytes (large, cleaved cells). Grading of such cases is controversial. According to the ICC classification, such cases would still be considered low grade (grade 1 to 2 of 3)[1]; others, however, have reported that FL, large cleaved cell type, has a prognosis similar to that of FL grade 3, so assigning a designation of grade 3 to such cases may be more appropriate.[5,8] For this reason, the WHO 5th edition consensus was to include these cases in the distinct uFL subgroup.

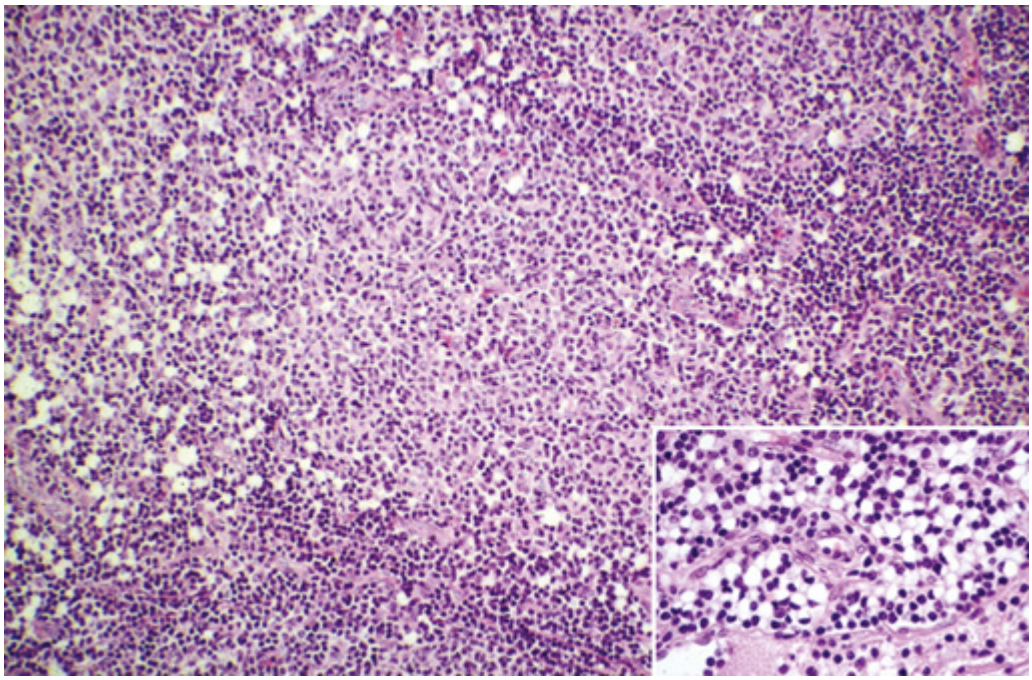

FIGURE 17-8 Follicular lymphoma (FL) with signet ring cells. In this case of FL with signet ring cells, many of the atypical lymphoid cells contain a large, clear cytoplasmic vacuole *(inset)*, simulating carcinoma cells of the signet ring type.

The proliferation fraction using immunohistochemical staining for Ki-67 typically mirrors grade, with grade 1 to 2 cases having a proliferation fraction of less than 20% and grade 3 greater than 30%. One study suggested that the Ki-67 fraction was less useful than the histologic grade in predicting outcome.[59] Occasional histologically low-grade cases have a high proliferation fraction.[60,61] In one study, patients with a high proliferation fraction (>40%) had a survival more similar to that of grade 3 FL than that of typical grade 1 to 2 FL.[61] Proliferation index using Ki-67 staining can be performed as an adjunct to grading, but it is has uncertain significance in isolation

and is not required for grading. The presence of a high Ki-67 fraction should not change the histologic grade.

Morphology in Sites Other Than Lymph Nodes

Spleen

Splenic involvement by FL typically produces uniform enlargement of white pulp, resembling reactive hyperplasia both on gross examination and at low magnification.[57] This phenomenon has been postulated to reflect the neoplastic cells' ability to "home" to normal B-cell regions (**Fig. 17-9A**). The white-pulp follicles in FL are increased in number and size and show a monomorphous infiltrate of centrocytes and centroblasts, similar to that in lymph nodes. The marginal zone may be preserved, making it difficult to differentiate FL from splenic marginal zone lymphoma (**Fig. 17-9B**). The red pulp typically contains numerous small follicles, but diffuse red pulp involvement is uncommon.

Bone Marrow
